Because of the conservation of Ψ and J within the boundaries of the plasma jet for uniform distribution of g_x, j_x, and b_x along the cathode radius, using (2.16) derived above we have

$$\int\limits_A j_\theta b_x r\, dA = -\frac{3}{2}\frac{\langle \beta_x\rangle}{R_s} J_d \Phi_k \left(1+\frac{a}{\xi}\right)\left[\frac{d\Phi^0}{dx^0}\right]_{x=0}. \tag{2.21}$$

Here, $\Phi^0 = \Phi/\Phi_k$, $\Phi = \int\limits_0^{R(x)} b_x r\,dr$, $x^0 = x/R_s$.

Near the cathode one can assume the magnitude of the magnetic field induction to be independent of radius, i.e., $\Phi_k = b_k(R_k^2/2)$. Equations (2.18) and (2.21) then make it possible to write the component of the force resulting from the interaction between the discharge current and the external magnetic field in the form

$$F_s = \frac{\langle \beta_x\rangle \varkappa}{4} J_d b_k R_k \left(1+\frac{a}{\xi}\right) f\left(\frac{\Phi_a}{\Phi_k},\ \frac{\Phi_d}{\Phi_a},\ \xi,\ a,\ \left[\frac{d\Phi^0}{dx^0}\right]_{x=0}\right). \tag{2.22}$$

Here, the function *f* is defined by

$$f = \frac{\Phi_a}{\Phi_k}\left[1+\frac{a}{a+\xi}\left(\frac{c}{2}\frac{\Phi_d}{\Phi_a}-1\right)\right]-\frac{1}{2}+\frac{3}{2}\frac{1}{\varkappa}\left[\frac{d\Phi^0}{dx^0}\right]_{x=0}. \tag{2.23}$$

According to Eq. (1.5), the average velocity of the plasma in the section dd when $F_c \ll F_B$ will be

$$u = \frac{\langle \beta_x\rangle \varkappa}{4}\frac{J_p b_k R_k}{G}\left(1+\frac{a}{\xi}\right) f. \tag{2.24}$$

3. ANALYSIS OF THE RESULTS

It is clear from Eqs. (2.8), (2.9), and (2.11) that the dimensionless parameters $\langle B_x\rangle$, $\varkappa$, α, $\xi = m_i J/(e\psi)$ determine the nature of the plasma flow in the channel. For example, the dimensionless parameter $\varkappa$ for the shape of the magnetic field defines the ratio between the axial force accelerating the plasma and the radial force leading to its compression. The complex parameter $\langle \beta_x\rangle \varkappa (1 + \alpha/\xi)$ defines the ratio between axial and torsional plasma forces. From the viewpoint of efficient plasma acceleration in the axial direction it is necessary to ensure a parameter value $\langle \beta_x\rangle \varkappa \gg 1$ with an increase in the value of the parameter $\varkappa$ being advisable. An increase in the Hall parameter will lead to simultaneous increase in the axial and compressive plasma forces. The parameters α and ξ in these accelerators are interrelated so that for sufficiently complete ionization of the plasma it is necessary to ensure that $\xi \geq 1$.

In addition, Eqs. (2.8), (2.9), and (2.11) indicate that the magnitudes of all the forces and moments which result from the interaction between the discharge current and the external magnetic field depend significantly on the shape of the magnetic field in the channel. For example, if the magnetic lines of force are closed from cathode to anode the values of the forces and moments will be zero because the equality $d\Phi = 0$ is satisfied.

As is clear from Eqs. (2.21) and (2.23), the plasma pressure force on the cathode will be determined completely if the axial dependence of the radius of the plasma jet boundary and of the quantity b_x is known. When the boundary of the plasma jet coincides with a magnetic line of force the pressure on the cathode will be zero. If $d\Phi^0/(dx^0) > 0$, the pressure on the cathode is positive because of plasma compression toward the axis, i.e., an increased pressure is created at the cathode relative to the pressure p_* outside the jet. If $d\Phi^0/dx^0 < 0$, the pressure at the cathode is negative relative to $p_* A_{kk}$. In that case, a region of reduced pressure relative to the pressure p_* is created at the cathode. Note that by definition $\Phi = \int\limits_0^R b_x r\,dr = b_x(R^2/2)$, where the dependence of b_x on x is usually known. The dependence on x of the radius R of the boundary of the plasma jet is not known precisely and is determined by the laws for plasma diffusion in electromagnetic fields.

Now let $d\Phi^0/dx^0 = 0$ and assume that $\Phi_d = \Phi_a$, $\alpha = c \simeq 1$. In addition, we assume the quantity 0.5 in Eq. (2.23) can be neglected in comparison with Φ_a/Φ_k. In this case, the expression for F_B is simplified significantly and is determined only by the reaction acting on the solenoid,

$$F_B \simeq \frac{\langle\beta_x\rangle\varkappa}{4} J_d b_k R_k \frac{\Phi_a}{\Phi_k}\left(1+\frac{\alpha}{2\xi}\right). \tag{3.1}$$

It is clear from Eq. (3.1) that the reaction force on the solenoid, which arises through the imposition of an external magnetic field on the discharge, is directly proportional to the quantity $J_d b_k R_k$, which has the dimensionality of a force multiplied by a number of dimensionless parameters. These dimensionless parameters, $\langle\beta_x\rangle$, α, $\varkappa$, ξ, and Φ_a/Φ_k, are similarity parameters because when they are the same for two different accelerator models the quantities F_B, u_d, and ω_d will be identical for $F_c < F_B$ and the equality of $J_d b_k R_k$.

Physically, the quantity $J_d b_k R_k$ is the force which acts on a linear current-carrying conductor of length R_k in a magnetic field of induction b_k perpendicular to the current. The factor $(1 + \alpha/2\xi)$ takes account of motion of the conductor in the magnetic field in the direction of the electric current through the quantity ξ. The shape parameter $\varkappa$ for the magnetic field determines the actual magnitude of the magnetic field induction, $\varkappa b_k$, with which the Hall current interacts. From the viewpoint of a current-carrying conductor, this parameter characterizes the slope of the magnetic induction vector relative to the axis of the current-carrying conductor in the direction of current flow. The parameter Φ_a/Φ_k characterizes the spatial structure of the discharge. The Hall parameter determines the degree of transformation of discharge current into Hall current, or the true current which must be transmitted along a linear conductor in order to simulate the force acting on the plasma.

In almost all experiments with accelerators, the magnitude of the Hall parameter is known inexactly. Here it is assumed constant in the derivation of the equations for the electromagnetic forces. This assumption is valid in two cases, which are also realized in practice in the operation of Hall accelerators. First, this occurs when the current flow in the accelerator follows the circuit proposed in ref. 3. In this case, current transport across magnetic lines of force occurs outside the accelerator in a gas cloud within which $n_e \simeq$ const, $T_e \simeq$ const, $\varkappa =$ const, and $b_x \simeq$ const. Second, the Hall parameter can be considered to be constant and equal to some effective value when oscillations of the electric field in the plasma are present.[12] Usually oscillations in electron density are a source of oscillations in the electric field intensity. An analysis of Ohm's law was given[13] including fluctuations in electron density and it was shown that the effective value of the Hall parameter remains constant over a broad range of variation of the "ordinary" value of the Hall parameter and is determined by the relative magnitude of the density fluctuations. Note that the first case is realized when the atom density in the surrounding space is comparable to the particle density in the plasma flow; the second case is realized in a high vacuum. In the general case, the magnitude of the Hall parameter can be determined and its role in the acceleration process explained only through a comparison of theoretical and experimental relations and by direct measurements.

It should be pointed out in conclusion that the region of applicability for the relations obtained here corresponds to plasma acceleration in the channel of a Hall accelerator with $\xi \geq 1$, $\langle\beta_x\rangle > 1$, $R_{iL} > R_a \gg R_{eL}$, and $R_c \gg R_k$.

The author thanks A. I. Morozov and I. P. Nekrasov for valuable discussions.

Theory of the positive column in neon

Yu. B. Golobovskii, Yu. M. Kagan, and R. I. Lyagushchenko

A. A. Zhdanov Leningrad State University

(Submitted July 16, 1973)
Zh. Tekh. Fiz., 44, 536-543 (March 1974)

A theory is developed for a stationary positive column in a neon discharge at pressures of tens and hundreds of torr; the analysis includes the non-Maxwellian nature of the fast-electron distribution function, stepwise ionization, the emission of resonance radiation, volume recombination, and heating of the atomic gas. The theory is compared with experimental results.

1. The development of a theory for the positive column at pressures of tens and hundreds of torr has been discussed recently.[1-4] Such a theory must take account of the actual form of the electron energy distribution function. This function is determined from the kinetic equation with elastic and inelastic collisions between electrons and atoms and interelectron interactions.[9] By means of this distribution function one can determine the total number of ionization events per unit volume per unit time. In this case, stepwise ionization from low metastable and resonance levels plays a fundamental role. If the emission of resonance radiation is neglected, the total number of ionization events is equal to the total number of inelastic collisions, which can be determined directly from the kinetic equation.[6] A theory of the positive column has been developed using such an approximation.[1-4] One can write a closed system of equations for determination of the electron density n, the electron temperature T_e, and the longitudinal field E. Further development of the theory includes nonuniform heating of the gas,[6-8] emission of resonance radiation,[9] and the effect of recombination.[10]

An attempt is made here to construct a theory for the positive column in a neon discharge including simultaneous consideration of nonuniform heating, resonance radiation emission, and volume recombination.

2. The basic equations are[1]

$$\left.\begin{aligned}&\frac{1}{\rho}\frac{d}{d\rho}\left\{\rho b_p\left[u_e\frac{dn}{d\rho}+\frac{1}{2}n\frac{du_e}{d\rho}\right]\right\}+Z-\Gamma=0,\\&n(R)=0\quad\left.\frac{dn}{d\rho}\right|_{\rho=0}=0;\end{aligned}\right\}\tag{1}$$

$$\left.\begin{aligned}&\frac{1}{\rho}\frac{d}{d\rho}\left[\rho\varkappa\frac{d\Theta}{d\rho}\right]+jE=0,\\&\Theta(R)=\Theta_R\quad\left.\frac{d\Theta}{d\rho}\right|_{\rho=0}=0;\end{aligned}\right\}\tag{2}$$

$$i=2\pi\int_0^R j(\rho)\rho d\rho,\tag{3}$$

$$u_e=0.27\sqrt{\frac{M}{m}}E\lambda,\tag{4}$$

$$p=Nk\Theta.\tag{5}$$

Here $j = eEb_en$ is the current density; $u_e = (kT_e)/e$; the thermal conductivity coefficient for neon is assumed to be $\varkappa = C\sqrt{\Theta}$, where[11] C = 265 (erg/sec) (cm/deg$^{3/2}$); $b_p = B\sqrt{\Theta}/p$, where[12] $B = 8.7\cdot10^4$; $b_e = A(\sqrt{\Theta}/\sqrt{p})(1/\sqrt{E})$, where[13] $A = 5.9\cdot10^4$; $\Gamma = \gamma n^2$ is the number of recombination events (per unit volume per unit time). It is assumed that $\gamma = \gamma_0\sqrt{300/T_e}$, where[14] $\gamma_0 = 1.75\cdot10^{-7}\ \mathrm{cm^3\cdot sec^{-1}}$.

We assume in Eq. (4), as earlier,[1] that the main energy loss for the electrons occurs through elastic collisions with gas atoms.

3. We determine the number of ionization events Z under the assumption that stepwise ionization occurs from the $2p^53s$ level in neon. It is therefore necessary to solve a system of balance equations for the population of all four $2p^53s$ levels. This leads to extremely cumbersome expressions and requires a knowledge of a large number of cross sections for the transitions between these levels. These cross sections are not known exactly. However, the known data for these cross sections[15] show that they are very large, which leads to strong mixing in the $^3P_{0,1,2}$ system. One can therefore assume that the atoms in $^3P_{0,1,2}$ levels are distributed in accordance with statistical weights. This makes it possible to regard the $^3P_{0,1,2}$ system as a single effective ^3P level. In constructing the balance equations for the ^3P and $^1P_1$ levels, we consider the following processes.

a. Excitation from the ground state. The number of excitation events in the effective ^3P level is determined under the assumption that the number of excitation events of the $^3P_0$, $^3P_1$, $^3P_2$, and $^1P_1$ levels goes like the statistical weights and the total number of excitation events in all four levels coincides with the total number of inelastic collisions α. Then the total number of excitation events of the effective ^3P level is $3\alpha/4$.

The basis for this assumption is the fact that the cross sections for direct excitation of the $^3P_0$, $^3P_1$, and $^3P_2$ levels calculated from tables[16] in an energy region of a few volts in the neighborhood of the excitation threshold are proportional to the statistical weights. This condition is less well satisfied for the $^1P_1$ level; however, the contribution from excitation of this level to the total excitation of all four levels is relatively small.

b. Radiative decay of the $^3P_1$ level. Radiative decay of the $^3P_1$ level is characterized by a decay probability. According to Holstein[17] we have

$$A_{\mathrm{eff}}=0.2\sqrt{\frac{\lambda}{R}}A,$$

for the dispersion tail of the line, where A is the probability of spontaneous transition. The probability for radiative decay of the effective ^3P level considering the proportionality to statistical weights for the populations of the $^3P_{0,1,2}$ levels is $(1/3)A_{\mathrm{eff}}$.

c. Transitions between ^3P and $^1P_1$ levels. The probability of a transition from level k to level m of the $2p^53s$ system through a $2p^53p$ level is nW_{km},

where

$$W_{km}=\sum_{i=1}^{10}\langle v\sigma\rangle_{ki}\frac{A_{im}}{\sum_{k=1}^{4}A_{ik}}. \tag{6}$$

The subscript i numbers the levels in the $2p^5 3p$ system, and the subscripts k and m, levels in the $2p^5 3s$ system. In all cases, numbering is in the order of increasing level energy. A_{im} is the probability of the radiative transition i → m. The product of rate by the cross section for the appropriate process averaged over a Maxwellian distribution is determined with the help of tables.[16]

The probability of transition from the effective ^3P level to the $^1P_1$ level through a $2p^5 3p$ level is nW_Y, where

$$W_Y=\frac{1}{\sum_{k=1}^{3}g_k}\sum_{k=1}^{3}g_k W_{kY}. \tag{7}$$

The probability of transition from the $^1P_1$ level to the effective ^3P level through a $2p^5 3p$ level is nW'_Y, where

$$W'_Y=\sum_{m=1}^{3}W_{Ym}. \tag{8}$$

A calculation for T_e = 30,000°K yields $W_Y = 0.87 \cdot 10^{-7}$ and $W'_Y = 3.1 \cdot 10^{-7}$.

Direct transitions between the $^3P_{0,1,2}$ and $^1P_1$ levels may also occur, but the cross sections for these transitions are not known. If it is assumed the cross sections for these transitions are no larger than the cross sections between $^3P_{0,1,2}$ levels, consideration of these transitions does not qualitatively change the particle balance in the $^3P_{0,1,2}$ system.

d. Stepwise ionization. We introduce $nW_{\Sigma\infty}$, the total probability of ionization from the ^3P level, where

$$W_{\Sigma\infty}=\sum_{k=1}^{3}\frac{g_k}{\sum_{k=1}^{3}g_k}\langle v\sigma\rangle_{k\infty}. \tag{9}$$

Using the material above, the equations of balance for the atomic densities N_Σ and N_Y in the ^3P and $^1P_1$ levels are written in the form

$$\frac{3}{4}\alpha+N_Y nW'_Y=N_\Sigma\left[nW_Y+nW_{\Sigma\infty}+\frac{g_2}{\sum_{k=1}^{3}g_k}A_{\text{eff}}\right], \tag{10}$$

$$\frac{1}{4}\alpha+N_\Sigma nW_Y=N_Y[nW'_Y+A_Y]. \tag{11}$$

In Eq. (11) we neglect breakdown of the fourth level because of ionization.

The number Z of ionization events is equal to $N_\Sigma nW_{\Sigma\infty} + N_Y nW_{Y\infty}$. Substituting N_Σ and N_Y from Eqs. (10) and (11), we obtain

$$Z=\alpha\frac{nW_{\Sigma\infty}\left(\frac{W_Y}{W'_Y}+\frac{3}{4}\frac{A_Y}{nW_Y}\right)}{A_Y+\left(\frac{A_Y}{nW_Y}+\frac{W'_Y}{W_Y}\right)\left(nW_{\Sigma\infty}+A_2\frac{g_2}{\sum_{i=1}^{3}g_i}\right)}. \tag{12}$$

Obvious limiting cases follow from Eq. (12).

When A_Y and $A_2 \to 0$ (neglect of resonance radiation emission), $Z = \alpha$.

When A_Y and $A_2 \to \infty$ (very high emission of resonance radiation), we have

$$Z=\frac{3}{4}\alpha\frac{nW_{\Sigma\infty}}{nW_Y+A_2\frac{g_2}{\sum_{i=1}^{3}g_i}}.$$

The quantities $\langle v\sigma\rangle_{k\infty}$ in Eq. (9) are calculated with the help of earlier results[18] using effective principal quantum numbers.

The results can be approximated by

$$nW_{\Sigma\infty}=225\tilde{n}u_e^3, \tag{13}$$

where $\tilde{n} = n \cdot 10^{-11}$ and u_e is in volts.

In this case, the calculation takes account only of direct ionization from the ^3P level. Associative ionization can also occur where there is excitation of levels separated from the ionization energy by an amount[19] less than, or equal to, 0.6 eV.

If we consider the limiting case, in which all excited atoms in this band are ionized, then the quantity $\sigma_{k\infty}$ in Eq. (9) should be understood to mean the sum of the cross sections for ionization and excitation of the corresponding levels. The calculation can be performed using tables of cross sections.[16] We then obtain

$$nW_{\Sigma\infty}=455\tilde{n}u_e^3, \tag{14}$$

where u_e is in volts.

The true value of $nW_{\Sigma\infty}$ lies between the values given by Eqs. (13) and (14). It is necessary to know the cross section for associative ionization, which is poorly known for neon. We therefore use the lower limit of the quantity given by Eq. (13).

The total number α of inelastic collisions is obtained from the expression[6]

$$\alpha=\frac{4\chi}{\sqrt{\pi}}n\nu_{ee}(u_e)(1+\gamma u_1^3)\exp\left[-\frac{u_1^2}{4}+\frac{u_1}{4\gamma}-\frac{1}{2\gamma}\left(1+\frac{1}{4\gamma}\right)\ln(1+2\gamma u_1)\right], \tag{15}$$

where $\nu_{ee}(u_e)$ and $\nu_{ea}(u_e)$ are the frequencies of interelectron and elastic electron–atom collisions at an energy $\varepsilon = eu_e$; $\gamma = (m/M)(\nu_{ea}/\nu_{ee})$; $u_1 = eV_1/kT_e$, where V_1 is the first excitation potential; χ is a function depending slightly on plasma parameters; we assume χ = 0.5 in the calculations.

In accordance with Eq. (12), the final expression for Z then is

$$Z=Z_1\alpha, \tag{16}$$

$$Z_1=225\tilde{n}u_e^3\frac{3.58+19.25\frac{1}{\tilde{n}\sqrt{R}}\exp\frac{2}{u_e}}{4.8\cdot 10^5\frac{1}{\sqrt{R}}+\left(3.58+\frac{25.7}{\tilde{n}\sqrt{R}}\exp\frac{2}{u_e}\right)\left(0.8\cdot 10^4\frac{1}{\sqrt{R}}+225\tilde{n}u_e^3\right)}; \tag{17}$$

u_e is in volts.

4. We turn to a solution of the system (1)-(5) by successive approximations. In Eq. (2), we introduce $x = \rho/R$ and $\tau = (\Theta/\Theta_0)^{3/2}$ and approximate the dependence of current density on ρ by a Bessel function, setting $j = j_0 J_0(2.4x)$. Then from Eq. (3) we have

$$j=\frac{i}{0.43\pi R^2}. \qquad (18)$$

The solution of Eq. (2) takes the form

$$\tau=\frac{1}{h}+\frac{h-1}{h}J_0(2.4x), \qquad (19)$$

where

$$h=\left(\frac{\Theta_0}{\Theta_R}\right)^{3/2}=1+\frac{0.19}{C}\frac{iE}{\Theta_R^{3/2}}. \qquad (20)$$

Using the expressions for current density, electron mobility, and Eq. (18), we obtain

$$n_0=\frac{1}{0.43\pi R^2 A}\frac{ip}{R^2\sqrt{E\Theta_0}}. \qquad (21)$$

Introducing the variables $x = \rho/R$ and $\omega = (n/n_0)\sqrt{\Theta/\Theta_0}$ in Eq. (1), we obtain

$$\frac{1}{x}\frac{d}{dx}\left[x\tau^{1/3}\frac{d\omega}{dx}\right]+\frac{(Z-\Gamma)R^2}{b_p(0)\,u_e(0)\,n_0}=0, \qquad (22)$$

$$\omega(0)=1,\ \frac{d\omega}{dx}\Big|_{x=0}=0,\ \ \omega(1)=0. \qquad (23)$$

Expressing n_0, $u_e(0)$, and Θ_0 through i/R, pR, Θ_R, and R by means of Eqs. (4), (5), and (21), we obtain an equation for ω in terms of the parameter ER. For given external parameters, the magnitude of ER is determined by the boundary conditions (23). The equation is solved numerically. The solution yields a profile of ω and a value of ER.

It should be noted that in the numerical integration of Eq. (22) with the initial conditions (23), the behavior of the function ω depends strongly on the parameter ER. In the numerical integration it is therefore necessary to vary the value of ER with a high degree of accuracy. This feature is illustrated in Fig. 1.

Using the function ω, one can find an expression for n_0 in the next approximation from Eq. (3) by calculating the integral $\int_0^1 \omega x dx$. The pressure p with the discharge on appears in the theory. The pressure p_0 with no discharge is usually measured experimentally. The relation between p and p_0 depends on the configuration of the discharge tube. If the cold volumes are small, this relation has the form

$$p=p_0\frac{\Theta_R}{3\Theta_k}\left[1+\sqrt{\frac{\Theta_0}{\Theta_R}}+\frac{\Theta_0}{\Theta_R}\right], \qquad (24)$$

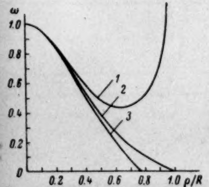

Fig. 1. Solution of Eq. (22) as a function of the parameter ER. pR = 96 torr · cm; i/R = 41.6 mA/cm; ER, V: 1) 34.2; 2) 34.268; 3) 34.3.

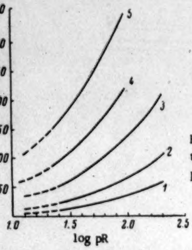

Fig. 5. Dependence of neutral gas temperature $\theta_0 - \theta_R$(°K) on pressure pR with discharge on.

for a cylindrical tube, where Θ_k is the temperature in the absence of a discharge.

In the derivation of this equation the Bessel function is approximated by a parabola.

Calculated results for ER, n_0R, u_e, and Θ_0 as functions of pR and i/R are shown in Figs. 2-5. The function ω is shown in Fig. 6.

A comparison is made in Table 1 of values for ER and n_0R which have been determined experimentally,[21] calculated from a theory not including emission of resonance radiation and recombination,[8] and calculated from the present theory. Consideration of resonance radiation emission and recombination significantly increases the value of the field and of the electron temperature. From Table 1, where the quantity Z_1 [see Eq. (16)] is also presented, it is clear that the role of emission is extremely important, especially at low currents.

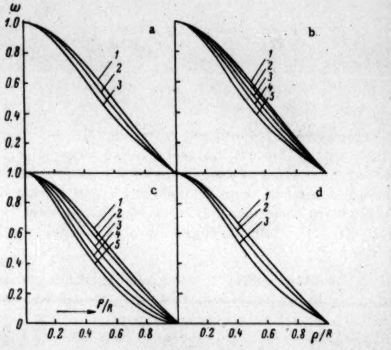

Fig. 6. Radial decrease in the function ω, pR, torr · cm: a) 36; b) 60; c) 96; d) 200.

TABLE 2. Check of Similarity Rules for Positive Column Parameters (pR = 60 torr · cm; i/R = 41.6 mA/cm)

	R, cm			
	1.2	2.8	9	36
ER	15.05	15.15	15.30	15.50
n_0R	10.66	10.62	10.55	10.47
u_e	2.95	2.96	3.01	3.05
Θ_0	443	445	446	447

The calculated values at low currents are in good agreement with experimental values. The agreement gets worse as the current increases. It should be noted that in the region i/R ≈ 40 an abrupt transition of the discharge into a contracted state occurs which is accompanied by the appearance of striations. The steady-state theory is not applicable under these conditions.

In addition to i/R, pR, and Θ_R, the quantity Z also clearly depends on $\sqrt{R}$, which may lead to a breakdown of the similarity rules.[20] In practice, however, the deviations from the similarity rules are small, as is clear from Table 2.

A number of the assumptions made in the calculation of the quantity Z_1 makes it possible to assume that the quantity Z is determined with a severalfold accuracy. Such variations in the quantity Z lead to variations of 10-20% in the values of the parameters ER, n_0R, and u_e.

In addition, the theory contains a number of assumptions such as neglect of the contribution of inelastic collisions to the energy balance and inaccuracies in the values used for elementary process cross sections.

The divergence between experimental and theoretical values up to the discontinuity is also in the range of 10-20%.

Similitude in Hall-current plasma accelerators

A. I. Morozov and I. V. Melikov

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 44, 544-548 (March 1974)

The various ionization regimes ("point," "drift," and "compact-jet") in a Hall-current plasma accelerator are discussed. For the case of drift ionization, which is the most efficient in terms of the energy expended in ionization and ion loss to the wall for the channel, an equation is found for the ionization length in terms of the flow parameters. This equation gives the efficiency of the accelerator for various working media. The ion dynamics in a Hall-current plasma in the case in which ionization occurs is treated in the kinetic approximation. The solution is shown to depend on two similarity criteria–analogs of the Froude and Knudsen numbers. The ionization length is found as a function of these criteria.

Experiments have shown that in Hall-current plasma accelerators, in which electron drift is suppressed and in which there is an extended acceleration zone, the working medium can be either a gas[1,2] or a metal.[3] The differences in behavior which are encountered in operation with various working media can be attributed primarily to the ionization process, whose course depends on the specific conditions. For example, if the working medium is supplied to the accelerator channel from some volume (anode) through an aperture, the frequent result is "point ionization,"[4] in which each aperture in the anode acts like a point plasma source. Under the influence of the supercritical pressure drop, the plasma expands from such a source in the channel at an angle of ~ 180°, leading to a significant loss of ions to the wall. On the other hand, volume ionization of the working medium can occur in a "compact jet," i.e., in a gas jet issuing from apertures in the anode. Such a jet can be followed well by probes in measurements of both the ion current and the potential profile. A distinguishing feature of a jet is the production of a pronounced gradient of the pressure (or of $E_\perp$), which also leads to the rapid loss of ions at the channel wall. These two ionization regimes occur particularly frequently in the case of operation with an easily ionizable substance.

There is another ionization regime, in principle the optimum regime, that of "drift" ionization, which arises in comparatively strong magnetic and electric fields. The ions which are produced are subjected to the axial electric field $E_\parallel$ due to the magnetization of the electrons. Again in this case there is component $E_\perp$, but since the ionization occurs over the entire width of the channel the pressure gradients are vanishingly small. The drift-ionization regime occurs in a Hall-current accelerator in the region in which the ion current reaches its maximum; the secondary ionization of neutrals reflected from the wall obviously also is of a drift nature. It is this ionization regime with which we are concerned in the analysis below.

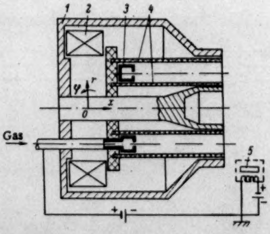

Fig. 1. The accelerator. 1) Magnetic circuit; 2) magnetization coil; 3) anode; 4) insulators; 5) neutralizer cathode.

1. Let us consider in more detail the ionization parameters in a Hall-current accelerator (Fig. 1). The criterion determining the efficiency of the accelerator operation with various working media (instead of considering the interaction of the ion flow with the channel wall) is taken to be the characteristic length of the channel over which the ionization of the working medium is essentially complete: λ_n. Assuming in a first approximation that this ionization length λ_n is shorter than the characteristic dimension of the inhomogeneity of the flow (e.g., the channel length L), we can assume

$$\lambda_n = \frac{v_a}{\beta n_e}. \tag{1}$$

Here, v_a is the characteristic velocity of the neutrals, n_e is the electron density averaged over the ionization length, and $\beta(T_e, A) \equiv \langle \sigma v_e \rangle_n$ is the ionization coefficient, which is a function of the electron temperature T_e and the nature of the working medium A (see, e.g., ref. 5). On the other hand, ions of mass M moving a distance λ_n in an electric field E acquire a velocity

$$v_i = \langle v \rangle = \frac{1}{n_i}\int_0^\infty v f(x, v)\, dv = \frac{1}{\chi}\left(\frac{2eE\lambda_n}{M}\right)^{1/2}. \tag{2}$$

Here $f(x, v)$ is the ion velocity distribution, and $\chi \sim 1$ is a dimensionless constant. Comparing Eqs. (1) and (2) we conclude that

$$\lambda_n = \frac{1}{\chi^2}\frac{2eEv_a^2}{M\beta^2 n_e^2 v_i^2}.$$

Also, taking account of the plasma-quasineutrality condition $n_e \simeq n_i$, and using

$$n_i v_i = q_i \simeq q_0 \quad \text{for} \quad x \simeq \lambda_n,$$

where q_i and q_0 are the flux of ions and the total heavy-particle flux at the entrance to the channel, we find

$$\lambda_n = \frac{1}{\chi^2}\frac{2eEv_a^2}{M\beta^2 q_0^2}. \tag{3}$$

We have thus derived an equation for a criterion of the operating efficiency. This criterion takes account of the nature of the working medium (M, β), the intensity of the flow (q_0, v_a), and the electrical parameters of the accelerator. We can now show that Hall-current accelerators operating with any working medium are similar in terms of efficiency if the condition λ_n = idem is satisfied, where λ_n is given by Eq. (3).

2. For a more detailed analysis of the processes occurring in a Hall-current accelerator we consider the dynamics of the ion flow in the accelerator channel, taking account of ionization and the consumption of neutral atoms. Since collisions between ions and other particles are negligibly rare, and since the ion Larmor radius is much longer than the length of channel, in describing the dynamics of the ion component we must use a kinetic equation in which collisions can be neglected but in which ionization must be taken into account.[6] As a first approximation we formulate the problem in the following manner.

The ion motion is steady-state and one-dimensional in a known longitudinal electric field E(x), and the quasineutrality condition $n_e \simeq n_i = \int_0^\infty f(v)dv$ is satisfied. We neglect the interaction of ions with the wall and the effect of the magnetic field on the ion trajectories. The profile of the electron temperature, $T_e(x)$, and the characteristic ion temperature T_i are known.

The motion of the neutrals before their ionization by electrons is also one-dimensional and collisionless (free-molecular flow). The atomic temperature T_a is known.

The (single-step) ionization of the atoms occurs by electron impact.

The flows of ions, q_{i0}, and atoms, q_{a0}, in the initial cross section of the channel are specified, and the particle velocities are described by one-sided Maxwell distributions with temperatures T_i and T_a, respectively.[7] The flows of ions and atoms are homogeneous over the cross section of the channel.

In this formulation of the problem the behavior of the ions and atoms is described by

$$\left.\begin{aligned} v\frac{\partial f(x,\,v)}{\partial x}+\frac{e}{M}E(x)\frac{\partial f(x,\,v)}{\partial v}&=\beta(x)\,n_e(x)\,g(x,\,v),\\ v\frac{dg(x,\,v)}{dx}&=-\beta(x)\,n_e(x)\,g(x,\,v)\end{aligned}\right\}\tag{4}$$

with the following boundary conditions at x = 0:

$$\left.\begin{aligned} f(0,\,v)&=\frac{Mq_{i0}}{kT_i}\exp\left(-\frac{Mv^2}{2kT_i}\right)\cdot\\ g(0,\,v)&=\frac{Mq_{a0}}{kT_a}\exp\left(-\frac{Mv^2}{2kT_a}\right)\cdot \end{aligned}\; v\geqslant 0, \quad f(0,\,v)=g(0,\,v)=0,\;\; v<0.\right\}\tag{5}$$

Here $f(x,v)$ and $g(x,v)$ are the ion and atom velocity distributions, and $\beta(x) = \beta(T_e, A)$ is the coefficient of electron-impact ionization of the atoms.[5] Knowing $f(0,v)$ and $g(0,v)$ we can determine the densities and average velocities of the ions and atoms at the entrance to the channel:

$$n_{i0}=\int_0^\infty f(0,\,v)\,dv=q_{i0}\left(\frac{\pi M}{2kT_i}\right)^{1/2},\quad v_{i0}=\left(\frac{2kT_i}{\pi M}\right)^{1/2},$$

$$n_{a0}=\int_0^\infty g(0,\,v)\,dv=q_{a0}\left(\frac{\pi M}{2kT_a}\right)^{1/2},\quad v_{a0}=\left(\frac{2kT_a}{\pi M}\right)^{1/2},\tag{6}$$

where $q_0 = q_{i0} + q_{a0}$, $n_0 = n_{i0} + n_{a0}$.

In addition, the particle flow at the entrance can be characterized by the velocity

$$v_0^*=\frac{q_0}{n_0}=\gamma v_{a0},$$

where

$$\gamma=1+\alpha_0\left(\frac{1}{\theta}-1\right),\quad \alpha_0=\frac{n_{i0}}{n_{i0}+n_{a0}},\quad \theta=\left(\frac{T_a}{T_i}\right)^{1/2}.\tag{7}$$

At the typical values $T_i/T_a \geqslant 10$ and with $\alpha_0 = 0.01$-0.1 this coefficient is $\gamma = 1.02$-1.2.

To convert to dimensionless variables we use the flow parameters at the entrance to the channel, n_0, v_0^*, β_0, and $E_0 = \varepsilon_0 U_p/L$, along with the channel length L:

$$\left.\begin{aligned} x'=\frac{x}{L},\;\; v'=\frac{v}{v_0^*},\;\; f'=\frac{f}{\frac{n_0}{v_0^*}},\;\; g'=\frac{g}{\frac{n_0}{v_0^*}},\;\; \varepsilon=\frac{EL}{\varepsilon_0 U_p},\\ n_i'=\frac{n_i}{n_0},\;\; n_a'=\frac{n_a}{n_0},\;\; \beta'=\frac{\beta}{\beta_0}\;\;\cdot\end{aligned}\right\}\tag{8}$$

We can now write Eqs. (4) and boundary conditions (5) as follows (below we omit the primes from the dimensionless quantities):

$$\left.\begin{aligned} v\frac{\partial f(x,\,v)}{\partial x}+\frac{1}{\xi}\varepsilon(x)\frac{\partial f(x,\,v)}{\partial v}&=\frac{1}{\zeta}\beta(x)\,n_e(x)\,g(x,\,v),\\ v\frac{dg(x,\,v)}{dx}&=-\frac{1}{\zeta}\beta(x)\,n_e(x)\,g(x,\,v),\end{aligned}\right\}\tag{9}$$

$$\left.\begin{aligned} f(0,\,v)&=\frac{2}{\pi}\alpha_0\gamma\theta\exp\left(-\frac{\gamma^2\theta^2}{\pi}v^2\right)\cdot\\ g(0,\,v)&=\frac{2}{\pi}(1-\alpha_0)\,\gamma\exp\left(-\frac{\gamma^2}{\pi}v^2\right), \end{aligned}\; v\geqslant 0, \quad f(0,\,v)=g(0,\,v)=0,\;\; v<0.\right\}\tag{10}$$

Here $\varepsilon(x)$ is the shape coefficient of the electric field.

We see that our problem contains two dimensionless similarity parameters:[8] an analog of the Froude number,

$$\xi=\frac{Mv_0^{*2}}{e\varepsilon_0 U_p}\tag{11}$$

and an analog of the Knudsen number,

$$\zeta=\frac{v_0^*}{\beta_0 n_0 L};\tag{12}$$

We also have the parameters α_0, γ, and θ, defined by (7).

3. The results of the solution of system (9), (10) are given in detail and analyzed in the following paper (ref. 9). Here we note that by specifying the parameter ζ by

$$\zeta=\frac{v_0^{*2}}{\beta_0 q_0 L}$$

and constructing the combination of similarity criteria

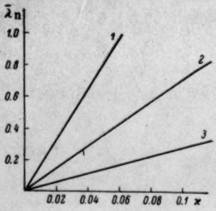

Fig. 2. Ionization length as a function of the complex similarity parameter. q_i: 1) 0.9; 2) 0.7; 3) 0.3.

$$\varkappa = \frac{\zeta^2}{\xi} = \frac{eE_0 v_0^{*2}}{M\beta_0^2 a_0^2 L}, \tag{13}$$

where $E_0 = \varepsilon_0(U_p/L)$, we can find a relation between Eq. (3) for the ionization length λ_n and similarity parameter $\varkappa$ in (13):

$$\bar{\lambda}_n = \frac{\lambda_n}{L} \sim \varkappa \tag{14}$$

Accordingly, we can assert that the relative ionization length $\bar{\lambda}_n$ is actually (within a constant factor which is a function of the structure of the flow and the ionization dynamics) the similarity criterion for the processes in a Hall-current accelerator.

Calculations[9] support this functional dependence. Figure 2 shows λ_n as a function of $\varkappa$ for three cases: When the ion flow over a length λ_n reaches 0.9, 0.7, and 0.3 of the total heavy-particle flow. [For these calculations it was assumed that $E(x) = E_0 = \text{const}$]. If we adopt the channel length corresponding to the first of these three cases, $\bar{\lambda}_n^{0.9}$, as the characteristic length of the ionization zone in the accelerator, we can approximate the functional dependence found by

$$\bar{\lambda}_n^{0.9} \simeq 5\pi\varkappa. \tag{15}$$

In conclusion the authors thank V. A. Abramov and V. V. Fishgoit for useful discussions.

Equilibrium flow in a Hall-current plasma accelerator

I. V. Melikov

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 44, 549-553 (March 1974)

The dynamical problem of the ion flow in the channel of a Hall-current plasma accelerator is solved for the case in which ionization and "consumption" of neutrals are taken into account. The profile of the ion distribution function and of its moments along the channel are determined on a computer. The effect of external parameters (the electric field, the flow rate of the working medium, the initial degree of ionization, etc.) on the length of the ionization zone is analyzed. The characteristic operating regions of such an accelerator are determined for various working media and for conditions under which the accelerator has an acceptable efficiency.

1. The following system of equations describing the dynamics of ions and atoms in the channel of a Hall-current plasma accelerator, in which electron drift is suppressed and in which there is an extended acceleration zone, is derived in dimensionless form in ref. 1:

$$\left.\begin{aligned} v\frac{\partial f(x,v)}{\partial x}+\frac{1}{\xi}\varepsilon(x)\frac{\partial f(x,v)}{\partial v}&=\frac{1}{\zeta}\beta(x)n_e(x)g(x,v),\\ v\frac{dg(x,v)}{dx}&=-\frac{1}{\zeta}\beta(x)n_e(x)g(x,v)\,.\end{aligned}\right\}\qquad(1)$$

The corresponding boundary conditions at x = 0 are

$$\left.\begin{aligned} f(0,v)&=\frac{2}{\pi}\alpha_0\gamma\theta\exp\left(-\frac{\gamma^2\theta^2}{\pi}v^2\right)\\ g(0,v)&=\frac{2}{\pi}(1-\alpha_0)\gamma\exp\left(-\frac{\gamma^2}{\pi}v^2\right)\end{aligned}\quad v\geqslant 0,\right.$$
$$f(0,v)=g(0,v)=0,\ v<0.\qquad(2)$$

Here, $f(x, v)$ and g(x, v) are the ion and atom velocity distributions, $\beta(x) = \beta(T_e, A)$ is the ionization coefficient,

$n_e \simeq n_i = \int_0^\infty f(x, v)dv$,

$$\xi=\frac{Mv_0^{*2}}{e\varepsilon_0U_p},\quad \zeta=\frac{v_0^*}{\beta_0n_0L},\qquad(3)$$

$$\left.\begin{aligned}\alpha_0=\frac{n_{i0}}{n_0},\ n_0=n_{i0}+n_{a0},\ \gamma=1+\alpha_0\left(\frac{1}{\theta}-1\right),\\ \theta=\left(\frac{T_a}{T_i}\right)^{1/2},\ v_0^*=\frac{q_0}{n_0}=\gamma v_{a0}.\end{aligned}\right\}\qquad(4)$$

Here, the subscript "0" denotes the characteristic value of a parameter at the entrance to the channel. The accelerator anode lies at the cross section x = 0, and the working medium is supplied in this cross section. The medium is assumed to be distributed homogeneously over the channel cross section.

To solve this problem we must know the functions E(x) and T_e(x). The electron dynamics in a Hall-current accelerator is not governed by collisional processes. It has been shown[2] that the anomalously high plasma conductivity across the magnetic field is due to electron drift in the crossed fields H_r and E_φ; these fields arise because of instabilities which build up in the accelerator. As a result, we do not at present have an acceptable method for calculating E(x) or T_e(x). However, following Morozov,[3] we can take these functional dependences directly from experiment in analyzing models for Hall-current accelerators. We find that in many of the most interesting cases the functional dependence $E_x(x)/H_r(x) \simeq$ const holds. Furthermore, since the behavior of E(x) and T_e(x) can be complicated, we simplify the calculations by seeking the solution over a short distance x_{k-1}-x_k, over which the functions E(x), T_e(x), and β(x) can be assumed to be linear. Moreover, since the quantity $n_e \simeq n_i$ which appears in Eq. (1) is governed by the unknown distribution function $f(x, v)$, the latter can be found within a specified error (0.01 in the calculated results shown below) by carrying out iterations with respect to n_i.

Under these assumptions, the equation for $f(x, v)$ can be solved by the method of characteristics,[4] while that for g(x, v) can be solved by direct integration.

We find

$$f_k(v)=\mu(v)f_{k-1}(v_0)+\frac{\xi}{\zeta}\int_{\mu(v)v_0}^{v}\frac{\beta(x')n_i(x')}{\varepsilon(x')}g(x',v')\,dv',\qquad(5)$$

$$g_k(v)=g_{k-1}(v)\exp\left(-\frac{1}{\zeta v}\int_{x_{k-1}}^{x_k}\beta(x)n_i(x)\,dx\right).\qquad(6)$$

Here,

$$\mu(v)=\begin{cases}1 \text{ for } v\geqslant\bar{v}\\ 0 \text{ for } v<\bar{v}\end{cases}\quad \bar{v}=\left(\frac{2}{\xi}\int_{x_{k-1}}^{x_k}\varepsilon(x)\,dx\right)^{1/2},\quad v_0^2=v^2-\bar{v}^2.\qquad(7)$$

The coordinate x' is found from the condition

$$v^2=v'^2+\frac{2}{\xi}\int_{x'}^{x_k}\varepsilon(x)\,dx.$$

For the case of a linear function ε(x) we have

$$x'=\frac{\delta x}{\delta\varepsilon}\left\{\varepsilon_k-\left[\varepsilon_{k-1}^2+\frac{\delta\varepsilon}{\delta x}\xi(v^2-v'^2)\right]^{1/2}\right\},\qquad(8)$$

where $\delta x = x_k - x_{k-1}$ and $\delta\varepsilon = \varepsilon_k - \varepsilon_{k-1}$.

The ion and atom velocity distribution functions are calculated on a computer. From the functions $f(x, v)$ and g(x, v) found this way we determine the first few moments of the distribution functions: the densities n(x), the fluxes q(x), the average directed velocities ⟨v⟩, and the momen-

tum flux of the particles r(x), defined by

$$\left.\begin{array}{l} n(x)=\int\limits_0^\infty f(x,\,v)\,dv;\quad q(x)=\int\limits_0^\infty vf(x,\,v)\,dv; \\ \langle v\rangle=\frac{q(x)}{n(x)};\quad r(x)=\int\limits_0^\infty v^2f(x,\,v)\,dv. \end{array}\right\} \tag{9}$$

2. We turn now to the specific functions E(x) and $T_e(x)$ adopted in this problem and to the method for calculating the ionization coefficient. It follows from criterial functional dependence (3) and solution (5) that the ion distribution function is a function of the electric field, in particular, of the value of the field at the entrance to the channel, E_0. Accordingly, in our first series of calculations we determine the effect of the electric field in the channel and of other flow parameters on the dynamics of the ion flow and the length of the ionization zone. For this case the calculations are carried out as a function of the ratio of the similarity criteria ξ and ζ for a homogeneous electric field over the channel length, $E(x) = E_0 = \text{const}$.

In a second series of calculations we adopt the behavior of E(x) and of the potential $\varphi(x)$ characteristic for this type of accelerator (Fig. 1).

Lacking more accurate experimental data, we adopt an electron temperature of $T_e(x) = 10$ eV = const for these rough calculations. The electron temperature is in fact observed to be on this order of magnitude over broad ranges of parameter values in Hall-current accelerators operating with various working media.[3]

The primary mechanism for the ionization of atoms in such an accelerator is ionization by drifting electrons.[1] We therefore use the procedure of ref. 5 to calculate the ionization coefficient. We take only single-step ionization into account, and we assume an equilibrium energy distribution for the electrons. Table 1 shows the calculated ionization coefficients β for $T_e = 10$ eV for several gaseous and metallic substances.

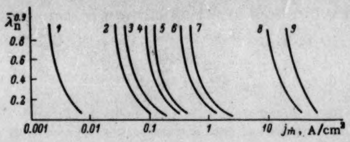

Fig. 2. Working regions of the Hall-current accelerator for various working substances. $E_0 = 15$ V/cm, $T_e = 10$ eV. 1) Cs; 2) Mg; 3) Xe; 4) Li; 5) Kr; 6) Ar; 7) N; 8) H; 9) He.

While the value of β for metals is essentially constant over the electron-temperature range $T_e = 5$–15 eV, that for the gases varies by a factor of 4–6 over this range. Accordingly, if the calculated results are to be a good approximation to the actual situation, it is important to accurately determine T_e experimentally in the various specific systems.

In calculating the ion and atom distribution functions we divide the channel length into 100 equal segments. The characteristic step in the velocity integration is $h_v = 0.3$.

3. We begin the discussion of results with an analysis of the effects of various factors on the ionization efficiency in a Hall-current accelerator. A criterial functional dependence of the ionization length λ_n (defined in terms of the relative ion flux q_i) on the complex similarity parameter is derived in ref. 1:

$$\bar{\lambda}_n=\frac{\lambda_n}{L}=a\varkappa;\quad \varkappa=\frac{\zeta^2}{\xi}=\frac{eE_0v_0^{*2}}{M\beta_0^2q_0^2L}. \tag{10}$$

On the basis of this functional dependence we can draw certain conclusions regarding the operation of a Hall-current accelerator with various working media. Below we choose as the characteristic length of the ionization zone the distance over which the relative ion flux reaches $q_i = 0.9$, $\bar{\lambda}_n^{0.9}$. Figure 2 shows $\bar{\lambda}_n^{0.9}$ as a function of the mass flow rate, expressed in current units, for several possible working media. Here, the characteristic parameters are $E_0 = 15$ V/cm, $T_e = 10$ eV, $T_a = 600$°K, L = 4 cm, and $\alpha_0 = 0.01$ (calculations show that a change in the ion temperature from $T_i \simeq T_a$ to $T_i \simeq 1$ eV because of the strong electric field and rapid ionization has essentially no effect on the integral flow charac-

teristics).

On the basis of these results we can determine the ranges of electrical parameters of the accelerators and the ranges of application for various working media. For example, we see that for an acceptable accelerator efficiency the ion current density in the channel must be above certain critical values: ~0.1 A/cm^2 for xenon and ~1 A/cm^2 for argon and nitrogen. The discharge currents differ by an order of magnitude. There is no upper limit on the current density in this formulation of the problem, since estimates show that collisions between ions are negligible, and resonant charge exchange of ions with atoms becomes appreciable as the flow of the substance is increased in a progressively narrowing part of the channel, having a dimension comparable to the length of the ionization zone, over which the potential drop is slight.

It follows from (10) that the length of the ionization zone is governed largely by the strength of the electric field in this part of the channel and by the temperature (velocity) of the neutral atoms. A reduction of either of these parameters tends to increase the rate of ionizing collisions because of the increase in the particle density (or lifetime) in the ionization zone. Figure 3 shows the ionization length $\bar{\lambda}_n^{0.9}$ as a function of the flow rate of the substance (xenon) for several characteristic values of E_0 and T_a. While T_a (and v_a) is strongly influenced by the method used to supply the working media and by heat evolution in and near the anode, the electric field intensity (within a coefficient which is a function of T_e) is in several cases governed by the geometry of the magnetic field, H_r, as was mentioned above. Accordingly, if the electric field is to be weak in the ionization zone, the magnetic field H_r in the channel must fall off from the end of the channel toward the anode. This conclusion is in qualitative agreement with experimental results,[6] according to which a magnetic field decreasing in the opposite direction leads to a slight increase in the ion current over the channel length, and "ionizational oscillations" are built up over the entire volume of the accelerator channel.

In the calculations we also studied the effect of the initial degree of ionization α_0 on the flow parameters.

Figure 4 shows $\bar{\lambda}_n^{0.9}$ as a function of the flow rate of the working medium for initial values of $\alpha_0 = 0.1$, 0.01, and 0.001. We see that at flow rates providing a comparatively narrow ionization zone, $\bar{\lambda}_n^{0.9} < 0.3$, the effect of α_0 in this range is slight, and there is essentially no effect at $\alpha_0 < 0.001$. Accordingly, the development of a discharge in the accelerator channel does not require any type of powerful preionizer.

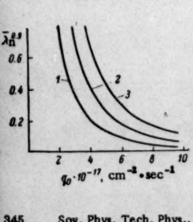

Fig. 3. Effects of the electric field and the atom temperature on the ionization length. Xe, T_a = 600°K; E_0, V/cm; 1) 7.5; 2) 15; 3) 25; E_0 = 7.5 V/cm; T_a^0 K: 1) 600; 2) 1200; 3) 2000.

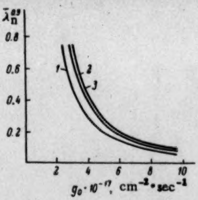

Fig. 4. Effect of the initial degree of ionization α_0: 1) 0.1; 2) 0.01; 3) 0.001.

4. As an example we consider the results calculated for equilibrium flow in a Hall-current accelerator having the E(x) and φ(x) distributions typical of this type of accelerator (Fig. 1). The basic initial data are as follows: a working medium of xenon, T_e = 10 eV, T_a = 600°K, T_i = 6000°K, $\alpha_0 = 0.01$, and L = 4 cm. Figure 5 shows the changes over the channel length in the ion velocity distribution, the ion flux q_i, the ion density n_i, and the quantity $\eta_v = R^2/2\dot{m}I_i(\varphi_a - \varphi_k)$, which gives the scatter in the ion velocities at the exit from the accelerator due to the extended ionization zone. Here R is the ion momentum, $\dot{m}$ is the mass flow rate of the medium, I_i is the ion current at the exit, φ_a is the plasma potential near the anode, and φ_k is the plasma potential at the end of the channel ($\varphi_a - \varphi_k$ = 140 V).

It is interesting to note the behavior of the ion flux, which qualitatively reproduces that of the measured ion current in the ionization zone after the entire cross section of the channel is filled with a working substance.[7,8] The subsequent reduction of the ion current which occurs under real conditions is attributed to the escape of ions to the wall, neglected in our calculation model.

It also follows from the calculated results that the maximum charged-particle density increases with increasing flow flux and shifts toward the anode. At comparatively low flow rates a region is observed near the anode which is depleted of charged particles, because the effect of the electric field on the ions is not balanced by the production of ions in ionization events.

Among the other results we note the behavior of the parameter η_v as a function of the total flux (Fig. 5d). This parameter is the limiting efficiency of a certain idealized model of an accelerator in which only the expenditure on ionization is taken into account. On the basis of these results, we can assert, e.g., that at flow rates of a gaseous working substance lower than $2 \cdot 10^{17}$ cm^{-2} · sec^{-1} an acceleration efficiency higher than 0.5-0.6 cannot be achieved in real accelerators.

Calculation of the flow dynamics of neutrals in a Hall-current accelerator has shown that low-velocity particles are "consumed" most rapidly in ionization, so that (under our assumptions regarding the nature of the flow, i.e., that it is collisionless, free-molecular flow) the atomic velocity averaged over the distribution function increases by a factor of about 2-3 by the end of the channel.

5. Accordingly, these calculations for equilibrium flow in a Hall-current accelerator have yielded a concrete criterial dependence of the length of the ionization zone on the complex similarity parameter, which incorporates the nature of the working medium, its flow rate,

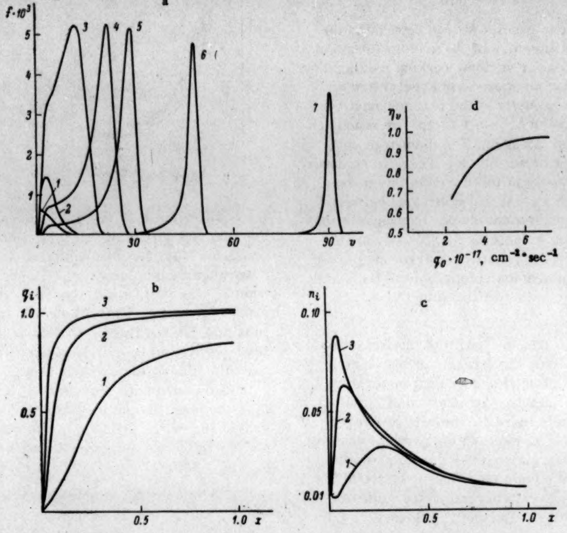

Fig. 5. Changes in the basic parameters of the ion flow in the accelerator channel. Xe, T_e = 10 eV, $T_a = 600°K$, $T_i = 6000°K$, $\alpha_0 = 0.01$, $L = 4$ cm, and φ and E(x) from Fig. 1. a: $q_0 = 4.8 \cdot 10^{17}$ cm^{-2}·sec^{-1}: 1) x = 0; 2) 0.01; 3) 0.1; 4) 0.2; 5) 0.3; 6) 0.5; 7) 1.0. b,c: 1) $q_0 = 2.4 \cdot 10^{17}$ cm^{-2}·sec^{-1}; 2) $4.8 \cdot 10^{17}$; 3) $7.2 \cdot 10^{17}$. d: $\varphi_a - \varphi_k = 140$ V.

the rate at which the neutral component is supplied, the channel length, and characteristic electrical and ionizational parameters in the anode region of the channel. This criterial dependence has been used to estimate the possible ranges of electrical parameters in Hall-current accelerators using various working media.

We have studied the effect of the magnitude and behavior of the electric field and of the initial degree of ionization on the dimensions of the ionization zone. We find that for efficiency of the ionization and acceleration the radial magnetic field must have a positive gradient in the direction from the anode toward the end of the channel. This conclusion agrees qualitatively with experimental results. The efficiency of an ideal accelerator was found as a function of the flow rate of the working medium with an account of the expenditure on ionization. This analysis gives us a more complete picture of equilibrium flow in a Hall-current accelerator.

In conclusion the author thanks A. I. Morozov for suggesting the topic and for constant interest in this work, and V. V. Fishgoit for discussion of the calculated results.

The focusing of a neutralized beam of hydrogen ions by a plasma lens is studied. An axisymmetric plasma-optics system with closed electron drift focuses a plasma flow effectively and can be used as an element in a plasma–injector system.

Considerable effort is currently being devoted to the study and development of plasma lenses because of their possible use in several important applications: plasma accelerators, high-current mass separators, etc. It is therefore useful to examine questions related to the collimation and focusing of high-current ion beams whose space charge is neutralized by electrons.

The corpuscular optics of low-current ion beams neglects the space-charge field on the beam and the electrostatic interaction between individual ions.[1] These simplifications are possible at low beam densities; in this case the space charge is negligible and the electric scalar potential satisfies the Laplace equation:

$$\Delta\Phi = 0. \tag{1}$$

These restrictions are not necessary for high-current ion beams whose space charge is neutralized, if appropriate conditions are arranged for penetration of the electric field into the low-density plasma. The basic factor opposing this penetration is the high electron mobility. The equation of motion of the electronic component of a plasma in the simplified hydrodynamic approximation is

$$mn_e \frac{d\mathbf{v}_e}{dt} = -\nabla p_e - en_e\left(\mathbf{E} + \frac{1}{c}[\mathbf{v}_e\mathbf{H}]\right) + \frac{en_e}{\sigma}\mathbf{j}, \tag{2}$$

where σ is the beam conductivity, $\mathbf{j}$ is the beam current density, and n_e is the electron density in the beam, which is equal to the ion density n_i in a neutral medium.

We use the following assumptions:

1. The random energy of the electrons is small in comparison with the potential difference in the system: $W_e \ll e\varphi$.

2. The current density in the beam is low enough to satisfy the condition $\mathbf{j} \ll \sigma\mathbf{E}$.

3. The directed electron velocities are lower than or of the order of the ion velocities: $v_e \lesssim v_i$.

Under these conditions the equation of motion for the electrons becomes

$$\mathbf{E} + \frac{1}{c}[\mathbf{v}_e\mathbf{H}] = 0. \tag{3}$$

It follows that an electric field can exist in a low-density plasma only if there is a magnetic field and if there is electronic drift; the electric field is perpendicular to both $\mathbf{H}$, and $\mathbf{v}_e$. Accordingly, the magnetic lines of force must lie along electric equipotentials. This conclusion holds when the electron pressure is negligible. More rigorously, we state that it is the "thermalized potential"

$$\Phi^*(\psi) = \Phi - \frac{kT_e(\psi)}{e}\ln\frac{n}{n_0} \tag{4}$$

which is conserved along a magnetic line of force. Here $T_e(\psi)$ is the electron temperature and n_0 is the normalization density. As $T_e \to 0$ or $\ln(n/n_0) \to 0$, a magnetic line of force is, in a first approximation, an equipotential:

$$\Phi = \Phi(\psi). \tag{5}$$

Morozov[2] has shown that axisymmetric electromagnetic systems in which the electric and magnetic fields do not have azimuthal components and in which the electron drift is in the azimuthal direction and is closed can be used to focus plasma or neutralized ion beams. These systems have been called "plasma-optics systems." We note that the use of plasma optics largely eases the restriction on the magnitude of the beam space charge. Furthermore, simple means can be used to correct aberrations in plasma-optics systems. Finally, in several cases such systems have a considerably higher refractive power than vacuum magnetic systems or electrostatic systems. These features of plasma lenses are related to the redistribution of the electric field within the lens and to the replacement of Laplace equation (1) by the condition that the magnetic lines of force be equipotentials, condition (5).

Let us consider an extremely simple focusing system – a thin ring carrying a current I, i.e., an ordinary magnetic lens – and let us assume that this ring has been charged to a potential φ. The focal length of such a lens for the transmission of a weak, unneutralized ion beam is (in the thin-lens approximation)

$$\frac{1}{F} = \frac{3\pi^3}{16}\frac{e^2}{M_i c^4}\frac{1}{W_i}\frac{I^2}{R} + \frac{3\pi}{128R}\left(\frac{e\varphi}{W_i}\right)^2. \tag{6}$$

In the particular cases $I \neq 0$, $\varphi = 0$ and $I = 0$, $\varphi \neq 0$ we find magnetic and electrostatic lenses, respectively. The focal length of the magnetic lens is given by

$$\text{a)}\quad \frac{1}{f_H} = \frac{3\pi^3}{16}\frac{e^2}{M_i c^4}\frac{1}{W_i}\frac{I^2}{R} \quad\text{or}\quad f_H = 1.8\cdot 10^5\frac{M_i W_i R}{I^2}$$

where M_i is in atomic units, W_i is in electron volts, and I is in amperes. In this case we have ion-momentum focusing. The focal length of the electrostatic lens is given by

$$\text{b)}\quad \frac{1}{f_E} = \frac{3\pi}{128R}\left(\frac{e\varphi}{W_i}\right)^2, \quad f_E = 13.6\left(\frac{W_i}{e\varphi}\right)^2 R;$$

in this case we have ion-energy focusing.

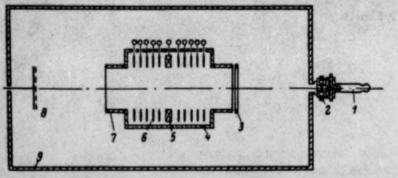

Fig. 1. The experimental apparatus. 1) Ion source; 2) electrostatic lens; 3) electronic compensator; 4) magnetic shield; 5) magnet coil; 6) disks; 7) fitting; 8) probe; 9) housing of vacuum chamber.

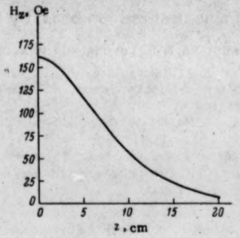

Fig. 2. Profile of the magnetic field along the axis of the plasma lens.

When a dense, neutralized ion beam with current I and a potential φ passes through such a lens the electric field is altered to the form $\Phi = \Phi(\psi)$, where $\psi = rA_\varphi$ is the magnetic flux function and A_φ is a component of the magnetic vector potential $\mathbf{A} = \mathbf{A}(0, A_\varphi, 0)$. The focal length of such a plasma lens is calculated in ref. 3 under the assumption of the simple functional dependence $\Phi = k\psi$:

$$\frac{1}{f}=\frac{1}{f_H}+\frac{2}{R}\left(\frac{e\varphi}{W_i}\right), \quad f=\frac{R}{2}\left(\frac{W_i}{e\varphi}\right)\frac{1}{1+\alpha}, \tag{7}$$

where $\alpha = 2.8 \cdot 10^{-6}[I^2(M_i\varphi)]$ (I is in amperes, M_i is in atomic units, and φ is in volts). In a real situation we have $\alpha \ll 1$.

The differences among these three cases become more apparent when we write the equations relating f, f_H, and f_E:

$$\frac{f}{f_H}=\frac{\alpha}{1+\alpha}, \quad \frac{f}{f_E}=3.68 \cdot 10^{-2}\frac{e\varphi}{W_i}\frac{1}{1+\alpha}. \tag{8}$$

For the specific case of the injection of a beam of hydrogen ions ($M_i = 1$) at 5 keV and for a lens having the properties $T = 3 \cdot 10^3$ A, R = 10 cm, and $\varphi = 1$ kV, we have $f \cong 25$ cm, $f_H = 10^3$ cm, $f_E = 3.4 \cdot 10^3$ cm, i.e., under these conditions the plasma lens has a refractive power two orders of magnitude better than that of an electrostatic lens or magnetic lens.

Experimental studies of plasma lenses and neutralized beams of helium and argon ions support the results of these calculations.[4]

The plasma lens which we have studied is an element of a quasisteady-state plasma injector; we calibrate and study the operation of this system with a neutralized beam of hydrogen ions.

EXPERIMENTAL APPARATUS

The experimental apparatus is shown in Fig. 1. The beam of hydrogen ions is produced by an rf ion source with an immersion lens; the beam energy is 4-8 keV, and the output current of the source can reach 200 μA. The ion source is connected to an evacuated chamber ~ 1 m^3 in volume, within which the plasma lens is mounted. The housing of the chamber is made of nonmagnetic steel in order to reduce magnetic distortions. The plasma lens has an inside diameter of 20 cm; in the median plane of the lens there is a multilayer magnet coil in a copper shield insulated from the winding. The magnet coil is fed a constant current from a storage battery; Fig. 2 shows the profile of the magnetic field of the lens along the axis of the system. Coaxial with the coil is a system of 10 copper disks; these disks, which are insulated from the shield of the magnet coil and from each other, are designed for the desired potential distribution in the focusing plasma. The entire plasma-optics system is enclosed in a shield of soft magnetic steel in order to suppress stray magnetic fields and to satisfy the thin-lens conditions. The voltage is fed to the shield of the magnet coil and to the disks from a bank of series-connected capacitors. The potential profile is symmetric with respect to the median plane of the lens, and the potential falls off linearly from the median plane to the edges of the system.

A ring-shaped electron emitter, coaxial with the entrance limiter of the lens, is used to compensate for the space charge of the beam.

The converging ion beam from the lens is analyzed by a multilayer, multichannel probe, which consists of a set of concentric copper rings 5 mm wide and 5 mm apart. The probe is coaxial with the lens and the source; the ion current is measured with each of the rings in succession.

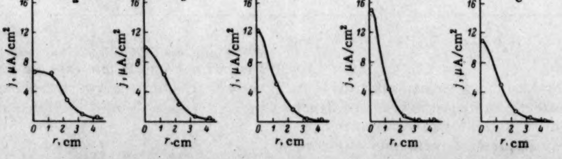

Fig. 3. Radial distributions of the ion current density at various distances from the median plane of the lens. z, cm: a) 33; b) 38; c) 48; d) 58; e) 68. The beam energy is $W_i = 6$ keV, and $\varphi = 1$ kV.

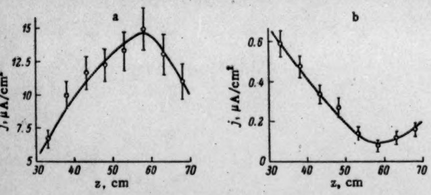

Fig. 4. Axial distribution of the ion current density at two radial positions. r: a) 0; b) 4.25 cm.

The probe can be moved along the axis of the system; the distance between the median plane of the lens and the point of the beam crossover near the exit limiter of the ion source is held constant at ~ 62 cm.

The working vacuum is ~ $5 \cdot 10^{-6}$ torr.

MEASUREMENTS OF THE FOCAL LENGTH OF THE PLASMA LENS

The lens causes a well-defined focusing of the beam only when the electric and magnetic fields are superimposed. The beam can be observed visually if the residual gas pressure in the chamber is increased to ~ $5 \cdot 10^{-5}$ torr because the excitation of the neutral gas is sufficient for visual observation. The diverging ion beam leaving the ion source and entering the plasma lens is converted into a converging beam after it leaves the plasma lens. This effect vanishes when the magnetic field of the lens is turned off ($I = 0$) or when the voltage is removed from the lens ($\varphi = 0$). In these cases the emission caused by the beam leaving the lens is similar to that in the case of a lens turned off completely ($I = 0$, $\varphi = 0$). This behavior is qualitative evidence that the refractive power of the plasma lens is much higher than that of an electrostatic or magnetic lens at the same levels of the current and potential.

To determine the position of the focal point of the ion beam we use the multilayer probe to study the radial distributions of the ion current density at various distances from the median plane of the plasma lens; the results are shown in Fig. 3. As the multilayer probe (collector) is moved along the axis, the radial distribution of the ion current density narrows, and there is a simultaneous increase in the current density at the axis. Beyond the plane of the focus, the radial distribution begins to broaden, and there is a simultaneous decrease in the current density at the axis. Figure 4 shows results found in measurements of the axial change in the current density at the axis of the system and at a radius of r = 4.25 cm. We see that in the image plane the current density at the axis reaches a maximum, while the current density at an appreciable distance from the axis reaches a minimum. Under these experimental conditions the distance from the median plane of the lens to the crossover point of the beam near the exit limiter of the ion source is roughly equal to the distance from the median plane to the current-density extremum at the axis of the system; hence we expect the half-width of the radial distribution of the current density in the focal region to be approximately equal to the beam diameter near the crossover point of the ion source. In fact, we find the half-width of the radial distribution of the current density near the focus to be ~ 20 mm, which is comparable with the diameter of the beam crossover at the exit from the ion source (~ 16 mm). However, the observed halo of the ion beam near the focus is evidence of spherical aberration in the system; this aberration could be eliminated by providing the appropriate potential distribution over the disks of the plasma lens.

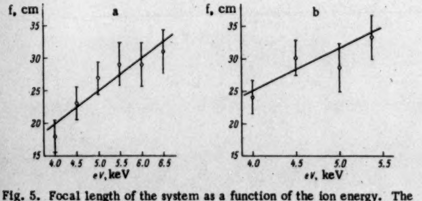

Fig. 5. Focal length of the system as a function of the ion energy. The lens potential φ is: a) 1; b) 0.8 kV.

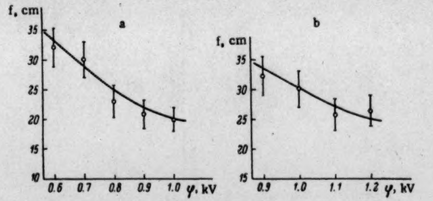

Fig. 6. Focal length of the system as a function of the lens potential. The ion energy is: a) 4; b) 6 keV.

We calculate the focal length of the plasma lens from the thin-lens equation,

$$\frac{1}{f}=\frac{1}{a}+\frac{1}{b}, \tag{9}$$

where a is the distance from the beam crossover at the exit from the ion source to the median plane of the plasma lens and b is the distance from the median plane of the lens to the image plane. Since the value of a is held constant in these experiments, we can calculate f simply by determining the distance b. We carry out these measurements with a magnetic field of ~ 150 Oe at the center of the magnet coil, an ion-beam current of 80 μA entering

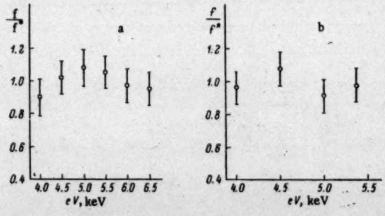

Fig. 7. Ratio of the experimental focal length of the system, f, to the calculated value, f^*, as a function of the ion energy. The lens potential φ is: a) 1; b) 0.8 kV.

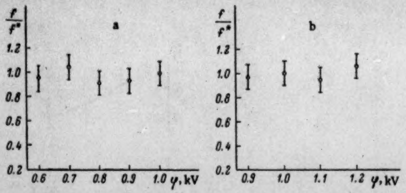

Fig. 8. Ratio of the experimental focal length f to the calculated length f^* as a function of the lens potential. The ion energy is a) 4; b) 6 keV.

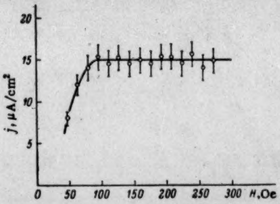

Fig. 10. Ion current density at the axis of the system in the focal region as a function of the magnetic field. W_i = 6 keV, φ = 1 kV, I_i = 120 μA.

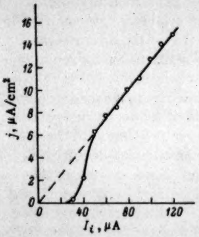

Fig. 9. Ion current density at the axis of the system in the focal region as a function of the beam current entering the lens. W_i = 6 keV, φ = 1 kV.

the lens, and various beam-ion energies and lens potentials.

We find that the focal length of the plasma-optics system varies in proportion to the energy of the beam ions at a fixed lens potential (Fig. 5), and it varies inversely with the lens potential at a fixed beam energy (Fig. 6). These results are in accordance with theoretical function (7).

We compare the values found for the focal length of the plasma lens in this manner (f) with the values calculated from Eq. (7) (f^*) for various beam energies and lens potentials. The results (Figs. 7 and 8) show that the experimental focal lengths agree within an error of less than 10% with the theoretical values found for a thin plasma lens.

DISRUPTION OF FOCUSING

The focusing of the neutralized ion beam by the plasma lens can be disrupted at a sufficiently high density of the plasma causing the focusing, at which the Debye shielding radius becomes comparable to the dimension of the magnetic ring. We study this disruption of focusing by measuring the current density at the axis of the system near the focus as a function of the current of ions entering the plasma lens. We find (Fig. 9) that the current density at the focus is a linear function of the ion current entering the lens over the current range 50-120 μA, i.e., the focusing effect of the plasma lens under these conditions is not a function of the ion beam current. However, at currents of ~ 40-50 μA we find a rapid drop in the ion current density at the axis near the focus, due to disruption of the focusing properties of the plasma lens.

The Debye shielding radius is given by

$$\lambda_D = \left(\frac{kT_e}{4\pi n_i e^2}\right)^{1/2}, \tag{10}$$

where $n_i = I_i/ev_i\pi R^2$ and $v_i = [2(W_i - e\varphi)/M_i]^{1/2}$; assuming $kT_e = 0.2$ eV, $M_i = 1.67 \cdot 10^{-24}$ g, $I_i = 40$ μA, $W_i = 5$ keV, and $\varphi = 1$ kV, we find $\lambda_D = 0.35$ R. In other words, at a beam current $I_i = 40$ μA the Debye shielding radius becomes comparable to the radius of the focusing system.

The focusing can also be disrupted when the magnetic field is reduced below a critical level. We see from Fig. 10 that the ion current density in the focal region is not a function of the magnetic field at fields H > 100 Oe. However, when the magnetic field is reduced to H < 100 Oe, we observe a rapid drop in the ion current density at the axis of the system in the focal region: evidence of the disruption of the focusing properties of the plasma lens.

These experiments have thus demonstrated plasma focusing in a system with closed electron drift. A plasma-optics system, whose refractive power is much higher than that of ordinary magnetic and electrostatic lenses, and for which there is no serious restriction on the ion beam current, can be used as an element in a plasma-injection system and for many other applications.

Fast electrons and x rays from nanosecond gas discharges at 0.1-760 torr

L. V. Tarasova, L. N. Khudyakova, T. V. Loiko, and V. A. Tsukerman

(Submitted April 10, 1973)
Zh. Tekh. Fiz., 44, 564-568 (March 1974)

The electron and x-ray pulses from nanosecond discharges are studied in various gases at pressures 0.1-760 torr. The pulse length at half-height does not exceed 1.5 nsec. A study by the method of attenuation curves shows that the effective energy of the x radiation is 9-15 keV; the effective energy beyond a copper filter 8-12 mm thick is 130-200 keV. The maximum x-ray dose is 0.1-10 mR/pulse, depending on the nature of the gas in the immediate vicinity of the anode. A group of fast electrons is detected having an energy higher than the applied voltage (which is of the order of hundreds of keV). These electrons are accelerated near the cathode of the discharge.

X rays are produced in discharges in gases;[1-7] the x-ray energies are 4-40 keV in air and helium at pressures up to 760 torr, implying the presence of fast electrons in gas discharges at comparatively high pressures. The appearance of fast electrons can be attributed to conditions in the discharge gap such that the energy lost due to elastic and inelastic collisions is less than the energy acquired by electrons as a result of their acceleration in an electric field. Attempts have been made[6-9] to establish a theoretical explanation for these runaway electrons.

The papers cited above contain no information about fast electrons capable of escaping from the discharge chamber. In the work reported here, an outgrowth of that reported in refs. 4 and 5, we have discovered additional effects, which imply that the radiation of nanosecond gas discharges has a complex composition. Under conditions similar to those of refs. 4 and 5 we detect [along with soft x rays (9-15 keV)] fast electrons, which escape through the anode and through the chamber window.

Below we report a study of the characteristics of the electronic and x-ray pulses produced in nanosecond discharges in various gases.

The experiments are carried out in a steel chamber with a plastic insulator. The chamber is filled with one of several gases: air, deuterium, helium, argon, or xenon. The pressure is varied over the range 10^{-2}-760 torr. The chamber is evacuated by rotating or oil-diffusion pumps. The cathodes are polished tungsten-alloy rods 12-14 mm in diameter having a hemispherical working surface with a curvature radius of r = 3-7 mm. In some of the experiments we notch the working surface in order to intensify the electric field at the resulting irregularities. A cutting tool is used to make notches 0.5 mm thick at 1-mm steps in two perpendicular directions. The anode is an aluminum foil 8-15 μ thick. The interelectrode distance d is 10-15 mm. The chamber window, behind the anode, is made of a thin polyethylene terephthalate film (5-10 μ).

In all the experiments the high voltage is produced by a high-voltage pulse transformer, in whose secondary circuit a high-pressure switch is connected in series with the chamber. A similar arrangement has been proposed by Belkin and described in refs. 10 and 11. The discharge capacitance, formed by the generator housing and the housing of the high-pressure switch, is about 40 pF, and the resistance shunting the discharge chamber is 200 Ω.

The high-pressure switch, which sharpens the front of the voltage pulse, is similar to the devices described in ref. 12. This switch is filled with hydrogen to an overpressure of ~ 50 atm. The voltage pulse reaches a height U_g of 160-180 kV, governed by the breakdown voltage of the switch. The rise time of the pulse does not exceed 1 nsec.

The x-radiation is detected by KID-2 and DK-02 dosimeters, thermoluminescent glass, and x-ray film. Electrons escaping from the chamber are detected by a Faraday cup and x-ray film. The time characteristics are studied by means of 14ÉLU10 electron x-ray multipliers having a resolution of ~ 1.2 nsec at the front; these multipliers were developed by Andreev and Guseva at the All-Union Scientific-Research Institute of Opticophysical Instruments and are described in ref. 13. The results which we find in measurements of the pulse characteristics by various methods are in satisfactory agreement.

In order of decreasing number of fast electrons detected beyond the chamber window, the gases we have studied are: helium, deuterium, air, argon, and xenon. The functional dependence of the electron yield on the pressure can vary; under constant experimental conditions ($U_g \simeq$ 160 kV, d = 15 mm, and polished cathode having r = 3 mm), the number of fast electrons observed in the case of helium increases as the pressure is raised from 100 to 760 torr, while the number observed for the case of argon decreases.

Figure 1 shows the number of electrons as a function of the pressure for discharges in air at a generator working voltage of 176 kV. The voltage drop across the chamber electrodes, measured from the oscillograms, is 100 kV at atmospheric pressure. The electron yield is determined by means of a Faraday cup. Here and in the figures which follow, each point on a curve represents the average of 30-50 measurements. Curve 1 corresponds to a filter of 5 mg/cm² (a transmitted-electron energy above 40 keV, while curve 2 corresponds to a filter of 53 mg/cm² (above 160 keV). We see that among the electrons escaping from the chamber there is a group having a relatively high energy; the relative number of electrons in this group is a function of the pressure.

We study the time characteristics of the radiation from the discharges and the penetrating power of this ra-

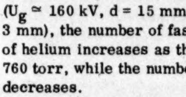

Fig. 1. Number of electrons detected outside the chamber window as a function of the pressure for discharges in air. d = 15 mm, smooth electrode, r = 6 mm.

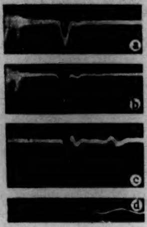

Fig. 2. Oscillograms of electron pulses (a, c) and x-ray pulses (b). a) Discharge in air, d = 15 mm, p = 760 torr, U_g = 170 kV; b) helium, d = 10 mm, p = 22 torr, U_g = 150 kV; c) helium, d = 10 mm, p = 22 torr, U_g = 150 kV; d) time marker, f = 100 MHz.

diation in most detail for two situations: discharges in air at atmospheric pressure with a smooth cathode, with electrodes 15 mm apart, and under conditions corresponding to the maximum electron yield; helium discharges at a pressure of 22 torr, with notched cathode, and with electrodes 10 mm apart. Figure 2 shows typical oscillograms of the x radiation and electrons, detected by the 14ÉLU10 multiplier and the Faraday cup. The pulse length at half-height does not exceed 1.5 nsec. The differences between the lengths and shapes of the electron pulses detected with the Faraday cup and the 14ÉLU10 multiplier result from the different resolving times of these detectors.

We can get a rough idea about the energetic inhomogeneity of the radiation by plotting attenuation curves based on the attenuation in metal filters.[14] Figure 3 shows the number of electrons escaping from the discharge chamber and detected by the Faraday cup as a function of the thickness of the aluminum filter for discharges in helium (Fig. 3a) and air (Fig. 3b). The attenuation curves are recorded under approximately identical experimental conditions, except that the switches (sharpeners) are different. The differences observed in the behavior of these curves can apparently be attributed to variations in the rise time of the voltage pulses.

Attenuation curves for electrons in the strong-filtration region (120-180 mg/cm^2) are recorded by means of the 14ÉLU10. When the voltage across the discharge gap is 100-120 kV, an appreciable number of electrons pass through a filter 170-180 mg/cm^2 thick; according to the estimates in refs. 15 and 16 (which are clearly on the conservative side), these electrons had energies of 340-360 keV. These energies are much higher than the measured voltage.

Figure 4 shows attenuation curves of the x radiation corresponding to the same discharge conditions as the electron curves. These measurements are made with the KID-2 dosimeter. The maximum x-ray dose for discharges in air at atmospheric pressure is 10^{-1} mR per pulse, while that for discharges in helium at 22 torr is 10 mR per pulse. The experimental data in Figs. 3 and 4 correspond to broad electron and x-ray beams, so we can draw definite conclusions about the energy only for the high-energy part of the spectrum. The energy of the x rays which pass through a copper filter 8-12 mm thick is 130-200 keV. Accordingly, the x-ray attenuation curves, like the electron curves, imply the existence of fast electrons in nanosecond-range discharges.

In general, the shapes of the electron and x-ray attenuation curves indicate that the fast electrons in the discharges do not all have the same energy. Curves 5 and 6 in Fig. 3b are typical monoenergetic electrons. The spectrum for helium has a large number of electrons at 200-270 keV; the number of electrons corresponding to 340 keV and above is two or three orders of magnitude lower. For discharges in air the spectrum is shifted toward higher energies (Fig. 3b).

The effective x-ray energy, determined from the half-attenuation thickness during photography of an aluminum wedge through 2 mm of beryllium, is 9-15 keV.

The fast electrons undergo relatively little scattering in the gas discharge, so it is possible to obtain a magnified image of the emitting centers on the cathode by placing a piece of film against the back of the anode. The degree of magnification corresponds to the geometry of the discharge gap. Figure 5 shows an image of this type for a notched cathode obtained in a discharge in helium at p = 22 torr. This photograph is taken through a filter of 43.5 mg/cm^2, so the image is formed by electrons at energies above 170 keV. These photographs verify that fast electrons are produced near the cathode.

Several workers studying discharges in vacuum and

in gases at low pressures (see, e.g., refs. 17-23) have detected a hard component of the x radiation and electrons at energies above the applied voltage. Our experimental results show that this "superhard" radiation can be obtained even at relatively high pressures under certain conditions. This effect can be attributed to the statistical acceleration of part of the beam of field-emitted electrons by turbulent pulsations excited near the cathode by this beam.[24]

It should be noted that the existence of these fast electrons, having energies above the voltage applied to the discharge gap, is responsible for an incorrect determination of the integrated x-ray dose in refs. 4 and 5. When a filter 7 mg/cm^2 thick is used, much of the film blackening is due to these fast electrons.

RESULTS

1. In nanosecond-range discharges in gases at pressures up to 760 torr there exists a group of fast electrons, having energies exceeding the applied voltage (hundreds of keV).

2. The maximum x-ray dose beyond the chamber window is ~ 10 mR/pulse for discharges in helium at 22 torr and ~ 0.1 mR/pulse for discharges in air at 760 torr.

3. The maximum number of electrons escaping from the chamber window is ~ 10^{12} per pulse for helium and ~ 10^9 per pulse for air.

Electron energy distribution in helium, nitrogen, and their mixtures

K. D. Asvadurov, I. A. Vasil'eva, and V. M. Torchinskii
Institute of High Temperatures,
Academy of Sciences of the USSR, Moscow

(Submitted December 19, 1972; resubmitted July 23, 1973)
Zh. Tekh. Fiz., 44, 569-574 (March 1974)

The electron energy distribution has been measured in helium, nitrogen, and mixtures of helium and nitrogen at pressures of 0.5-3 torr, currents of 0.1-0.5 A, and nitrogen contents from 0.5 to 50%. In mixtures with a nitrogen content below 5% the distribution function is close to that in helium. As the nitrogen content is increased the distribution function is at first broadened and the average and most probable values of the electron energy increase; when the nitrogen content of the mixture reaches 30-50% the distribution approaches that in nitrogen and the average electron energy decreases. In discussing the errors of the procedure for finding the energy distribution function particular attention is paid to the determination of the plasma potential. The most important contribution to the difference between the potential zero and the maximum of the second derivative of the probe current comes from the deterioration of the relation between the probe—plasma resistance and the resistance of the probe circuit at the plasma potential. An argument is given for determining the plasma potential from the zero of the second derivative.

The electron energy distribution function has been investigated in the positive column of an arc in helium, nitrogen, and mixtures of these gases at pressures from 0.5 to 3 torr, currents from 0.1 to 0.5 A, and nitrogen admixtures from 0.5 to 50%. The tubes use indirectly heated cathodes and hollow cylindrical anodes with inner diameters of 22 and 30 mm. Cylindrical tungsten probes 50 to 100 μ in diameter and 4 mm long are located at the axis. The filament power is supplied by batteries, and the anode and probe circuit power by regulated power supplies.

The electron energy distribution function $f(\varepsilon)$ is determined from the second derivative of the probe current by superposing the modulated potential

$$v_1(t)=a(1+M\cos\omega t)\sin\Omega t, \tag{1}$$

on the probe potential; $\omega = 1$ kHz, $\Omega = 80$ kHz, $a = 0.5$ V, $M = 8$.

Oscillations and plasma noise in the probe circuit are displayed on an oscilloscope by connecting a 12 Ω noninductive resistor between the probe and the input to a selective amplifier. The ratio of the useful signal plasma to the plasma noise current in the probe circuit is greater than 10. No measurements are performed in the presence of significant electrical oscillations. Stationary striations are also monitored. Although the positive column looked uniform, a high-contrast photograph showed a regular nonuniformity. Poorly defined stationary striations are photographed in helium and in helium–nitrogen mixtures. The discharge in nitrogen is uniform.

Sicha and Rezacova[1] have shown that in striations of sufficiently small amplitude, in which there is no secondary maximum on the distribution function in the fast electron region, the distribution function remains constant along the column. We have also taken some distribution functions along a poorly defined striation. No hump is observed in the fast electron region; the distribution function remains essentially constant along a striation, i.e., the results characterize the positive column as a whole rather than individual points within a striation. The error in the determination of the distribution function is made up of the error in determining the second derivative and the error in determining the plasma potential. We first estimate the error in determining the second derivative. The instrumental error in isolating a harmonic of frequency ω is determined mainly by the error of the recording instrument and does not exceed 2%. In order to find how much a harmonic of frequency ω affects the second derivative the current must be decomposed into its spectrum, as in refs. 2 and 3 for the second-harmonic method. If the plasma is nonstationary, the potential varies according to $b\cos\omega' t$, where ω' is not a multiple of ω, and the distribution function is a periodic function of the time with frequency ω' the current component at frequency ω can be written in the form

$$i_\omega=\frac{a^2}{2}i_0''+\frac{a^2b}{4}i_1''+\left(\frac{7}{64}a^4+\frac{a^2b^2}{8}\right)i_0^{\mathrm{IV}}+\ldots, \tag{2}$$

where i_0 and i_1 are the zeroth and the first approximation terms, and i_ω is determined not only by the second, but also by higher derivatives of the current. In these experiments $a/b \geq 10$, and the contribution of higher harmonics is less than 3%. Thus the total error in determining the second derivative is less than 5%.

In obtaining electron distribution functions from curves of the second derivatives some authors[4–8] take the plasma potential to be the potential at which the second derivative passes through zero; others[9–11] assume that the plasma potential is equal to the potential at which the second derivative is a maximum.

For an ideal probe characteristic the potential at the maximum of the second derivative would agree with the space potential. Usually the characteristic and its derivatives are distorted. Distortion arises because of the decrease in the electron density near the probe. This effect has been studied in refs. 12 and 13. Also, as the probe potential approaches that of the plasma, the relation between the resistance of the probe sheath R_{sh} and the sum of the other resistances in the probe circuit deteriorates. The probe circuit includes the resistance of the plasma gap between the outer edge of the probe sheath and the reference electrode Rd_{pl}, and also the resistance of the electric circuit elements R_{ci}. R_{ci} can be different for direct and alternating currents ($R_{ci=}$ and $R_{ci\sim}$).

If V is the dc voltage in the probe circuit and ε_{pl} is the potential difference in the arc between the probe and the reference electrode, for an ideal probe characteristic

$$V-\varepsilon_{pl}=V_{sh} \tag{3}$$

while in the actual case

$$V-\varepsilon_{\mathrm{pl}}=V_{\mathrm{sh}}+i(R_{\mathrm{pl}}+R_{\mathrm{ci}\,-}). \qquad (4)$$

For negative probe potentials which do not exceed the absolute magnitude of the floating potential the probe current is opposite in sign to the potential applied to the sheath; hence, for an actual characteristic $|V - \varepsilon_{pl}| < |V_{sh}|$. This inequality is strengthened as the plasma potential is approached, but in constructing the probe characteristic it is assumed that Eq. (3) holds. This leads to an apparent decrease in the probe current and its derivatives close to the plasma potential. The range of potentials ΔV_1 in which the distortion occurs for direct current can be found by first estimating the decrease in probe current

$$\frac{i_{\mathrm{id}}}{i_{\mathrm{act}}}=\frac{R_{\mathrm{sh}}+R_{\mathrm{pl}}+R_{\mathrm{ci}\,-}}{R_{\mathrm{sh}}}. \qquad (5)$$

In order to find ΔV_1 by using (5) it is necessary to specify the current as a function of the potential for a known electron distribution function.

In finding the second derivative of the probe current by (2) it is assumed that the whole variable signal of amplitude *a* is applied across the probe sheath. As a matter of fact, as the plasma potential is approached an increasingly larger part of the potential drop is across the resistance $R_{pl} + R_{ci\,\sim}$, and this leads to a decrease in the amplitude of the harmonic, and consequently to an apparent decrease of the second derivative in the following ratio:

$$\frac{i''_{\mathrm{id}}}{i''_{\mathrm{act}}}=\left(\frac{R_{\mathrm{sh}}+R_{\mathrm{pl}}+R_{\mathrm{ci}\,\sim}}{R_{\mathrm{sh}}}\right)^2. \qquad (6)$$

For a known distribution function the range of potentials ΔV_2 in which the value of the second derivative is distorted can be found by using (6).

All the distortions described make the potential at which the second derivative is a maximum more negative with respect to the plasma potential. We now estimate the region of distortion of the probe characteristic close to the plasma potential under the experimental conditions described here.

According to refs. 12 and 13 the electron drain decreases the electron density and the current to a 50 μ diameter probe close to the plasma potential by 4-5%, which corresponds to a value of ΔV_3 of less than 0.2 V for a Maxwellian distribution.

In estimating the effect of the probe circuit we take $R_{ci=} = 100\,\Omega$, $R_{ci\,\sim} = 120\,\Omega$; R_{pl} and R_{sh} vary from 130 Ω and 2.7 kΩ for helium at a pressure of 0.5 torr and a current of 0.5 to 1 kΩ and 7.4 kΩ for nitrogen at 1 torr and 0.2 A. We note that the distance between the probe and the reference electrode has only a small effect on the value of R_{pl} since the largest part of this resistance comes from the part of the plasma with a small transverse cross section adjoining the probe sheath.

An estimate using (5) and (6) for a Maxwellian distribution and the experimental average energies $\bar{\varepsilon}$ gives $\Delta V_1 = 0.5$ V and $\Delta V_2 = 1.0$ V in helium at a pressure of 0.5 torr and a current of 0.5 A; in nitrogen at a pressure of 1 torr and a current of 0.2 A $\Delta V_1 = 0.3$ V and $\Delta V_2 = 0.5$ V; in a mixture of helium and nitrogen (5%) at a pressure of 0.5 torr and a current of 0.5 A $\Delta V_1 = 0.8$ V and $\Delta V_1 = 1.7$ V. A comparison of the values shows that the drain leads to the smallest distortion of the probe characteristic. The greatest distortion gives rise to an apparent decrease in the second derivative according to (6). These conclusions hold independently of the form of the electron distribution function.

The region of distortion of the second derivative due to the effects described above can be obtained from the summation $\Delta V = \Delta V_1 + \Delta V_2 + \Delta V_3$. ΔV agrees with the experimental value of the difference between the positions of the maximum and the zero of the second derivative for a distribution of the form

$$f(\varepsilon)=\sqrt{\varepsilon}\,\exp(\alpha\varepsilon)^n \text{ and } 1<n<2. \qquad (7)$$

This is the basis for assuming that the space potential is the potential at which the second derivative is zero.

The zero potential can be determined to an accuracy of 0.5 V. If the distribution function is written in the form (7) the error is given by

$$\delta\left\{f(U)\right\}=\frac{1}{2}\frac{\Delta U}{U}+n\alpha^n U^{n+1}\Delta U.$$

An estimate for n = 2 shows that an uncertainty of ~ 0.5 V in the plasma potential leads to an error of less than 10% in the distribution function.

Thus the total error in measuring the distribution function in our experiments is less than 15%. The inaccuracy in determining the space potential significantly affects the determination of the distribution function, and therefore in refs. 14 and 15 there were attempts to find the space potential independently of the probe characteristics method. To do this the transmission of characteristic low-frequency noise and plasma oscillations to the probe is investigated. It seems to us that this method does not furnish more information than the stationary probe characteristic and its derivatives as long as oscillations with frequencies substantially lower than the plasma frequency are observed.[16] The conclusions of ref. 16 are

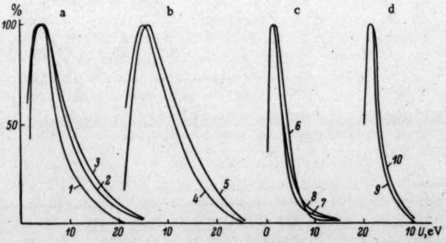

Fig. 1. Effect of current (i) and tube diameter (d_T) on the shape of the electron distribution in helium and nitrogen. a) Helium, p = 0.5 torr: 1) i = 100 mA, d_T = 3 cm, $\bar{\varepsilon}$ = 6.4 eV; 2) i = 300 mA, d_T = 3 cm, $\bar{\varepsilon}$ = 7.5 eV; 3) i = 550 mA, d_T = 3 cm, $\bar{\varepsilon}$ = 7.9 eV; b) helium, p = 0.5 torr: 4) i = 200 mA, d_T = 2.2 cm, $\bar{\varepsilon}$ = 7.9 eV; 5) i = 400 mA, d_T = 2.2 cm, $\bar{\varepsilon}$ = 9.5 eV; c) nitrogen, i = 200 mA: 6) p = 0.9 torr, d_T = 2.2 cm, $\bar{\varepsilon}$ = 3.3 eV; 7) p = 1 torr, d_T = 3 cm, $\bar{\varepsilon}$ = 2.9 eV; 8) p = 2 torr, d_T = 3 cm, $\bar{\varepsilon}$ = 3.2 eV; d) nitrogen, p = 3 torr: 9) i = 200 mA, d_T = 3 cm, $\bar{\varepsilon}$ = 2.9 eV; 10) i = 500 mA, d_T = 3 cm, $\bar{\varepsilon}$ = 3.2 eV.

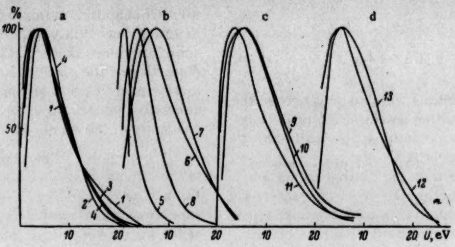

Fig. 2. Distribution functions in mixtures of helium and nitrogen. a: 1) helium, p = 0.5 torr, i = 500 mA, d_T = 3 cm, $\bar{\varepsilon}$ = 7.9 eV; 2) the same + 0.5% nitrogen; 3) the same + 1% nitrogen; 4) the same + 5% nitrogen. b: 5) nitrogen, p = 1 torr, i = 500 mA, d_T = 3 cm, $\bar{\varepsilon}$ = 3.3 eV; 6) helium, p = 0.5 torr, i = 200 mA, d_T = 2.2 cm, $\bar{\varepsilon}$ = 7.9 eV. 7) the same + 10% nitrogen, $\bar{\varepsilon}$ = 9.8 eV; 8) the same + 30% nitrogen, $\bar{\varepsilon}$ = 5.9 eV. c: 9) helium, p = 1 torr, i = 200 mA, d_T = 2.2 cm, $\bar{\varepsilon}$ = 10 eV; 10) the same + 10% nitrogen, $\bar{\varepsilon}$ = 9 eV; 11) the same + 50% nitrogen, $\bar{\varepsilon}$ = 8.2 eV. d: 12) helium, p = 0.5 torr, i = 400 mA, d_T = 2.2 cm, $\bar{\varepsilon}$ = 9.5 eV; 13) the same + 20% nitrogen, $\bar{\varepsilon}$ = 8.8 eV.

confirmed by experiments.[17]

Figure 1 shows the energy distribution curves for electrons in helium and nitrogen for various currents, pressures, and tube diameters. As the current increases and the tube radius decreases the curves are displaced toward higher energies with an increase in the average energy and the relative content of faster electrons. A change in pressure has little effect on the distribution function in nitrogen. These experimental curves agree with published distribution functions in helium[18] and nitrogen.[5] A comparison of $f(\varepsilon)$ in helium and nitrogen shows the depletion of the distribution function in the region just above the most probable energy which characterizes a molecular gas. Figure 2 shows mixtures with various percentage contents of nitrogen. Additions of nitrogen not exceeding 5% (Fig. 2a) have little effect on the distribution function independently of the tube diameter, pressure, or current. A larger amount of nitrogen (Fig. 2, b, c and d) produces a sharp change in the electron distribution function. A comparison of curve 6 with 7 and 12 with 13 shows that the distribution functions can be broader in mixtures with 10–20% nitrogen than in helium. A still larger nitrogen content (30% for curve 8 and 50% for curve 11) narrows the distribution function and changes its shape toward that characteristic of pure nitrogen (curve 5). The energy distribution function for electrons in mixtures is different from that in helium as a result of many processes, the most important of which are the following.

First, there are inelastic collisions of electrons with nitrogen molecules. Secondly, the gas is more easily ionized since the ionization potential of nitrogen is substantially lower than that of helium. Ionization can occur as the result of collisions of excited helium atoms with nitrogen molecules. For small admixtures of nitrogen (up to 5%) these effects apparently nearly compensate one another, which accounts for the weak dependence of the distribution function and the average energy on the nitrogen content. The broadening of the distribution function and the increase in $\bar{\varepsilon}$ for 10–20% admixtures of nitrogen may be a result of easier ionization. The addition of still more nitrogen so diminishes the role of helium in the mixture that the distribution function takes on the characteristic nitrogen shape, and the average energy decreases.

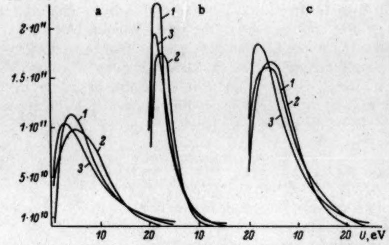

Fig. 3. Comparison of experimental distributions (1) with Druyvesteyn (2) and Maxwellian (3) distributions. a) Helium, p = 0.5 torr, i = 300 mA, $\bar{\varepsilon}$ = 7.4 eV; b) nitrogen, p = 1 torr, i = 500 mA, $\bar{\varepsilon}$ = 3.3 eV; c) mixture of He, p = 0. 5 torr + 5% N_2, i = 500 mA, $\bar{\varepsilon}$ = 6.6 eV.

In all the cases investigated the electron distribution function differs from a Maxwellian. Nevertheless it is convenient to use the Maxwellian distribution in calculations of the kinetics of plasma processes, and sometimes this is possible. This is shown in Fig. 3, where experimental distribution functions obtained under certain conditions are plotted together with Druyvesteyn and Maxwellian functions normalized at the average energy and the electron density obtained from the experimental distribution functions.

It is clear that the experimental curve is closer to a Maxwellian in helium (Fig. 3a) than in nitrogen and mixtures (Figs. 3b, c). However, in the 8–25 eV energy range for all cases of helium and helium–nitrogen mixtures, and in the 3–15 eV range for nitrogen, the divergence does not exceed the error in measuring the distribution function.

Use of plasma accelerator for optical pumping of lasers

N. P. Kozlov and Yu. S. Protasov

N. É. Bauman Moscow Technical College

(Submitted February 12, 1973; resubmitted August 6, 1973)
Zh. Tekh. Fiz., 44, 575-579 (March 1974)

On the basis of a study of the radiation properties of a dense plasma focus and an analysis of the requirements that must be met by a light source for exciting organic dye solutions it is shown that pulsed plasma accelerators of the erosion type can, in principle, be used for the optical pumping of organic dye lasers. A laser has been designed for pumping by the plasma focus of a pulsed accelerator operating in a vacuum of ~ 10^{-6} torr; the working medium and a protective liquid filter are pumped through the active zone of the laser. The lasing properties of a laser with the dye rhodamine 6G are studied. Methods for increasing the efficiency of the laser are discussed.

A distinctive feature of pulsed plasma accelerators of the erosion type is the possibility of regulating the spectral composition of the radiation over a broad range through the choice of an appropriate working medium: a metal, a dielectric, a combination, etc. Furthermore, the self-focusing of the plasma jet in the accelerator in the compression mode and the high radiation energy can be exploited to excite a population inversion in the active media of essentially all types of laser: solid-state, gas, organic-dye, etc. Study of the temporal characteristics of the plasma emission and of the discharge dynamics[1-3] shows that it may be possible to obtained focused light bursts having the required length, front curvature, pulse shape, and magnitude and spectral distribution.[4]

One way to increase the power of a laser is to increase the power of the pumping source. As a rule, this approach causes the peak of the source radiation to shift toward shorter wavelengths (in our case, to the vacuum-UV, at wavelengths shorter than 1000 Å). Accordingly, the most promising materials for pumping by powerful sources of incoherent light are those in which the absorption bands are broad in the visible and UV ranges. Organic dyes are such materials.[5]

Organic dye lasers are currently the only type of lasers whose radiation frequency can be tuned over a broad spectral range (several hundred angstroms) either by changing the parameters of the solution or resonator or by inserting a wavelength selector (e.g., a diffraction grating) into the resonator. With the appropriate dye it is possible to achieve intense coherent radiation at nearly any wavelength between 3400 and 11,750 Å.

It has been found experimentally and theoretically[6,7] that in the case of pumping in the visible range by flashlamps or harmonics of a ruby or neodymium-glass laser the lower threshold for lasing of the more suitable dyes is four or five times higher than that for ruby, so high-intensity sources are required for laser action. Furthermore, since the molecules in organic dyes are in an excited singlet state, there can be a radiationless transition to a lower triplet state in addition to the transition to the ground state. Accordingly, an effort should be made to reach the lasing threshold before the number of molecules in the triplet state becomes large. For such a pumping source the light pulse must have a steep front.

Plasma light sources have an essentially unlimited maximum deexcitation energy, and the freedom to regulate the temporal and spectral characteristics of the discharge makes them the most promising source for achieving high energy and power levels in dye lasers.

Noteworthy among the working materials having comparatively low lasing thresholds are the oxazoles, coumarins, and rhodamines.[7]

Extrapolation of the functional dependence of the lasing energy on the energy input[7] reveals the lasing threshold for rhodamine 6G, which is ~ 17 J. The source which we have studied has a high deexcitable energy and can be used to achieve lasing without a reduction of the steepness of the light-pulse front (4-6 μsec). Since much of the radiation energy falls at wavelengths shorter than 2700 Å, where rhodamine 6G undergoes photodecomposition, protective filters must be used to cut off this part of the plasma radiation.

ORGANIC DYE LASER

A plasma focus exists as a stable plasma formation, localized in space and over the discharge time, only for ambient pressures below ~ 10^{-4} torr, so that serious difficulties arise in the construction of such a laser. If the laser lead is removed from the evacuated volume, it cannot be placed close to the illuminator, so there is a severe loss in the efficiency at which light energy is transferred from the focus to the laser head. Placing the head in vacuum with the accelerator, on the other hand, also requires some optimization, since even slight contact with a plasma jet would lead to the destruction of the resonator mirrors. Nor is it possible to "tie" the discharge to the metal frame of the illuminator or to metal parts of the head, for they would be destroyed. Accordingly, the selection of a highly efficient illuminator and the optimum layout largely govern the efficiency of the laser.

As mentioned above, heating of the dye leads to a spatial stratification of the active medium and the lasing level is lowered sharply; since the characteristic for thermal stabilization of the dye is long, the active medium must be pumped through the cavity of a cuvette. The UV component of the radiation from the focus leads to the photodecomposition of rhodamine 6G even before the lasing threshold is reached, so filters (usually liquid) must be used to absorb the light at wavelengths shorter than 2700 Å. This hard component of the radiation leads to intense erosion of the illuminator, which therefore must be coated with a diffusely reflecting protective material (e.g., silicon dioxide). Several experiments have shown[7] that stable lasing characteristics can be achieved only by pumping

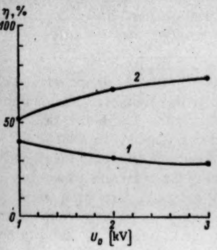

Fig. 1. Efficiency of an elliptical reflector. 1) The $\eta(U_0)$ functional dependence in integrated light; 2) that in the transmission region of quartz.

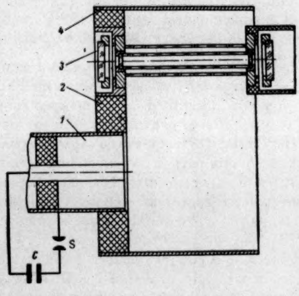

Fig. 2. Arrangement of the organic dye laser. 1) M2-K accelerator; 2) insulating bushing; 3) laser head; 4) reflector.

the protective filter. A four-channel contact with the atmosphere is therefore necessary, and the experiment is significantly complicated; the tubes through which the materials are pumped must be as small as possible, withstand a vacuum of ~ 10^{-6} torr, and be transparent, so that a check can be made to ensure that there are no air bubbles in either cavity of the cuvette.

In our experiments we study various possible arrangements of the laser and reflector, made from polished duralumin and having various shapes; a combination of spherical and elliptical half-cylinders, an ellipse, and a cone.

We evaluate the efficiency of the illuminator in the following manner: The reflector is originally held on a dielectric bushing 30 mm thick, pressed against the outer electrode of the accelerator. At the first focus of the illuminator is a compressed plasma zone; at the second, at the position of the cuvette, a hollow cylinder having the same diameter as the cuvette is placed. Two Chromel–Copel thermocouples are fused to the thin-walled cylinder, which is a blackbody, and the thermal emf is detected by an M254 instrument. In this manner, the integrated radiation flux transferred from the plasma focus to the cuvettes is determined, and the efficiency of the illuminator is calculated as the ratio of the energy received by the blackbody to the radiation energy of the focus. The best illuminator among those we have studied is the elliptical reflector, which permits the closest packing of the cuvette and the accelerator without loss of contact with the plasma. Figure 1 (curve 1) shows the efficiency determined in this manner for an elliptical illuminator with a major semiaxis of 240 mm and a minor semiaxis of 210 mm, as a function of the initial voltage on the capacitor bank. It should be kept in mind here that the absorption coefficient of aluminum is approximately unity[8] at wavelengths shorter than 2000 Å, so it is better to determine the efficiency in the transmission region of quartz (2320 Å) (curve 2 in Fig. 1). According to these results, the efficiency of the elliptical mirror reaches ~ 70%. The $\eta(U_0)$ function must have an extremum, since an increase in U_0 leads to an improvement in the focusing of the plasma jet and to a shift of the radiation maximum of the system toward shorter wavelengths and an increase in the relative amount of energy absorbed by the reflector. Taking these circumstances into account, we conclude that the difference between the behavior of curves 1 and 2 for U_0 = 1 and 2 kV is plausible.

The resonator of the laser is formed by external plane mirrors having dielectric coatings with reflection coefficients of 99 and 60%. The mirrors are mounted in metal holders, with which it is possible to adjust the mirrors with respect to the ends of the cuvette and the entire head. At the dead end of the cuvette a supporting metal cup is mounted in a dielectric flange between the accelerator and the reflector. The cup, used for protection against the plasma, is made from ebonite and is in immediate contact with the measuring elements of the system. The head is made rigid by means of two thin pins connecting the cups. The diameter of the outer quartz tube is 10 mm, its length is 30 mm, and the diameter of the inner tube is 3 mm.

Figure 2 shows the laser. The laser head is attached rigidly in a bushing connecting the accelerator and the illuminator. The extensions of the tube for pumping the dye and the filter pass through the bushing at one end; at the other end they emerge from the reflector and, after passing through special connectors, are mounted on the vertical flange of the vacuum chamber.

LASING PROPERTIES OF A RHODAMINE 6G LASER

We have studied the lasing properties of this laser, in which the working medium is a solution of rhodamine 6G in dehydrated alcohol at a concentration of ~ $1.5 \cdot 10^{-4}$ M. The filter protecting the working medium from photodecomposition is a 4% solution of sodium acetate. It should be noted that our purpose in these experiments is not to optimize the laser by choosing the best dye concentration, resonator parameter, cuvette volume, etc.; we choose these parameters to be approximately the same as the optimum parameters for a rhodamine 6G laser with flash pumping.[6]

It was shown previously[7] that the lasing energy is quite sensitive not only to the Q of the resonator, but

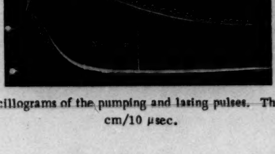

Fig. 3. Oscillograms of the pumping and lasing pulses. The scale is 1 cm/10 μsec.

also to the purity of the dye and of the other materials and items in contact with the solutions; thus, before we fill the system with the dye and the filter we wash the cuvettes, the hoses, and the connectors with ordinary alcohol and then dehydrated alcohol.

In the experiment the dye is pumped through the active zone after each discharge, and the filter is pumped through after three or four discharges, since the lasing energy falls off by a factor of nearly 2 at the second pumping pulse. Since part of the dye in the leadout tubes is subjected to the UV radiation of the plasma, we replace all the dye in the circulation volume.

The light source is an M2-K coaxial accelerator,[1] which operates with a copper plasma with $U_0 = 3$ kV, since we have shown previously that the emission spectrum of a copper plasma has intense regions of continuum at 3500-5500 Å, corresponding to the absorption bands of rhodamine 6G.

The system we use to detect the lasing allows us to determine the absolute value of the lasing energy and its time dependence.

The protective cup of the external mirror of the head is held against the screen of a calibrated F-1 photocell and a metallic bolometer, whose output signals are amplified by a preamplifier and sent to the input of an S1-16 oscilloscope. The photocell housing and the electromagnetic shield are designed to prevent optical contact with the plasma. At the same time we use a DMR-4 monochromator and an FÉU-12A photomultiplier to detect the plasma emission at 5900 ± 3 Å through an aperture in the reflector. We also detect the discharge current and the integrated (over the spectrum) radiation of the pumping pulse by means of photomultipliers.

Figure 3 shows oscillograms of the pumping and lasing pulses for $U_0 = 3$ kV. We see that the lasing pulse has a shape reminiscent of that of the pumping pulse. The pumping intensity is several times higher than the threshold level, so the lasing occurs with an essentially negligible delay. The length of the lasing pulse is ~ 14 μsec. The lasing energy, determined by integrating the signal, is ~ 0.22 J, while the lasing power is 0.15 MW. When the pumping pulse is repeated, the lasing energy falls by a factor of 2.5, and at the third pumping pulse we detect only a slight lasing peak, due to the appearance of a radial temperature gradient in the cuvette, a temperature stratification of the active medium, and the partial photodecomposition of this medium; these results agree with results found with flash pumping.[8] The temperature-relaxation time is 4-5 min. Accordingly, the energy content is 0.35 J/cm^3, which is not the limiting value[7] and which shows that it may be possible to significantly increase the lasing energy.

The divergence of the radiation in the unoptimized system, governed by essentially the geometric dimensions of the cuvette alone, is $\sim 2 \cdot 10^{-3}$ rad. The lasing efficiency in our case is ~ 0.11% and corresponds to a laser with flash pumping. It should be noted that this efficiency can be increased: first, by choosing the optimum concentration of the active medium, the optimum reflection coefficients of the resonator mirrors, the optimum resonator Q, and the optimum cuvette volume; second, by increasing the steepness of the front of the pumping signal, by using the optimum distribution of radiation energy in the spectrum of the plasma focus, and by increasing the pumping energy (it has been shown[7] that the lasimg energy is a linear function of the energy supplied to the discharge).

The advantages of a plasma focus as a pumping source are displayed most fully when the active media used have absorption bands in the UV part of the spectrum; one such medium is a solution of paraterphenyl in cyclohexane and in standard[9] POPOP, since the radiation maximum of the focus is nearer this part of the spectrum. The possibility of controlling the spectral distribution of the deexcited energy through the appropriate choice of working media makes this source more suitable than ordinary straight pinches[10] for the design of powerful lasers. The use of a plasma focus as a pumping source in a dye laser makes it possible, in principle, to design a laser which operates in the vacuum-UV part of the spectrum (up to 1200 Å): an extremely important feature.

In conclusion the authors thank A. N. Rubinov for advice and assistance in constructing the laser.

Efficiency of light-beam conversion by dynamic three-dimensional phase holograms

D. I. Stasel'ko and V. G. Sidorovich

(Submitted August 23, 1973)
Zh. Tekh. Fiz., 44, 580-587 (March 1974)

The efficiency with which energy is transferred between waves propagating in dynamic phase holograms is analyzed. Under certain conditions, the energy of one of the beams incident on the hologram can be almost completely transferred to the other beam, regardless of the initial ratio of beam intensities.

There has been a great deal of interest in the properties of holograms recorded in media whose optical properties can be changed reversibly by incident light. Such holograms are frequently called "dynamic," since they are capable of reacting to spatial and temporal changes in the parameters of the incident beam during recording. Most of the reported work on dynamic holography has involved phase gratings in media whose refractive indices vary in proportion to the intensity of the optical field. The conversion of the incident beams into beams of higher diffraction orders has been treated as the basic result of the effect of a dynamic hologram.[1-4] Considerably less attention has been paid to the redistribution of energy between the objective and reference beams. This topic is treated in ref. 5, in connection with a study of the mechanism for the formation of three-dimensional phase diffraction gratings in lithium niobate crystals. On the basis of the theory worked out by Kogelnik and their own experimental data, Staebler and Amodei[5] conclude that the energy exchange between the object and reference beams observed in the recording of holograms in these crystals occurs because the holographic phase grating is displaced by approximately one fourth of a period with respect to the sinusoidal interference pattern which forms this grating.

However, this energy exchange between the object and reference beams in the recording of dynamic holograms can be of much independent importance, especially if it is found possible to transfer a considerable amount of energy to one of the original beams. It follows from general considerations that the energy transfer between light beams should be most efficient in three-dimensional phase holograms, but no theory is presently available for such holograms. Below we attempt to partially bridge this gap by analyzing the recording of simple dynamic phase holograms in various media. We proceed by analyzing the steady-state system of truncated nonlinear coupled equations for the amplitudes of the waves propagating in the hologram. Effects of the three-dimensional nature of the dynamic phase gratings are taken into account, as is the displacement of the gratings with respect to the interference patterns which form them. We find that under certain conditions energy can be transferred from one of the beams incident on the hologram to the other, regardless of the initial intensity ratio of these beams. This property of dynamic holograms presents us with an opportunity to effectively control the spatial and temporal characteristics of light beams by means of considerably less intense beams, and it furnishes a basis for solving one of the most important problems of dynamic holography: that of correcting nonstationary wave fronts in real time.

To derive the coupled equation for the amplitudes of the propagating waves we begin by analyzing the nonlinear wave equation. We assume that two plane monochromatic waves at the same frequency ω are incident on the surface of the medium in which the hologram is formed; we assume that the waves are polarized normally with respect to the incidence plane. Then the amplitude of the electric field vector, E(x, z), satisfies the equation

$$\nabla^2 E(x, z) + k_0^2 \varepsilon [E(x, z)] E(x, z) = 0, \tag{1}$$

where $k_0 = \omega/c$ is the wave number of the light incident on the hologram, $\varepsilon[E(x, z)]$ is the dielectric constant of the medium, the XOZ plane is the incidence plane of the wave, the X and Y axes are along the boundary of the hologram, and the Z axis is normal to it. For the assumed wave polarization and orientation of axes we have $E_x = E_z = 0$ and $E_y = E$. In specifying the boundary conditions we start by assuming that two plane waves with amplitudes $C_1(0)$ and $C_{-1}(0)$ are incident on the hologram at angles of $\pm\theta$ with respect to the normal (Fig. 1). Also assuming that the hologram has an approximately unit dielectric constant and that the relative changes in ε caused by the light are small, we write $\varepsilon(E)$ as

$$\varepsilon(E) = 1 + \Delta\varepsilon(E), \tag{2}$$

where $\Delta\varepsilon(E) \ll 1$. The first of these latter assumptions is not crucial; we adopt it only so that we can neglect reflection and refraction of light at the boundaries of the hologram. The second assumption is more fundamental; it allows us to write the solution of Eq. (1) in the form

$$E(x, z) = e^{ik_z z} U(x, z), \tag{3}$$

where U(x, z) is a slowly varying function of z and where $k_z = k_0 \cos\theta$.

Substituting Eq. (3) into Eq. (1), cancelling out the exponential terms, and discarding the second derivatives of U with respect to z, we find a truncated equation for U:

$$2ik_z \frac{\partial U}{\partial z} + \frac{\partial^2 U}{\partial x^2} + k_z^2 U + k_0^2 \Delta\varepsilon(E) U = 0. \tag{4}$$

Exploiting the periodicity of the conditions at the boundary of the hologram, we write U(x, z) as

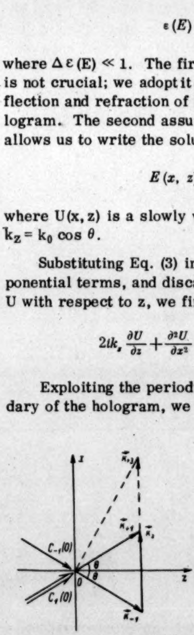

Fig. 1. Vector diagram of waves propagating in a dynamic hologram system.

$$U(x,\ z)=\sum_{n=-\infty}^{\infty} C_n(z)\,e^{ink_x x}. \tag{5}$$

Substituting (5) into (4) we find

$$2ik_z\frac{\partial}{\partial z}\sum_{n=-\infty}^{\infty} C_n(z)\,e^{ink_x x}+k_z^2\sum_{n=-\infty}^{\infty} C_n(z)(1-n^2)\,e^{ink_x x}$$
$$+k_0^2\Delta\varepsilon(E)\sum_{n=-\infty}^{\infty} C_n(z)\,e^{ink_x x}=0. \tag{6}$$

To proceed further in this analysis we must specify a concrete functional dependence of $\Delta\varepsilon$ on E. Here we consider the cases in which

$$\Delta\varepsilon=\alpha\,|E|^2 \tag{7}$$

and

$$\Delta\varepsilon=\beta\frac{\partial |E|^2}{\partial x}. \tag{8}$$

Equation (7) gives an approximate description of the functional dependence of the dielectric constant of a nonlinear medium on the amplitude of the light field in dynamic holograms recorded in absorbing liquids, while Eq. (8) corresponds to a recording in a crystal like lithium niobate: With a sinusoidal intensity distribution in the interference pattern this reaction of the medium corresponds to the observed displacement of the grating by one fourth of the period with respect to this pattern. [The plus sign on the right side of Eq. (8) corresponds to the case in which $\beta > 0$ and in which the C axis of the crystal lies along the X axis.] Since the phase gratings in nonlinear media obeying Eq. (7) coincide in position with the interference pattern which forms them, we call such gratings "undisplaced gratings."

Substituting Eqs. (7) and (8) into Eq. (6), using Eqs. (3) and (5) for E(x, z) and U(x, z), cancelling out the factor of $2ik_z$, and equating to zero the sums of the coefficients of terms having identical exponential factors, we find systems of coupled differential equations for the two cases:

$$\frac{dC_n}{dz}-\frac{i}{2}(1-n^2)\,k_x\,\mathrm{tg}\,\theta C_n$$
$$=\frac{i}{2}\alpha\frac{k_0^2}{k_z}\sum_{l+m-k=n} C_lC_mC_k^*\ (n=\pm 1,\ \pm 3\ldots) \tag{9}$$

for the case of undisplaced phase gratings;

$$\frac{dC_n}{dz}-\frac{i}{2}(1-n^2)\,k_x\,\mathrm{tg}\,\theta C_n=-\frac{\beta}{2}\frac{k^2}{k_z}k_x\sum_{l+m-k=n}(m-k)\,C_lC_mC_k^*$$
$$(n=\pm 1,\ \pm 3\ldots) \tag{10}$$

for the case of displaced gratings. Introducing the notation

$$B_n=\frac{1}{2}(1-n^2)\,k_x\,\mathrm{tg}\,\theta=\frac{1-n^2}{2}\frac{2\pi}{\lambda}\frac{\sin^2\theta}{\cos\theta}, \tag{11}$$

$$f_n(z)=\begin{cases}\dfrac{i}{2}\alpha\dfrac{k^2}{k_z}\displaystyle\sum_{l+m-k=n} C_lC_mC_k^* & \text{for undisplaced gratings}\\ -\dfrac{\beta}{2}\dfrac{k^2}{k_z}k_x\displaystyle\sum_{l+m-k=n}(m-k)\,C_lC_mC_k^* & \text{for displaced gratings,}\end{cases} \tag{12}$$

and multiplying the equations in systems (9) and (10) by the corresponding interference factors e^{-iB_nz}, we convert them to "total-differential" form, so that we can now write the equations for $C_n(z)$ in integral form:

$$C_n(z)=e^{iB_nz}\left[\int_0^z f_n(z')\,e^{-iB_nz'}\,dz'+C_n(0)\right]. \tag{13}$$

It follows from Eqs. (13) that the nature of the light propagation in the hologram is strongly influenced by the ratio between the rates of change of the functions $f_n(z')$ and e^{-iB_nz} in the integrand. The first of these functions describes the scattering of the amplitudes of the interacting waves into a wave of a given order by the thin layer of the hologram with coordinate z'; the second takes into account the phase difference which arises when the amplitudes of the light scattered by different thin layers are combined. We have n = ± 1 for the incident beams, so that the exponential term is equal to unity, regardless of the geometry of the recording; this circumstance corresponds to satisfaction of the Bragg condition for these waves. For waves of higher order ($n \neq \pm 1$) we have $B_n \neq 0$, and the radiation scattered by different thin layers is not in phase. When the rates of change of the wave amplitudes due to scattering by the hologram are small by comparison with the oscillation rates of the functions e^{-iB_nz}, we can neglect integrals like (13) for the amplitudes of the higher-order waves and retain in systems (9) and (10) only the terms corresponding to the several lowest orders of diffraction. Furthermore, in correspondence with a case of practical importance, we assume that the waves incident on the hologram differ markedly in amplitude, e.g., that $|C_{-1}(0)| \ll |C_1(0)|$.

Under these assumptions we can retain three coupled equations, for n = ± 1 and n = 3, in each of systems (9) and (10):

$$\frac{dC_1}{dz}=iA\,[2C_3C_{-1}C_1^*+(|C_1|^2+2|C_{-1}|^2+2|C_3|^2)\,C_1], \tag{14a}$$

$$\frac{dC_{-1}}{dz}=iA\,[C_1C_1C_3^*+(|C_{-1}|^2+2|C_1|^2+2|C_3|^2)\,C_{-1}], \tag*{14b)}$$

$$\frac{dC_3}{dz}-iB_3C_3=iA\,[C_1C_1C_{-1}^*+(|C_3|^2+2|C_1|^2+2|C_{-1}|^2)\,C_3] \tag{14c}$$

for the case corresponding to Eq. (7); and

$$\frac{dC_1}{dz}=-\gamma\,|C_{-1}|^2C_1+\gamma\,|C_3|^2C_1, \tag{15a}$$

$$\frac{dC_{-1}}{dz}=\gamma\,|C_1|^2C_{-1}+\gamma C_1^2C_3^*, \tag{15b}$$

$$\frac{dC_3}{dz}-iB_3C_3=-\gamma C_1^2C_{-1}^*+\gamma\,|C_1|^2C_3 \tag{15c}$$

for the case corresponding to Eq. (8). Here

$$A=\frac{\alpha}{2}\frac{k^2}{k_z},\quad \gamma=\beta\frac{k^2}{k_z}k_x. \tag{15d}$$

Substituting $C_i = \bar{C}_i\exp\left(-i2Az\sum_i |C_i|^2\right)$ into (14), we find the following system of equations for $\bar{C}_i(z)$:

$$\frac{d\bar{C}_1}{dz}+iA\,|\bar{C}_1|^2\bar{C}_1=2iA\bar{C}_3\bar{C}_{-1}\bar{C}_1^*, \tag{16a}$$

$$\frac{d\bar{C}_{-1}}{dz}+iA\,|\bar{C}_{-1}|^2\bar{C}_{-1}=iA\bar{C}_1\bar{C}_1\bar{C}_3^*, \tag{16b}$$

$$\frac{d\bar{C}_3}{dz}+iA\left(|\bar{C}_3|^2-\frac{B_3}{A}\right)\bar{C}_3=iA\bar{C}_1\bar{C}_1\bar{C}_{-1}^*. \tag{16c}$$

[In deriving (16) we have exploited the circumstance that the sum $\sum_i |C_i(z)|^2 = \text{const} = \sum_i |C_i(0)|^2$ is an integral of system (14).]

The terms with quadratic amplitudes on the left side of (16) cause a difference between the phase velocities of plane waves because of their self-interaction, as can be seen by setting the right sides of Eqs. (16) equal to zero. Energy exchange between the waves is described by the terms on the right sides of Eqs. (16). Let us consider the general features of this process as light propagates into the interior of the hologram. Near the surface of the hologram we can neglect the third term on the left side of Eq. (16c) by virtue of the smallness of $\overline{C}_3$. Determining $\overline{C}_3(z)$ from (13), and substituting the result into Eqs. (16a) and (16b), we find that the increment in the amplitude of the weaker wave is in phase with the amplitude $\overline{C}_{-1}(0)$, while the increment in the amplitude of the stronger wave is shifted by π radians with respect to the initial amplitude $\overline{C}_1(0)$. This result corresponds to the intensification of the weaker wave $\overline{C}_{-1}$ at the expense of the stronger wave $\overline{C}_1$. In turn, as we see from Eq. (16c), an increase in $\overline{C}_{-1}$ increases the rate at which $\overline{C}_3$ increases. It is not difficult to show that in a thin layer near the surface of a hologram the amplitudes of both waves increase exponentially, with an argument of $A|C_1(0)|^2 z$. As we move away from the surface of the hologram the influence of the discarded term in Eq. (16c) becomes significant; as a result, the increments in the amplitudes of the interacting waves become increasingly out of phase with respect to the amplitudes themselves. With $z_0' \sim \pi/B_3$ this displacement is 180°, and energy begins to be returned from the amplified waves to the stronger wave. In the case of a low conversion efficiency, with $|\overline{C}_{-1}(z)|$ and $|C_3(z)| \ll |\overline{C}_1(z)|$, the subsequent energy exchange between waves is oscillatory, with a spatial period of $2z_0'$. Accordingly, in undisplaced dynamic gratings there exists an effective amplification length for weak beams, governed by z_0'. Substituting the value of B_3 from (11) into the equation for z_0', and using $\Lambda = \lambda/2\sin\theta$ (which relates the period of the interference patterns, Λ, to the wavelength and the angle between the beams), we find that holograms having a thickness equal to the effective amplification depth z_0' satisfy the condition $z_0' < \Lambda^2/\lambda$; such holograms can be treated as thin holograms.[6] It is therefore natural to expect that the efficiency with which light beams are converted by means of undisplaced dynamic phase gratings should not exceed about 30%, which corresponds to the limiting diffraction efficiency of thin phase holograms.[6] It is clear from this discussion that attempts to raise the efficiency of dynamic holograms of this type by resorting to a recording of a more three-dimensional nature (by increasing the angle between the beams) are counterproductive, since the result is a decrease in z_0'. At large values of θ the beams in such holograms will propagate essentially without energy transfer.

We turn now to an analysis of system (15), which describes the propagation of waves in displaced dynamic three-dimensional holograms. The most important difference between these equations and relations (16) (for undisplaced gratings) is the appearance of the terms $-\gamma|C_{-1}|^2 C_1$ and $\gamma|C_1|^2 C_{-1}$, which provide energy transfer from one of the Bragg beams to the other without the participation of higher-order waves. We will show that under certain conditions this process plays a decisive role and is capable of leading to a complete energy transfer between Bragg beams.

Let us first evaluate the influence of the most intense higher order (n = 3). Assuming $|C_3(z)| \ll |C_{-1}(z)$ and $C_1(z) \simeq C_1(0)$, we find from Eq. (15b) that

$$C_{-1}(z) \simeq C_{-1}(0)\, e^{\gamma |C_1(0)^2| z}. \qquad (17)$$

Substituting this equation into the equation for $C_3(z)$, from (13) we find

$$C_3(z) = -e^{-\gamma |C_1(0)|^2 z} e^{iB_3 z} \gamma C_1^2(0)\, C_{-1}(0) \int_0^z e^{2\gamma |C_1(0)|^2 z'} e^{2-iB_3 z} dz'. \qquad (18)$$

The integral in (18) can be evaluated easily and we can evaluate the intensity ratio of the waves with n = 3 and n = − 1:

$$\frac{|C_3|^2}{|C_{-1}|^2} = \left(\frac{\gamma |C_1(0)|^2}{B_3}\right)^2. \qquad (19)$$

From (19) we find a condition for the suppression of waves of higher diffraction orders in a dynamic three-dimensional hologram:

$$\frac{\gamma |C_1(0)|^2}{B_3} = \frac{\Delta\varepsilon}{8\sin^2\theta} \ll 1. \qquad (20)$$

We see from Eq. (20) that, in contrast with the case of static three-dimensional holograms,[6] the degree to which higher-order beams are suppressed by dynamic three-dimensional holograms is not dependent on the thickness of the hologram. A numerical estimate of the ratio $|C_3|^2/|C_{-1}|^2$ on the basis of (19) shows that for angles θ of the order 1° and for $\Delta\varepsilon \simeq 10^{-5}$ this ratio is 10^{-5}. Accordingly, at $\theta \geq 1°$ the effect of the higher orders on the energy exchange between Bragg beams can be neglected, and the analysis can be restricted to the equations for the amplitudes of the original waves:

$$\frac{dC_1}{dz} = -\gamma |C_{-1}|^2 C_1, \qquad (21a)$$

$$\frac{dC_{-1}}{dz} = \gamma |C_1|^2 C_{-1}. \qquad (21b)$$

Rewriting system (21) in integral form,

$$C_1(z) = C_1(0)\, e^{-\gamma \int_0^z |C_{-1}(z)|^2 dz}, \qquad (22a)$$

$$C_{-1}(z) = C_{-1}(0)\, e^{\gamma \int_0^z |C_1(z)|^2 dz}, \qquad (22b)$$

we note that the integrals in the exponential functions of these equations are positive, nondecreasing quantities. It follows that energy transfer between Bragg waves is unidirectional, and when the hologram is thick enough the energy of one wave can be transferred completely to the other. Accordingly, dynamic three-dimensional phase holograms recorded in media with a displacement of the grating are capable of light-beam conversion with an efficiency of nearly 100%. The direction of the energy transfer is governed by the direction in which the grating is displaced with respect to the interference pattern: The peaks of $\varepsilon(E)$ must be displaced with respect to those of the interference pattern in the direction of the amplifying wave.

The explicit functional dependence of amplitudes C_{-1} and C_1 on z can be found in the following manner. Dividing Eq. (22b) by Eq. (22a) we find

$$\frac{C_{-1}(z)}{C_1(z)}=\frac{C_{-1}(0)}{C_1(0)}e^{\gamma\int_0^z(|C_1(z)|^2+|C_{-1}(z)|^2)dz} \tag{23}$$

Since the sum

$$|C_1(z)|^2+|C_{-1}(z)|^2=\mathrm{const}=|C_1(0)|^2+|C_{-1}(0)|^2 \tag{24}$$

is an integral of system (22), the integration in (23) yields

$$\frac{C_{-1}(z)}{C_1(z)}=\frac{C_{-1}(0)}{C_1(0)}e^{\gamma(|C_1(0)|^2+|C_{-1}(0)|^2)z}. \tag{25}$$

Converting from (25) to an equation for the intensities of the Bragg waves, $J_1(z) = |C_1(z)|^2$ and $J_{-1}(z) = |C_{-1}(z)|^2$, and taking the logarithms of both sides of the resulting equation, we find

$$\ln\frac{J_{-1}(z)}{J_1(z)}=\ln\frac{J_{-1}(0)}{J_1(0)}+2\gamma[J_{-1}(0)+J_1(0)]z. \tag{26}$$

This equation can be used to determine the intensity ratio of the waves at an arbitrary cross section of the hologram from the intensities of the incident waves specified at the boundary, $J_1(0)$ and $J_{-1}(0)$, and from the value of the parameter γ, a characteristic of the medium. The values of the intensities themselves can be easily found by means of integral (24). The family of equations (26) for different values of γ and for different intensities $J_1(0)$ and $J_{-1}(0)$ describes a set of straight lines whose ordinate intercepts are governed by the value of $\ln[J_{-1}(0)/J_1(0)]$ and whose slopes are governed by the value of $\gamma\,[J_1(0) + J_{-1}(0)]$. The linear nature of this expression shows that the necessary degree of energy transfer between the Bragg beams, governed by the ratio $J_{-1}(z)/J_1(z)$, can be attained, regardless of the initial intensity ratio of the waves incident on the hologram, $J_{-1}(0)/J_1(0)$. This relation affects only the depth at which this transfer is achieved.

Figure 2 shows the result of an illustrative calculation of $J_{-1}(z)$ and $J_1(z)$ from Eq. (26); the solid curves show the intensity of the waves propagating in the hologram, while the dashed curve shows the profile of the modulation depth of the dielectric constant over the thickness of the hologram, $\Delta\varepsilon(z) = 2(\Delta\varepsilon)'\sqrt{J_1(z)\,J_{-1}(z)}/J_1(0)$. For this calculation we assume the parameter $(\Delta\varepsilon)' = 2\beta k_x[J_1(0) + J_{-1}(0)]$, which governs the changes in the dielectric constant of the medium, is 10^{-5}; we also assume $J_{-1}(0)/J_1(0) = 10^{-8}$, $\lambda = 7\cdot10^{-5}$ cm, and $\theta = 0.2$ rad. The additional stage of the energy transfer, according to (17), is characterized by an exponential increase in C_{-1} and a corresponding exponential increase in the modulation depth of the hologram. Then, because of the decrease in the intensity of the stronger wave, the process slows down; at $C_{-1}(z_m) = C_1(z_m)$ the modulation depth reaches a maximum, and then it decreases as wave $C_1(z)$ is attenuated. In this example we find that the energy of this wave has essentially been converted to the originally weaker wave, C_{-1}, at a depth of about 25 cm.

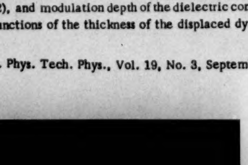

Fig. 2. Normalized intensities of the Bragg beams, $J_{-1}(z)/J_1(0)$ (1) and $J_1(z)/J_1(0)$ (2), and modulation depth of the dielectric constant of the medium, $\Delta\varepsilon$ (3), as functions of the thickness of the displaced dynamic hologram.

In concluding this analysis of dynamic holograms, we turn to an estimate of the amplification coefficients for weak beams in the exponential growth regions [with $C_{-1}(z) \ll C_1(z) \simeq C_1(0)$], in which, as was shown above, the amplitudes of the waves in the undisplaced and displaced gratings increase in proportion to $e^{A|C_1(0)|^2z}$ and $e^{\gamma|C_1|(0)|^2z}$, respectively. Using Eqs. (7), (8), and (15d) along with the approximation

$$\Delta n(|E|^2)\simeq\frac{\Delta\varepsilon(|E|^2)}{2n_0}\simeq\frac{\Delta\varepsilon(|E|^2)}{2},$$

we can convert the quantities $2A|C_1(0)|^2$ and $2\gamma|C_1(0)|^2$ (which represent the initial intensity amplifications of the waves) to the same form:

$$2A|C_1(0)|^2,\ 2\gamma|C_1(0)|^2=k_{\mathrm{am}}(0)=\frac{4\pi}{\lambda\cos\theta}\Delta n(|E_1|^2)_{z=0}, \tag{27}$$

where $\Delta n(|E_1|^2)_{z=0}$ are the characteristic changes in the refractive index of the medium under the influence of a light field of amplitude E_1. Substituting $\lambda = 7\cdot10^{-5}$ cm, $\cos\theta \simeq 1$, and the values $\Delta n(|E|^2) = 10^{-4}$–$10^{-5}$ (typical for dynamic holograms) into (27), we find that the initial amplification coefficients for dynamic holograms range from 2 to 20 cm^{-1}, some two or three orders of magnitude higher than those achievable in inversion media of solid-state coherent-radiation sources. Accordingly, by using a dynamic hologram as amplifier we can achieve a significant amplification of weak signals at comparatively small thicknesses of the amplifying layer.

Amplification of weak light beams is not the only possible application: The ability of displaced dynamic holograms to cause an essentially complete energy transfer between incident light beams, regardless of their initial intensity ratio, can be exploited to stabilize the propagation of light beams having a uniform distribution of the field over their cross section. Figure 3 shows an arrangement for this stabilization. The beam whose direction is to be stabilized is split into two parts by half-silvered mirror M. Most of the beam passes through the mirror and reaches the dynamic displaced hologram DDH (beam I), while the weaker beam (II) is expanded by telescope system T, with a Γ^x-fold increase, and sent to the DDH, at some angle with respect to the first beam. When the con-

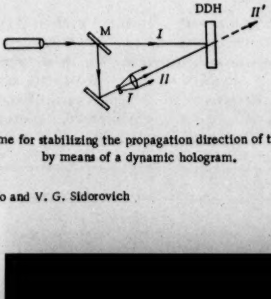

Fig. 3. Scheme for stabilizing the propagation direction of the light beam by means of a dynamic hologram.

ditions described above are satisfied, beam I can be converted into beam II', moving in the same direction as beam II; the change in the direction of beam I by an angle of α leads to a change (lower by a factor of Γ^x) in the angular deviation of converted beam II'.

In conclusion we should point out that these results can be generalized to the case in which the beams are polarized in the plane of incidence; this case is of interest in connection with the recording of holograms in lithium niobate crystals. In this case a description of the wave propagation in the hologram is more convenient in terms of the equation for the amplitude of the magnetic field vector, H (see also ref. 7). Calculations analogous to those above for the case of displaced dynamic holograms lead to a system of equations like (21), differing only in the replacement of the factor γ by $\gamma' - \gamma_e \cos^2 2\theta$, where γ_e may be quite different from γ (e.g., we would have $\gamma_e \gg \gamma$, in lithium niobate crystals[5]).

The authors thank Yu. N. Denisyuk for his assistance and for interest in this work and Yu. A. Anan'ev and S. G. Przhibel'skii for useful discussion of certain topics.

Zh. Tekh. Fiz., 44, 588-590 (March 1974)

Questions related to the maintenance and focusing of a beam in an accelerator having inductive energy storage are examined. Equations are derived and curves are plotted to determine beam and accelerator parameters such that the charged-particle beam is not cut off or defocused.

We are concerned here with certain general questions related to the maintenance and focusing of the beam in a pulsed accelerator. The charged-particle beam, which links the winding of a solenoid, produces a magnetic field which is used to focus the beam itself. Below we analyze the conditions under which the beam passing through the solenoid produces a magnetic field strong enough to conduct the beam through the solenoid.

The equation of the envelope for a magnetically confined beam (i.e., for the case in which the cathode is in a magnetic field B) is

$$\frac{d^2r}{dz^2}=\frac{I}{4\pi\varepsilon\sqrt{2\eta}\,U_0^{3/2}r}-\frac{\eta B^2r}{8U_0}\left(1-\frac{r_k^4}{r^4}\right). \quad (1)$$

Here, r is the beam radius, r_k is the beam radius at the cathode, I is the beam current, U_0 is the potential corresponding to the energy of the particles at the axis, ε is the permittivity of free space, and $\eta = e/m$ is the charge-to-mass ratio of the particles. Since we are interested in the case in which the currents are at nearly their limiting values, we consider the dip in the potential over the beam cross section. For this purpose we assume $U_0 = 0.5U$, where U is the potential of the electron chamber. We write B in terms of the solenoid current, which is equal to the beam current:

$$B=\mu NI. \quad (2)$$

Here, μ is the vacuum permeability, and N is the number of turns per meter.

Substituting (2) into (1), we find

$$\frac{d^2r}{dz^2}=\frac{I}{2\pi\varepsilon\sqrt{\eta}\,U^{3/2}r}-\frac{\eta\mu^2N^2I^2r}{4U}\left(1-\frac{r_k^4}{r^4}\right). \quad (3)$$

To find an approximate solution of Eq. (3) for small changes in the beam envelope we assume that $r - r_k = \Delta r \ll r_k$ over the length of the solenoid, l. Expanding the right side of Eq. (3) in a series, we find

$$\frac{d^2(\Delta r)}{dz^2}+K^2\Delta r=C_1, \quad (4)$$

where

$$C_1=\frac{I}{2\pi\varepsilon\sqrt{\eta}\,U^{3/2}r_k};\quad C_2=\frac{\eta\mu^2N^2I^2}{U};\quad K^2=C_2+\frac{C_1}{r_k}.$$

The solution of Eq. (4) for the initial conditions

$$\Delta r\big|_{z=0}=0,\quad \frac{d(\Delta r)}{dz}\bigg|_{z=0}=0$$

is

$$\Delta r=\frac{c_1}{K^2}(1-\cos Kz). \quad (5)$$

Specifying a definite value $\Delta r = (\Delta r)_{max}$, we can find the functional dependence of the minimum potential $V = V_{cr}$ at which the condition $\Delta r \le \Delta r_{max}$ is satisfied for a specified beam current I and solenoid length. Figure 1 shows an illustrative case for the following parameters: $\Delta r/r_k = 0.2$, $r_k = 0.1$ m, $l = 1$ m, and $N = 10^3$ turns/m.

The region above the curve $V_{cr} = V_{cr}(I_{cr})$ corresponds to the situation in which the beam is not defocused after passing through the solenoid.

However, the beam cannot pass through the solenoid at all values of I and V which satisfy the focusing conditions: The maximum beam current which can be drawn at an energy eV_{lim} is limited, being equal to[1]

$$I_{lim}=1.6\pi\varepsilon\sqrt{2\eta}\,U_{lim}^{3/2}\frac{1}{1+2\ln\frac{R}{r}}. \quad (6)$$

The current calculated from this equation corresponds to the situation in which $V_0 = 0.5V$ because of the dip in the potential over the beam cross section. Here, R is the tube radius. Figure 1 shows the functional dependence $V_{lim}(I_{lim})$. The cross-hatching shows the region which satisfies conditions (5) and (6).

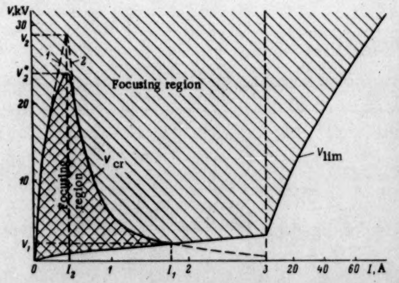

Fig. 1. Region in which a focused beam exists for r = 0.1 m, (Δr)/r = 0.2, l = 1 m, and N = 10^3 turns/m.

The intersection of the V_{cr} and V_{lim} curves gives the lower boundary of the region in which a focused beam exists. An analytic expression for the parameters of this point, V_1 and I_1, can be found from (5) and (6) by setting $I_{lim} = I_{cr}$:

$$V_1 = \frac{\left(1 + 2\ln\frac{R}{r_k}\right)^{1/3}}{2.12\pi\varepsilon\mu\eta r_k\left(\frac{\Delta r}{r_k}\right)^{1/3} N}, \tag{7}$$

$$I_1 = \frac{0.73}{\sqrt{\pi\varepsilon}\,\eta\left(1 + 2\ln\frac{R}{r}\right)^{1/4}(\mu r_k N)^{2/3}\left(\frac{\Delta r}{r_k}\right)^{3/4}}. \tag{8}$$

At the specified solenoid and beam parameters (Fig. 1) we have $I_1 = 1.64$ A and $V_1 = 2.2$ kV.

To find the (approximate) parameters of the second characteristic point (I_2, V_2), which governs the region in which a focused beam exists, we consider two extreme cases: 1) $K_z \ll \pi/2$; 2) $K_z \geq \pi/2$.

At low currents, with $K_z \ll \pi/2$, the quantity Δr is governed primarily by the Coulomb repulsive forces. Using Eq. (5), we can write, approximately,

$$\Delta r_{max} \simeq \frac{C_1 l^2}{2}. \tag{9}$$

Substituting in the value of C_1, we find

$$V_{cr} = \left[\frac{I l^2}{4\pi\varepsilon\sqrt{\eta}\, r_k^2\left(\frac{\Delta r_{max}}{r_k}\right)}\right]^{1/3} \tag{10}$$

(curve 1 in Fig. 1).

As the current is increased the focusing effect of the magnetic field becomes increasingly important, until a force equilibrium is reached, i.e., until $C_1 = C_2\Delta r_{max}$. Then $K^2 \simeq C_2$, and from (5) we find

$$\Delta r_{max} \simeq \frac{C_1}{C_2} \tag{11}$$

(curve 2 in Fig. 1). Substituting the values of C_1 and C_2, we find

$$V_{cr} = \frac{1}{\left[2\pi\varepsilon\eta^{2/3}(\mu N r_k)^2\left(\frac{\Delta r_{max}}{r_k}\right) I_{cr}\right]^2}. \tag{12}$$

To determine the intersection of branches 1 and 2, we equate Eqs. (10) and (12), finding

$$V_2 = \frac{l}{2\sqrt{2}\,\pi\varepsilon\eta\mu N r_k^4\left(\frac{\Delta r_{max}}{r_k}\right)}, \tag{13}$$

$$I_2 = \frac{1}{2^{1/4}(\pi\varepsilon l)^{1/2}\eta(\mu N)^{3/2} r_k\left(\frac{\Delta r_{max}}{r_k}\right)^{1/2}}. \tag{14}$$

For the example considered above (Fig. 1) we have $I_2 = 0.45$ A and $V_2 = 29$ kV. We note that this value of V_2 differs only slightly from the exact value of the maximum potential, $V_2^* = 24$ kV, calculated from Eq. (5).

The quantity V_2 represents the minimum potential at which the beam can pass through the solenoid over the entire current range, from zero to the limiting value [given by Eq. (6)]. This is an important situation for the case in which the solenoid is driven by a charged-particle beam. If, on the other hand, the solenoid is charged beforehand by means of a current source, and if the working beam current is higher than I_1 (which is usually the case), the minimum beam potential is governed by condition (6) alone.

High-current pulsed electron accelerator with an annular beam

M. I. Avramenko, V. A. Glukhikh, O. A. Gusev, E. G. Komar,
O. L. Komarov, V. S. Kuznetsov, A. S. Perlin, and M. P. Svin'in

D. V. Efremov Scientific-Research Institute of Electrophysical Apparatus, Leningrad

(Submitted August 15, 1973)
Zh. Tekh. Fiz., 44, 591-595 (March 1974)

Certain questions related to the design and construction of a high-current pulsed accelerator with a pulse length of 10^{-4} sec, a beam current of $2 \cdot 10^{4}$ A, and an electron energy of 1 MeV are discussed. The pulsed accelerating voltage is produced by an electrical solenoid in which energy from an auxiliary power supply is stored with a high-speed current switch. It is shown that an annular thermionic cathode should be used to produce a beam having the specified parameters. The focusing and maintenance of the annular structure of the beam are achieved by means of the inhomogeneous magnetic field of the solenoid.

INTRODUCTION

Beam power levels of the order of 10^{12} W per pulse with pulse lengths of 10^{-8}-10^{-7} sec have been achieved in high-current electron accelerators. In certain cases, however, it is necessary to have pulsed electron beams with pulse lengths two to three orders of magnitude longer.

In this work we examine certain aspects of the design of a high-current pulsed accelerator with a pulse length of $\sim 10^{-4}$ sec, a beam current of $\sim 2 \cdot 10^{4}$ A, and an electron energy of ~ 1 MeV. We assume that the pulsed accelerating voltage is provided by an electrical solenoid in which energy from an auxuliary power supply is stored with a high-speed current switch.

A field-emission cathode cannot be used with high-voltage pulses with lengths of the order of 10^{-4} sec because of the mechanical destruction of the cathode and because the plasma which appears at the surface of the field-emission cathode and moves with a velocity of the order of 10^{6} cm/sec moves 100 cm in 100 msec. In other words, the plasma moves much farther than the distance between the electrodes; thus, the plasma short circuits the gap, cutting off the beam current.

It is essentially impossible to obtain directly a beam with an energy of $\varepsilon = 1$ MeV from a plasma source, since the dielectric strength of the emitter-accelerating electrode gap is too low. We therefore turn to a thermionic cathode with a large emission surface. Cathodes of this type can produce a current density of the order of 40-50 A/cm² at pulse lengths of $\sim 10^{-4}$ sec.

ELECTRON GUN

The shaping and transporting of high-current electron beams is complicated by the effect of the space charge, which limits the beam current.

We have considered two methods for shaping the electron beam: plasma and vacuum methods. The plasma method cannot be used in this case because the various instabilities which arise as the electron current flows through the plasma restrict the limiting (or critical) beam current. In particular, the growth time for the most dangerous instability, the beam-drift instability, is given by[2]

$$\tau = \left(\frac{\omega_{He}}{\omega_{Hi}}\right)^{1/3} \left(\frac{a^2}{2v^2}\right)^{1/3}, \tag{1}$$

where $\omega_{He} = eH/(mc)$, m and e are the electron mass and charge, H is the external magnetic field, $\omega_{Hi} = eH/(m_i c)$; m_i is the ion mass, a is the beam radius, and v is the velocity of the beam electrons. With the plasma and beam parameters under consideration here, the growth time for this instability is of order $\tau = 100$ nsec, much shorter than the current pulse.

Furthermore, at a power level of order 1 MW the acceleration region cannot be protected from the penetration of plasma from the drift region.

We therefore adopt the vacuum method for shaping the electron beam in the drift region. The limiting current of a nonneutral relativistic electron beam moving along the axis of a metal tube of radius R in the drift region is[2]

$$I_0 = \frac{17}{1 + 2\ln\frac{R}{r_0}} (\gamma^{2/3} - 1)^{3/2}\ [\text{kA}], \tag{2}$$

where r_0 is the beam radius and γ is the Lorentz factor.

Equation (2) states that when the beam completely fills the cross section of the tube ($R = r_0$) the limiting current at an energy of $\varepsilon = 1$ MeV is 19 kA. However, when we take account of the circumstance that the beam cannot be allowed to strike the walls of the drift tube, we conclude that the ratio R/r_0 should be no smaller than 2. In this case the limiting current is about 10 kA, lower than the desired value. Considerably higher currents can be achieved through the use of annular electron beams. The limiting current for an annular beam is

$$I = \frac{17 (\gamma^{2/3} - 1)^{3/2}}{1 + 2\ln\frac{R}{r_0}} \left(\frac{r_0}{a}\right) [\text{kA}], \tag{3}$$

where a is the thickness of the ring ($r_0 \gg a$).

We see from Eq. (3) that if we choose the ratio r_0/a to be 5, the limiting current is 50 kA, 2.5 times the desired value.

Accordingly, an annular electron beam at a current of ~ 20 kA can be stably transported in vacuum at a ratio $r_0/a = 5$. We choose the parameter of the annular gun to be as follows: an outer cathode radius of 22 cm, an inner radius of 17 cm, a cathode–anode separation of 8.3 cm, a maximum voltage of 1 MV, and a current density of 50 A/cm².

The maximum electric field at the anode is $|E|_{\max} = 160$ kV/cm.

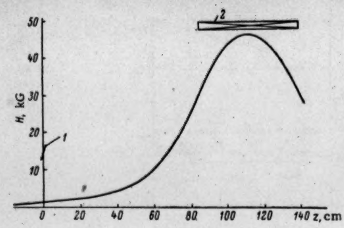

Fig. 1. Profile of the magnetic field at the solenoid axis. 1) Annular cathode; 2) solenoid.

BEAM-FORMING SYSTEM

An inhomogeneous magnetic field should be used to focus an intense annular electron beam; the cathode of the gun should also be in the magnetic field. We make this choice because the focusing system must, first, preserve the hollow structure of the beam at the selected ratio $r_0/a = 5$ and, second, provide a beam radius of 3 cm at the exit from the accelerator, i.e., the beam must be compressed by a factor of about 7. If the cathode is in a strong magnetic field the electrons will follow the magnetic lines of force and the shape of the beam boundary will be governed by the lines of force. The magnetic field required for this focusing method can be found from[3]

$$B=\frac{1}{2}\sqrt{\frac{I}{\frac{\pi\varepsilon_0}{\sqrt{2}}\left(\frac{e}{m_0}\right)^{1/2}\{U(1+\eta U)\}^{1/2}\Delta r r_k}}\ [\mathrm{T}], \qquad (4)$$

where I is the beam current, U is the beam potential, r_k is the beam radius at the cathode, Δr is the magnitude of the pulsations in the beam boundary, e and m_0 are the charge and rest mass of the electron, $\eta = e/(2m_0c^2)$, and ε_0 is the permittivity of free space.

Assuming that the pulsation amplitude must not exceed 3% of the width of the annular beam, from Eq. (4) we find that the magnetic field at the cathode must be about 1 kG. If a beam with an initial radius of $R_0 = 22$ cm is to be compressed to a radius of 3 cm, the magnetic field must be about 50 kG.

Figure 1 shows the profile of the magnetic field at the axis of the solenoid producing the accelerating voltage. We see from this figure that the cathode of the gun must be 86.5 cm from the center of the solenoid in order to satisfy the requirements imposed on the parameters of the annular beam. Then the necessary magnetic field of 1 kG is established near the cathode.

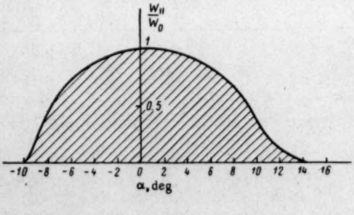

Fig. 2. The $W_{\parallel}/W_0(\alpha)$ functional dependence.

It is also necessary to take account of certain features of the motion of particles in strong and inhomogeneous magnetic fields. Particles moving in such fields can, under certain conditions, be reflected from regions in which the field is strong.[4] In our case we must not only suppress this reflection, but also any significant loss in the longitudinal energy of the particles, since the limiting current decreases with decreasing longitudinal velocity.

Reflection does not occur under the condition[4]

$$\sin\alpha_0 \leqslant \sqrt{\frac{H_0}{H_{\max}}}, \qquad (5)$$

where α_0 is the angle between the vector representing the total velocity of the particle and the magnetic field vector at $H = H_0$, and $H_{\max}$ is the maximum magnetic field.

It follows from (5) that with the specified values of the magnetic field at the cathode and at the center of the solenoid the beam is cut off if the initial inclination angle exceeds 9°. The inclination angle of the magnetic lines of force near the cathode varies from 13 to 17°, so the cathode surface must be moved through an angle of 15° with respect to the normal to the axis of the system in order to satisfy condition (5). In this case the initial inclination angle of the trajectory of the extreme electrons deviates by less than ± 2° from the inclination angle of the magnetic lines of force. We have carried out numerical calculations in order to evaluate the change in the longitudinal velocity of the particles in this case.

In our case the Coulomb forces have a slight effect in comparison with that of the external focusing magnetic field, and there are no accelerating electric fields, so the equations of motion become[5]

$$\left.\begin{aligned}\ddot{r} &= -\frac{e^2}{4\pi^2 m_0^2\gamma^2}\frac{\Psi-\Psi_k}{r}\left[2\pi B_z-\frac{\Psi-\Psi_k}{r^2}\right],\\ \ddot{z} &= -\frac{e^2}{4\pi^2 m_0^2\gamma^2}\frac{\Psi-\Psi_k}{r^2}\frac{\partial\Psi}{\partial z},\end{aligned}\right\} \qquad (6)$$

where e and m_0 are the charge and rest mass of the electron, γ is the Lorentz factor, Ψ is the magnetic flux, and B_z is the axial component of the magnetic field.

We have calculated the functional dependence $W_{\parallel}/W_0(\alpha)$, where W is the energy associated with the longitudinal motion at the exit from the accelerator and W_0 is the total energy.

Figure 2 shows the results of the numerical calculations. The inclination angle of the lines of force lies within ± 2° of the center of the cathode over the width of the cathode. It follows from Fig. 2 that this change in the initial inclination angle of the trajectories of extreme electrons with respect to the magnetic lines of force does not lead to any significant loss in longitudinal energy, so the limiting beam current is essentially unaffected.

Figure 3 shows a schematic diagram of the accelerator optics and the profile of the electron beam.

It follows from Fig. 3 that this optical scheme both preserves the hollow structure of the beam with a ratio

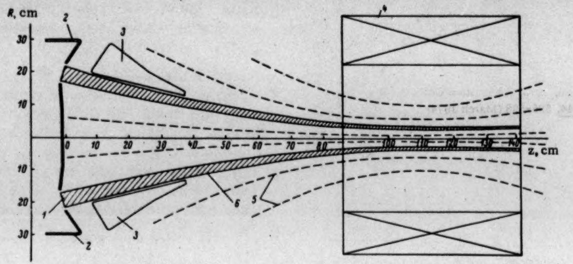

Fig. 3. Schematic of the accelerator and profile of the electron beam. 1) Annular cathode; 2) electrode near the cathode; 3) anode; 4) focusing solenoid; 5) magnetic lines of force; 6) profile of the annular beam.

$r_0/a = 5$ and produces a beam with the specified diameter at the exit from the accelerator. The pulsations in the boundary of the beam are smaller than 5%, essentially undistinguishable in this figure.

Stability of field-emission beams in nanosecond discharges

L. P. Babich

(Submitted June 25, 1973; resubmitted October 15, 1973)
Zh. Tekh. Fiz., 44, 596-598 (March 1974)

The stability of the field-emission beams in a plasma is analyzed in the collisionless approximation. It is assumed that turbulent heating of the plasma can occur near the cathode in nanosecond vacuum and gas discharges; it is also assumed that a group of stochastically accelerated electrons, having an energy exceeding the applied voltage, can be produced.

There is currently considerable interest in nanosecond discharges in gas and in vacuum.[1,2] In such discharges, a system consisting of a field-emission beam and a plasma is established near a microscopic irregularity on the cathode; this system can be unstable. The appearance, in nanosecond discharges, of electrons with energies exceeding the applied voltage[3,4] can be due to the stochastic acceleration of electrons of the field-emission beam in the turbulence generated by the beam itself in the plasma near the cathode.

To study the stability of field-emission beams in the plasma near the cathode we use the dispersion relation in the collisionless approximation:[5]

$$\varepsilon^{l}(\omega, k)=1-\frac{4\pi e^{2}}{m}\left\{\int_{c}\frac{f_{0}(\mathbf{v})\,d\mathbf{v}}{(\omega-\mathbf{kv})^{2}}+\int_{c}\frac{f_{1}(\mathbf{v})\,d\mathbf{v}}{(\omega-\mathbf{kv})^{2}}\right\}=0, \qquad (1)$$

where the integration is carried out in accordance with the Landau contour[5] and the positive x axis is opposed to the external field **E**.

Assuming a Maxwellian distribution displaced by a velocity $\mathbf{v}_0$ for the plasma electrons and assuming that the distribution function for the field-emission beam satisfies[6]

$$\int_{-\infty}^{\infty} f_{1}(\mathbf{v})\,dv_{z}dv_{y}=\frac{4\pi m^{2}}{h^{3}}e^{-c}\exp\left(-\frac{mv_{x}^{2}-2eEx+2|\zeta|}{2d}\right)$$
$$\times\,\theta\left(eEx-|\zeta|-\frac{mv_{x}^{2}}{2}\right)\left(eEx-|\zeta|-\frac{mv_{x}^{2}}{2}\right),$$
$$\left(x^{2}\geqslant\frac{e^{2}}{4eE},\ v_{x}\geqslant\sqrt{\frac{2W_{e}}{m}}\right), \qquad (2)$$

we find the following dispersion relation from (1):

$$\varepsilon_{0}^{l}(\omega, k)-\frac{1}{d_{1}^{2}k^{2}}\left\{\int_{u_{1}}^{u_{2}}\frac{f(u)}{\left(u-\frac{\omega}{kv_{d}}\right)^{2}}+2\pi i\eta\left(\frac{\omega}{kv_{d}}\right)\frac{\partial f(u)}{\partial u}\bigg|_{\frac{\omega}{kv_{d}}}\right\}=0, \qquad (3)$$

where $\varepsilon_0^l(\omega, k)$ is the dielectric constant of the Maxwellian plasma,[7]

$$v_{d}=\sqrt{\frac{2d}{m}},\quad d_{1}^{2}=\frac{\pi\hbar^{3}\exp(c)}{\sqrt{2}\,m^{1.5}e^{2}},\quad u=\frac{v_{x}}{v_{d}},\quad u_{1}=\sqrt{\frac{eEx-|W_{e}|}{d}},$$

$$u_{2}=\sqrt{\frac{eEx-|\zeta|}{d}},\quad f(u)=(u_{2}^{2}-u^{2})\exp(u^{2}-u_{2}^{2})\,\theta(u_{2}^{2}-u^{2}).$$

Since $(\Delta u_{21})/u_2=(u_2-u_1)/u_2 \ll 1$, we find the following equation from (3) for unstable states ($\eta = 0$):

$$1+\frac{1}{d_{0}^{2}k^{2}}\left\{1+i\sqrt{\pi}\,\frac{\omega-kv_{0}}{kv_{Te}}\,W\left(\frac{\omega-kv_{0}}{kv_{Te}}\right)-\left(\frac{\omega_{p1}d_{0}k}{u_{2}v_{d}k-\omega}\right)^{2}\right\}=0, \qquad (4)$$

where W is the Cramp function[8] and where

$$\omega_{p1}^{2}=\frac{v_{d}^{2}}{2d_{1}^{2}u_{2}}\left[1-(1+2u_{2}\Delta u_{21})\exp(-2u_{2}\Delta u_{21})\right].$$

From Eq. (4) we can determine the frequencies and growth rates of the modes excited by the field-emission beam in the plasma.

When $|(\omega-kv_0)/kv_{Te}| \ll 1$ it follows from (4) that

$$1+\frac{1}{d_{0}^{2}k^{2}}\left(1+i\sqrt{\pi}\,\frac{\omega-kv_{0}}{kv_{Te}}\right)-\left(\frac{\omega_{p1}}{u_{2}v_{d}k-\omega}\right)^{2}=0. \qquad (5)$$

Assuming $\omega = u_2v_dk + \omega^{(1)}$ here, where $\operatorname{Re}\omega^{(1)} \equiv \omega_1$ and $\operatorname{Im}\omega^{(1)} \equiv \gamma$, we consider three different cases.

a) $|(\omega_1/k)| \ll |u_2v_d-v_0|$:

$$\begin{cases}\omega_{1}=\pm\omega_{p1}\left[\dfrac{1+d_{0}^{-2}k^{-2}+\sqrt{(1+d_{0}^{-2}k^{-2})^{2}+\pi d_{0}^{-4}k^{-4}v_{Te}^{-2}(u_{2}v_{d}-v_{0})^{2}}}{2(1+d_{0}^{-2}k^{-2})^{2}+2\pi d_{0}^{-4}k^{-4}v_{Te}^{-2}(u_{2}v_{d}-v_{0})^{2}}\right]^{1/2};\\[2ex] \gamma=-\sqrt{\dfrac{\pi}{2}}\,\omega_{p1}\dfrac{u_{2}v_{d}-v_{0}+\dfrac{\omega_{1}}{k}}{d_{0}^{2}k^{2}\omega_{1}v_{Te}\left[(1+d_{0}^{-2}k^{-2})^{2}+\pi d_{0}^{-4}k^{-4}v_{Te}^{-2}(u_{2}v_{d}-v_{0})^{2}\right]}.\end{cases} \qquad (6a)$$

b) With $1+d_0^{-2}k^{-2} \gg \sqrt{\pi}\,d_0^{-2}k^{-2}v_{Te}^{-1}(u_2v_d-v_0+\omega_1/k)$:

$$\begin{cases}\omega_{1}=\pm\omega_{p1}(1+d_{0}^{-2}k^{-2})^{-1/2};\\[1ex] \gamma=-\sqrt{\dfrac{\pi}{2}}\,\omega_{1}\dfrac{u_{2}v_{d}-v_{0}+\dfrac{\omega_{1}}{k}}{d_{0}^{2}k^{2}v_{Te}(1+d_{0}^{-2}k^{-2})}.\end{cases} \qquad (6b)$$

c) With condition a) and with the inequality opposite b):

$$\begin{cases}\omega_{1}=\pm\omega_{p1}d_{0}k\left[\dfrac{v_{Te}}{2\sqrt{\pi}(u_{2}v_{d}-v_{0})}\right]^{1/2};\\[1ex] \gamma=|\omega_{1}|.\end{cases} \qquad (6c)$$

The condition $|(\omega-kv_0)/kv_{Te}| \ll 1$ can be satisfied in a hot plasma which is essentially at the emitter surface; this case could arise, e.g., in explosive emission[9,10] in vacuum discharges.

When $|(\omega-kv_0)/kv_{Te}| \gg 1$, it follows from (4) that[7]

$$0=1-\frac{\omega_{p1}^{2}}{(\omega-u_{2}v_{d}k)^{2}}-\frac{\omega_{p0}^{2}}{(\omega-u_{2}v_{d}k)^{2}}, \qquad (7)$$

and the problem reduces to the analysis of the two-stream instability.

a) With $|\omega| \gg kv_0$, it follows from (7) that[7]

$$\begin{cases}\operatorname{Re}\omega=u_{2}v_{d}k;\\[1ex] \gamma=\omega_{p1}\left[\left(\dfrac{\omega_{p0}}{u_{2}v_{d}k}\right)^{2}-1\right]^{-1/2},\ \left(\dfrac{\omega_{p0}}{k}>u_{2}v_{d}\right).\end{cases} \qquad (8a)$$

if u_2v_dk is far from ω_{p0}, or

$$\begin{cases} \operatorname{Re}\omega = u_2v_dk - \frac{1}{2}\left(\frac{1}{2}\omega_{p1}^2\omega_{p0}\right)^{1/3}; \\ \gamma = \sqrt{\frac{3}{4}}\left(\frac{1}{2}\omega_{p1}^2\omega_{p0}\right)^{1/3}, \end{cases} \tag{8b}$$

if $u_2v_dk = \omega_{p0}$.

b) If $|\omega| \ll kv_0$, then

$$\begin{cases} \operatorname{Re}\omega = u_2v_dk; \\ \gamma = \omega_{p1}\left[\left(\frac{\omega_{p0}}{kv_0}\right)^2 - 1\right]^{-1/2}, \quad \left(\frac{\omega_{p0}}{k} > v_0\right). \end{cases} \tag{8c}$$

c) The cases $|\omega| \gg u_2v_dk$ and $|\omega| \ll u_2v_d$ reduce to cases a) and b), respectively, with the substitutions $u_2v_dk \rightleftharpoons kv_0$, $\omega_{p0} \rightleftharpoons \omega_{p1}$. The condition $|(\omega - kv_0)/kv_{Te}| \gg 1$ is satisfied if the boundary of the cold plasma is far from the emitter; this condition can be satisfied in gaseous discharges.

An instability in the field-emission electron beam can influence the characteristics of discharges. The beam can give up a large part of its energy in the gas-discharge plasma, thereby heating the plasma electrons. As these electrons are heated, nonlinear processes become more important,[11] and some of the electrons of the field-emission beam can be stochastically accelerated to high energies. This mechanism is apparently responsible for the experimental observation of electrons with energies exceeding the applied voltage in nanosecond vacuum and gaseous discharges.

Optimum dimensions of a coaxial thermionic converter

V. V. Sinyavskii

(Submitted February 12, 1973)
Zh. Tekh. Fiz., 44, 599-605 (March 1974)

The condition for the maximum specific energy is used to obtain simple expressions for the optimum values of the relative length, diameter, and thickness of the emitter shell, of the collector, and of the collector insulation in a coaxial thermionic converter. The optimum values are given in terms of functional dependences on the appropriate similitude criteria. The results calculated from these equations agree with the results of the many-parameter optimization.

The optimum geometric parameters of a thermionic converter cell must be chosen before experimental assemblies are constructed. The most complete answer to this problem comes from the many-parameter optimization, e.g., ref. 1. However, cases are possible in which most of the parameters are known or specified on the basis of external considerations, so that only certain ones can be chosen arbitrarily. In these cases it is necessary to find relations that can be used to choose the free parameters of the optimization.

In this work we use the condition for maximum useful electrical power per unit volume to obtain simple expressions to determine the optimum values of such parameters as the length of the emitter, the diameter of the core, the thickness of the emitter shell, that of the collector, and that of the collector insulation in a coaxial thermionic converter cell.

TARGET FUNCTION

The target function for the optimization of individual parameters of a thermionic cell is taken to be the expression for the specific energy (the useful electrical power per unit volume) written in terms of the electrical and geometric characteristics of a section containing a single cell:[1)]

$$E=\frac{W}{V_{se}}, \qquad (1)$$

where W is the specific energy of the cell and

$$V_{se}=\frac{\sqrt{3}}{2}s^2t \qquad (2)$$

is the volume of the section. The radial and axial dimensions of the section can be determined from

$$s=2(r_0+\delta_E+\Delta_E), \qquad (3)$$

$$t\approx l_E+l_K, \qquad (4)$$

where

$$\Delta_E=L+\delta_C+\delta_I+\delta_{st}+\frac{\delta_t}{2}\cdot \qquad (5)$$

The following equation is derived for W in ref. 1:

$$W=2\pi r_E\left\{\int_0^{l_E} jv\,dz-\frac{r_E}{r_E\delta_E}\int_0^{l_E}\rho_E\left[\int_0^{z} j\,dz\right]^2dz-\frac{r_E}{r_C\delta_C}\int_0^{l_E}\rho_C\left[\int_z^{l_E} j\,dz\right]^2dz\right.$$

$$\left.-\frac{2\pi r_E\rho_K l_K}{S_K}\left[\int_0^{l_E} j\,dz\right]^2-\frac{r_I}{r_E\delta_I}\int_0^{l_E}\frac{\Delta V^2}{\rho_I}dz\right\}, \qquad (6)$$

where the first term in the brackets is the power generated at the electrodes, while the following terms are, respectively, the ohmic losses of electrical power in the emitter, the collector, and the connector and the loss due to current leakage through the collector insulation.

To obtain simple results we consider a simplified equation for E; this follows from (6) under the assumption that the distributions of current density j and the potential difference v are constant along the emitter and that ρ_E, ρ_C, ρ_I, and ΔV are homogeneous:

$$E=\frac{4\pi r_E l_E}{\sqrt{3}\,s^2t}jv\left(A-B_I\frac{r_I}{\delta_I}\right), \qquad (7)$$

where

$$A=1-l_E^2\frac{j}{v}\left(\frac{1}{3}\frac{\rho_E}{\delta_E}+\frac{1}{3}\frac{r_E\rho_C}{r_C\delta_C}+2\pi r_E\frac{l_K\rho_K}{S_K l_E}\right), \qquad (8)$$

$$B_I=\frac{\Delta V^2}{jvr_E\rho_I} \qquad (9)$$

are dimensionless parameters.

From the condition

$$\frac{\partial E}{\partial x_i}=0, \qquad (10)$$

where x_i is the parameter to be optimized, we can find equations for the optimum values of the emitter length l_E^{opt}, the core radius r_E^{opt} (or the emitter radius $r_E^{opt}=r_0^{opt}+\delta_E$), the thickness of the emitter part of the shell δ_E^{opt}, the collector thickness δ_C^{opt}, and the insulation thickness δ_I^{opt}.

To find x_i^{opt} we introduce into target function (7) an equation for the optimum connector cross section, S_K, which is a function of some of the parameters x_i which are to be optimized:

$$S_K^{opt}=2\pi r_E l_E l_K j\sqrt{\frac{\rho_K}{\lambda_K(T_E-T_C)\eta}}. \qquad (11)$$

Then we can rewrite Eq. (8) as

$$A=1-l_E^2\frac{j}{v}\left\{\frac{1}{3}\frac{\rho_E}{\delta_E}+\frac{1}{3}\frac{r_E\rho_C}{r_C\delta_C}+\frac{\sqrt{\rho_K\lambda_K(T_E-T_C)\eta}}{l_E^2j}\right\}. \qquad (12)$$

As a result of the introduction of S_K^{opt} into (7) in the optimization of any of the x_i, the connector cross section S_K takes on the optimum value in accordance with x_i^{opt}.

OPTIMUM VALUES OF THE PARAMETERS

In this section we derive equations for the optimum values of the parameters of a coaxial thermionic cell on the basis of condition (10). Since the leakage current is relatively low, $j_{leak} \ll j$, we neglect the power loss due to the leakage currents in the derivation of all the equations except that for δ_I^{opt}.

Optimum emitter length. The optimum value of the relative length of the emitter, $\tilde{l}_E = l_E/l_K$, is

$$l_E^3 - \frac{2}{3} l_E^2 + \frac{1}{4} B_l = 0, \tag{13}$$

where

$$B_l = \frac{12}{l_K^2 j} \frac{v - \sqrt{\rho_E \lambda_E (T_E - T_C)\eta}}{\frac{\rho_E}{\delta_E} + \frac{r_E}{r_C}\frac{\rho_C}{\delta_C}} \tag{14}$$

is a dimensionless parameter.

For all cases of practical interest (B > 2) the discriminant of the cubic equation is positive and we can write the solution of (13) in the form

$$l_E^{opt} = \frac{1}{2}\left(1 + \sqrt[3]{1 + B_l + \sqrt{B_l^2 - 2B_l}} + \sqrt[3]{1 + B_l - \sqrt{B_l^2 - 2Bl}}\right). \tag{15}$$

When $Bl \geq 10$ Eq. (15) reduces to

$$l_E^{opt} = 1 + \sqrt[3]{\frac{1}{4} B_l}. \tag{16}$$

Optimum emitter radius. For r_0^{opt}, and, correspondingly, r_E^{opt} we find the following equation from condition (10):

$$A\left(1 - \frac{4r_E}{s}\right) + l_E^2 \frac{j}{v}\left(\frac{r_E}{2\delta_E}\frac{\rho_E}{\delta_E}\frac{\rho_E^*}{\rho_0} + \frac{r_E}{r_C}\frac{\Delta_E}{r_C}\frac{\rho_C}{\delta_C}\right) = 0, \tag{17}$$

where A, r_E, r_C, and s are functions of r_0.

When $\rho_E^* \ll \rho_0$ and $\delta_E \ll r_0$ Eq. (17) becomes the simple equation

$$r_E^{opt} = \Delta_E, \tag{18}$$

or for the dimensionless emitter radius $\tilde{r}_E = r_E/s$ we find from (18)

$$\tilde{r}_E^{opt} = \frac{1}{4}. \tag{19}$$

Optimum emitter thickness. From condition (10) we find a cubic equation for the optimum relative thickness of the emitter shell, $\tilde{\delta}_E = \delta_E/l_E$, for the case of a nonconducting core. This equation is conveniently written in the form

$$\left(\tilde{\delta}_E + \frac{b}{3}\right)^3 + p\left(\tilde{\delta}_E + \frac{b}{3}\right) + q = 0, \tag{20}$$

where the dimensionless coefficients

$$\left.\begin{aligned} b &= \frac{r_0 - \Delta_E}{l_E} - 2B_E, \quad p = -\frac{b^2}{3} - 3B_E\frac{r_0}{l_E}, \\ q &= 2\left(\frac{b}{3}\right)^3 + bB_E\frac{r_0}{l_E} - B_E\frac{r_0}{l_E}\left(\frac{r_0 + \Delta_E}{l_E}\right) \end{aligned}\right\} \tag{21}$$

are functions of the dimensionless parameter

$$B_E = \frac{1}{3}\frac{l_E j \rho_E}{v - \frac{1}{3} l_E^2 j \frac{\rho_C}{\delta_C} - \sqrt{\lambda_E \rho_E (T_E - T_C)\eta}}. \tag{22}$$

The solution of Eq. (20) is governed by the sign of the discriminant

$$D = \left(\frac{p}{3}\right)^3 + \left(\frac{q}{2}\right)^2. \tag{23}$$

In the case of a nonconducting core we would usually have D < 0, so we will use trigonometric solution (20). Of the three real positive roots of (20) there is generally only a single positive root for typical parameter values; this root is given by

$$\left.\begin{aligned} \tilde{\delta}_E^{opt} &= 2\sqrt{-p/3}\cos\frac{\alpha}{3} - \frac{b}{3} \quad \text{for} \quad q < 0, \\ \delta_E^{opt} &= 2\sqrt{-p/3}\cos\left(\frac{\pi}{3} - \frac{\alpha}{3}\right) - \frac{b}{3} \quad \text{for} \quad q \geqslant 0, \end{aligned}\right. \tag{24}$$

where α is found from

$$\cos\alpha = \frac{|q|}{2\sqrt{-(p/3)^3}}.$$

The value of $\tilde{\delta}_E^{opt}$ is strongly influenced by the conductivity of the core, which can be taken into account through the effective resistivity of the emitter,

$$\rho_E^* = \frac{\rho_E}{1 + \frac{r_0}{2\delta_E}\frac{\rho_E}{\rho_0}}. \tag{25}$$

Using (25) we again find Eq. (20) from condition (10) for $\tilde{\delta}_E^{opt}$ for the case of a conducting core; however, the coefficients b, p, and q are

$$\left.\begin{aligned} b &= \frac{r_0 - \Delta_E}{l_E} - 2B_E + \frac{r_0}{l_E}\frac{\rho_E}{\rho_0}, \\ p &= -\frac{b^2}{3} - 3B_E\frac{r_0}{l_E} + \frac{r_0}{2l_E}\frac{\rho_E}{\rho_0}\left(2\frac{r_0 - \Delta_E}{l_E} - B_E + \frac{r_0}{2l_E}\frac{\rho_E}{\rho_0}\right), \\ q &= 2\left(\frac{b}{3}\right)^3 - \frac{b}{3}\left[-3B_E\frac{r_0}{l_E} + \frac{r_0}{2l_E}\frac{\rho_E}{\rho_0}\left(2\frac{r_0 - \Delta_E}{l_E} - B_E + \frac{r_0}{2l_E}\frac{\rho_E}{\rho_0}\right)\right] \\ &\quad - B_E\frac{r_0}{l_E}\frac{r_0 + \Delta_E}{l_E} - \frac{r_0}{2l_E}\frac{r_0 - \Delta_E}{l_E}\frac{\rho_E}{\rho_0}\left(B_E - \frac{r_0}{2l_E}\frac{\rho_E}{\rho_0}\right). \end{aligned}\right\} \tag{26}$$

Optimum collector thickness. For optimum relative collector thickness $\tilde{\delta}_C = \delta_C/l_E$ is given by the following expression from condition (10):

$$\tilde{\delta}_C^{opt} = \frac{\rho_C}{6A_C}\left\{1 + \sqrt{1 + \frac{12A_C}{\rho_C l_E}\left(r_E + L + \delta_I + \delta_{st} + \frac{\delta_f}{2}\right)}\right\}. \tag{27}$$

where

$$A_C=\frac{1}{jl_E}\left[4v-\sqrt{\rho_E\lambda_E(T_E-T_C)\eta}\right]-\frac{1}{3}\frac{\rho_E}{\delta_E}l_E. \tag{28}$$

Using

$$\frac{12A_C}{\rho_C l_E}\left(r_E+L+\delta_\mathrm{I}+\delta_\mathrm{st}+\frac{\delta_t}{2}\right)\gg 1,$$

we find

$$\tilde{\delta}_C^{\mathrm{opt}}=\sqrt{\frac{\rho_C l_E}{3A_C}\left(r_E+L+\delta_\mathrm{I}+\delta_\mathrm{st}+\frac{\delta_t}{2}\right)}\approx\sqrt{\frac{\rho_C l_E}{6A_C}s}. \tag{29}$$

If we take

$$\sqrt{\lambda_E\rho_E(T_E-T_C)\eta}\leqslant 0.1\ \mathrm{V},$$

i.e., more than an order of magnitude smaller than 4v, and simultaneously using

$$\frac{4v}{l_E j}\gg\frac{1}{3}l_E\frac{\rho_E}{\delta_E},$$

we conclude that we can write $\tilde{\delta}_\mathrm{C}^{\mathrm{opt}}$ as

$$\tilde{\delta}_C^{\mathrm{opt}}=\frac{1}{2}\sqrt{B_C}, \tag{30}$$

where

$$B_\mathrm{C}=\frac{1}{3}\frac{j}{v}\rho_C\left(r_E+L+\delta_\mathrm{I}+\delta_\mathrm{st}+\frac{\delta_t}{2}\right)\approx\frac{1}{6}\frac{j}{v}\rho_C s \tag{31}$$

is a dimensionless parameter.

OPTIMUM THICKNESS OF THE COLLECTOR INSULATION

The optimum relative thickness of the collector insulation $\tilde{\delta}_\mathrm{I}=\delta_\mathrm{I}/r_\mathrm{I}$ is given by the following equation from condition (10):

$$\tilde{\delta}_\mathrm{I}^{\mathrm{opt}}=\frac{3}{2}\frac{B_\mathrm{I}}{2A+B_\mathrm{I}}\left\{1+\sqrt{1+\frac{2}{9}\frac{2A+B_\mathrm{I}}{B_\mathrm{I}}\left(1+\frac{\delta_\mathrm{st}+\delta_t/2}{r_\mathrm{I}}\right)}\right\}, \tag{32}$$

where the dimensionless parameters A and B_I are given by (8) and (9).

For plausible values of ΔV and ρ_I and $B_\mathrm{I} < 10^{-2}$, we can simplify Eq. (32). If we assume A to be of the order of unity, so that $A/B_\mathrm{I} \gg 1$ and

$$\frac{2}{9}\frac{2A+B_\mathrm{I}}{B_\mathrm{I}}\left(1+\frac{\delta_\mathrm{st}+\delta_t/2}{r_\mathrm{I}}\right)\gg 1,$$

we can rewrite (32) as

$$\tilde{\delta}_\mathrm{I}^{\mathrm{opt}}=\frac{3}{4}\left\{\frac{B_\mathrm{I}}{A}+\frac{2}{3}\sqrt{\frac{B_\mathrm{I}}{A}\left(1+\frac{\delta_\mathrm{st}+\delta_t/2}{r_\mathrm{I}}\right)}\right\} \tag{33}$$

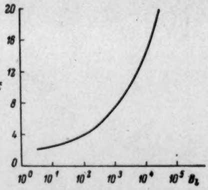

Fig. 1. Optimum relative emitter length $\tilde{l}_\mathrm{E} = l_\mathrm{E}/l_\mathrm{K}$ as a function of the dimensionless parameter B_l.

When $B_\mathrm{I}/A < 10^{-2}$ we can use the condition $[\delta_\mathrm{st} + (\delta_t/2)]/r_\mathrm{I} < 1$ to find a simpler expression for $\tilde{\delta}_\mathrm{I}^{\mathrm{opt}}$ from (33):

$$\tilde{\delta}_\mathrm{I}^{\mathrm{opt}}=\frac{1}{2}A_\mathrm{I}\sqrt{B_\mathrm{I}}, \tag{34}$$

where

$$A_\mathrm{I}=\sqrt{\frac{1}{A}\left(1+\frac{\delta_\mathrm{st}+\delta_t/2}{r_\mathrm{I}}\right)}\approx\sqrt{\frac{s}{2r_\mathrm{I}A}} \tag{35}$$

is a dimensionless coefficient approximately equal to unity.

DISCUSSION

Let us consider certain results of this determination of the optimum values of certain parameters of a thermionic cell and, in particular, the use of these equations.

The optimum relative emitter length $\tilde{l}_\mathrm{E}^{\mathrm{opt}} = l_\mathrm{E}^{\mathrm{opt}}/l_\mathrm{K}$ is governed by the dimensionless parameter B_l alone, which is proportional to the ratio of the useful potential difference to the voltage drop per unit length across the electrodes. Figure 1 shows the relation $\tilde{l}_\mathrm{E}(B_l)$ obtained from (15).

For w = 5 W/cm² and for typical values of the other cell parameters we have $l_\mathrm{E}^{\mathrm{opt}} \approx 3$ cm. As w increases, $l_\mathrm{E}^{\mathrm{opt}}$ decreases. The quantity $l_\mathrm{E}^{\mathrm{opt}}$ is independent of the cell radius and (at constant values of the electrode resistivities) of the other radial dimensions of the cell. Of the geometric parameters, that which has the greatest influence on $l_\mathrm{E}^{\mathrm{opt}}$ is connector length l_K. Figure 2 shows the relative emitter length $\tilde{l}_\mathrm{E}^{\mathrm{opt}}$ and its absolute length $l_\mathrm{E}^{\mathrm{opt}}$

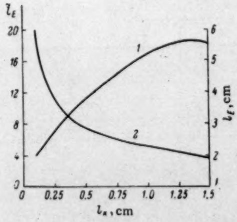

Fig. 2. Effect of the connector length l_K on $\tilde{l}_\mathrm{E}^{\mathrm{opt}}$: 1) l_E; 2) $\tilde{l}_\mathrm{E}$.

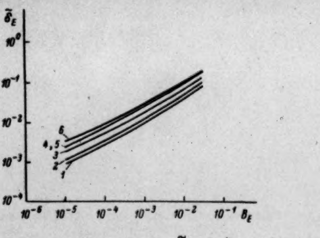

Fig. 3. Optimum relative emitter thickness $\tilde{\delta}_E = \delta_E/l_E$ as a function of the dimensionless parameter B_E. r_0/l_E: 1) 0.5; 2) 0.1; 3, 4) 0.25; 5,6) 0.5. Δ_E/l_E: 1, 2, 3, 5) 0.01; 4,6) 0.1.

as functions of l_K for a typical thermionic converter.

It should be noted that the result found for l_E^{opt} from (15) agrees with the results of the many-parameter optimization.

Equation (18) can be used to determine r_0^{opt} and thus r_E^{opt} (or r_E^{opt} directly); this latter radius corresponds to the maximum emitter surface area per unit volume:

$$F_{sp} = \frac{4\pi r_E l_E}{\sqrt{3}\, s^2 t};$$

condition (18) can be obtained from the condition $F_{sp} \to \max$.

We see from (19) that $\tilde{r}_E^{opt}$ is not explicitly a function of the axial dimensions of the cell, the specific energy, or the resistivities of the electrodes. However, there is an implicit functional dependence if δ_E, δ_C, and δ_I in (18) are assigned their optimum values in accordance with (24), (30), and (34). However, r_E^{opt} cannot always be chosen from (18); in choosing r_E it is necessary to take account of several restrictions associated with strength, criticality, techniques for constructing and assembling the devices, etc. These restrictions usually lead to values of r_E larger than given by (18). Accordingly, (18) and (19) can be recommended only for use in finding certain limiting values of r_E; the final choice of r_E must be based on the restrictions mentioned above.

The optimum relative thickness of the emitter shell, $\tilde{\delta}_E = \delta_E/l_E$, is governed, according to (24), by the dimensionless parameter B_C, which is proportional to the ratio of the voltage drop per unit length at the emitter to the useful potential difference of the cell. Figure 3 shows a typical functional dependence of $\tilde{\delta}_E^{opt}$ of B_E for the case of a nonconducting core.

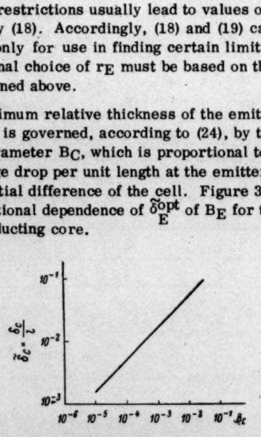

Fig. 4. Optimum relative collector thickness $\tilde{\delta}_C = \delta_C/l_E$ as a function of the dimensionless parameter B_C.

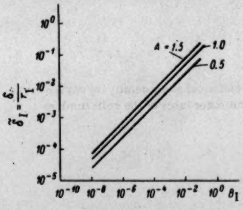

Fig. 5. Relative thickness of the collector insulation $\tilde{\delta}_I = \delta_I/r_I$ as a function of the dimensionless parameter B_I.

As the conductivity of the core is increased, δ_E^{opt} decreases in the limit $\delta_E^{opt} \to 0$, because, as the current flows through the conducting core, and δ_E is reduced, the volume of the section decreases slightly, so the useful electrical power per unit volume increases.

The optimum relative collector thickness $\tilde{\delta}_C^{opt} = \delta_C^{opt}/l_E$ is a function of the dimensionless parameter B_C alone; the functional dependence $\tilde{\delta}_C^{opt}(B_C)$ found from (30) is shown in Fig. 4.

The thickness of the collector insulation δ_I^{opt} in this formulation of the problem, in which δ_I is governed only by the leakage current through the insulation and the radial cell dimension s, is proportional to r_I and $\sqrt{B_I}$. The dimensionless insulation thickness $\tilde{\delta}_I = \delta_I/r_I$ is governed, according to (34), essentially by the dimensionless parameter B_I; physically, this parameter corresponds to the ratio of the leakage power density $w_{le} = j_{le}\Delta V$ at an insulation thickness equal to the emitter thickness, to the power density of the thermionic converter, w = jv. Figure 5 shows the $\tilde{\delta}_I^{opt}(B_I)$ functional dependence. With w = 5 W/cm², ΔV = 30-50 V, and $\rho_I = 10^7$-10^9 Ω·cm, the value of δ_I^{opt} does not exceed a few tens of microns. However, the final choice of δ_I^{opt} can also be influenced by such phenomena as thermal and dielectric breakdown of the insulation or the electrical transport of ions as well as by considerations related to the radiation strength of the insulation and the facility with which the collector assembly can be constructed. Accordingly, the appropriate corrections must be made to the value of δ_I^{opt} found from (34).

CONCLUSION

The equations derived above can be used to find the optimum values of such geometric parameters as the length of the cell, the thickness of the emitter, that of the collector, and that of the collector insulation. The results found for these parameters agree with the results of the many-parameter optimization of the cell,[1] so we can recommend Eqs. (16), (24), (31), and (34) above for determining the optimum geometry of the cell. When it is necessary to optimize several parameters, the latter can also be determined from these equations by the method of successive approximations. In certain cases the optimum values found for certain of the parameters must be corrected on the basis of additional restrictions and requirements.

(Submitted June 4, 1973)
Zh. Tekh. Fiz., 44, 606-611 (March 1974)

An experimental study has been made of the end current in a magnetron with a cold cathode. The volume in which the number of electrons is multiplied by the input microwave signal is determined. There is an azimuthal modulation of the space charge at the period of the slow-wave system. New data are reported on the radial profile of the end current.

In order to understand the operation of M-type devices, it is important to determine the conditions under which the space charge interacts with the rf field of the slow-wave system. It is customary to assume (see, e.g., refs. 1-3) that the general features of the operation of generators and amplifiers with crossed fields can be understood on the basis of an analysis of the interaction of electrons with only the fundamental spatial harmonic of the microwave field. In this case the mechanism for energy transfer by electrons to the microwaves becomes clear. However, several features of the operation of M-type devices cannot be explained on the basis of such a crude specification of the field of the slow-wave system. The azimuthal modulation of the electron and ion bombardment of the cathodes observed in refs. 4 and 5 apparently implies that inhomogeneities of the electric field of the slow-wave system influence the motion of space charge. Malyugin et al.[5] believe that the modulation of the ion current to the cathode must be due to the existence of azimuthal inhomogeneities of the electron cloud, which can observed in a study of the space-charge distribution.

It has been shown[6-8] that information about the space-charge distribution in crossed-field devices can be obtained by analyzing the characteristics of the end current (the flow of electrons parallel to the magnetic field). We report here a study of the distribution of the end current in a magnetron. We have also studied the interaction region by probing with an electron beam directed parallel to the magnetic field. We are primarily interested in the azimuthal inhomogeneities of the space charge under conditions corresponding to intense microwave oscillations.

2. EXPERIMENTAL PROCEDURE AND APPARATUS

The measurements are carried out in pulsed 10-cm magnetrons with cold secondary-emission cathodes of a CuBeAl alloy, triggered by a microwave signal from an auxiliary magnetron.[9] The magnetic field B, parallel to the axis of the device, is produced by two Helmholtz coils, between which the magnetron is placed. The inhomogeneity of the magnetic field in the working region is less than 2%. Pulses of anode voltage U_a, whose repetition frequency f and length τ can be varied over broad ranges, are fed to the cathode of the magnetron with respect to the grounded anode unit. Most of the measurements are carried out at pulse lengths $2 \le \tau \le 10\,\mu$sec. The experimental devices are continuously evacuated; the operating pressure does not exceed 10^{-6} torr.

Figure 1 shows the experimental device. The diameters of the anode 1 and cathode 2 are 16 and 6 mm, respectively. The anode unit is 20 mm high. The end shields usually used to prevent electrons from escaping along the magnetic field are replaced by grids 3 and 4. In the analysis of the end current electrons move from the interaction region to fluorescent shell 5, passing through grids 3, 6, and 7. Fine grid 7, held against the shield surface, is used to prevent the shield from being charged by the electron current. A slow-wave voltage U_{sw}, which can be used to cut off the end current, is applied between the cathode and grid 6, which is 3 mm from end grid 3. In the 3-mm gap between grids 6 and 7, electrons are accelerated by a voltage of U ~ 5-10 kV before they strike the shield. Since the value of eU is considerably higher than any possible initial energy of the electrons emitted from the working region of the magnetron, the glow of the fluorescent shield caused by the electron bombardment reflects the distribution of the end-current density in the plane perpendicular to the axis of the device.[6]

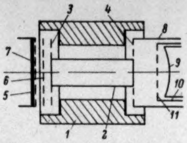

Fig. 1. The experimental magnetron. 1) Anode; 2) cathode; 3,4) end shields; 4,5) fluorescent shield; 6,7) grids; 8) cylinder of cathode mount; 9) cathode of electron gun; 10) guard electrode with grid 11.

To produce the electron beam used to probe the space charge, an electron gun is placed in cathode mount 8. The gun consists of a cathode 9 with an emitting end surface about 15 mm in diameter and a guard electrode 10 with grid 11. A negative bias voltage of $U_b = -400$ V, applied between cathode 9 and grid 11, cuts off the gun until pulse U_s, synchronized with the pulses of the magnetron anode voltage, is fed to the control electrode. The electrons emerging from the gun are accelerated by the pulsed voltage $U_p \sim 8$-16 kV applied between the control electrode and the cathode mount; these pass through grid 4 into the working region of the experimental device. The length of the probing-beam pulses, τ_{pr}, is shorter than τ.

The beam electrons which traverse the magnetron reach the shield if the voltage U_p is greater in magnitude than the retarding voltage U_r. In observation of the glow of the shield induced by the probing beam the end current of electrons from the space charge is cut off by a voltage of $U_r \simeq -2$-3 kV. Accordingly, under all the experimental conditions studied, the inequality $|U_p| > |U_r|$ is satisfied. Grids 3, 4, 6, and 11 have a transparency of 30%, while grid 7 has a transparency of 80%. Special measurements show that the use of grids 3 and 4 instead of solid elec-

trodes has essentially no effect on the operation of the experimental device, whose basic characteristics (the voltage–current characteristic, the functional dependence of the rf output power on the anode voltage, and the spectrum of the rf power) do not differ appreciably from the characteristics of a magnetron with solid end shields.

3. EXPERIMENTAL RESULTS

The changes in the shape of the end-current distribution accompanying a change in the operating conditions of the experimental device are conveniently followed on photographs of the fluorescent shield taken at a constant magnetic field and at various values of the anode voltage. Figure 2 shows photographs taken with B = 0.12 T. Under the condition $U_a \leqslant 3$ kV (Fig. 2a) the shield glows near the anode, apparently because of the existence of space charge, which arises as a result of the secondary-emission multiplication of electrons at the anode surface under the influence of the input microwave signal P_{in}. As U_a is increased electron multiplication begins near the cathode. For example, when $U_a = 4.7$ kV (Fig. 2b), the cathode and anode regions are the brightest objects on the shield. A further increase in the anode voltage is accompanied by a fading of the glow at the anode. Over the range $7.0 \leqslant U_a \leqslant 9.5$ kV the only appreciably bright ring is that near the cathode (Fig. 2c). When U_a reaches 9.5 kV the anode current falls abruptly (Fig. 3), because electrons begin to interact effectively with oscillations of the slow-wave system.

The glow, which becomes appreciable in the region far from the cathode at $U_a > 9.5$ kV, results from the space charge of the electrons emitted by the cathode and moving toward the anode. The glow in the region far from the cathode is azimuthally inhomogeneous (Fig. 2d). As U_a is increased beyond 9.5 kV the anode current behaves nonmonotonically. On the voltage–current characteristic measured at B = 0.12 T we see three peaks, corresponding to different oscillation modes. As the anode voltage is varied over the range $9.5 \leqslant U_a \leqslant 13.1$ kV, there is no qualitative change in the shape of the image on the fluorescent shield; there is only a change in its intensity. Fixed bright features or "spokes" can be distinguished on the shield; the periodicity of their spatial pattern approximately reproduces that of the slow-wave system of the anode unit, which consists of eight resonators (Figs. 2d-2f). Similar changes are observed in the images corresponding to other values of the magnetic field over the entire range studied ($0.1 \leq B \leq 0.14$ T).

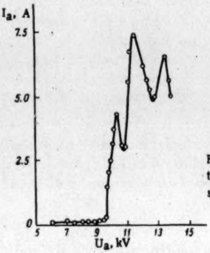

Fig. 3. Voltage–current characteristic of the experimental magnetron measured at a magnetic field of B = 0.12 T.

To obtain quantitative information about the end-current distribution we carry out a photometric study of photographs of the shield, using an MF-4 microphotometer. Figure 4 shows a typical functional dependence of the quantity I (the relative intensity of the light) on the azimuthal coordinate φ. Here, I is the ratio of the negative transparency at the cathode surface I'_k to the value of I' at the given point. In the recording of an $I = I(\varphi)$ curve the values of I were determined at points lying on circles of a given radius r. The characteristic in Fig. 4 is measured at B = 0.12 T, $U_a = 12.8$ kV, and r = 5.5 mm. Analysis of these $I = I(\varphi)$ curves shows that under conditions corresponding to intense microwave oscillations in the interaction region there is a deep azimuthal modulation of the end current, which apparently reflects inhomogeneities in the space charge. The space charge can be modulated by inhomogeneities of both the electrostatic and rf fields due to the "broken" nature of the anode (due to the gaps

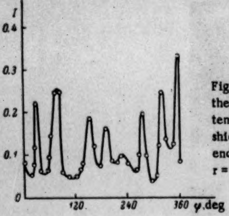

Fig. 4. The $I = I(\varphi)$ characteristic for the azimuthal distribution of the intensity of the glow on the fluorescent shield during its bombardment by the end current. B = 0.12 T, U_a = 12.8 kV, r = 5.5 mm.

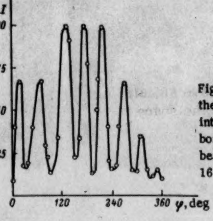

Fig. 6. The $I = I(\varphi)$ characteristic for the azimuthal distribution of the glow intensity on the fluorescent shield in bombardment by the probing electron beam. B = 0.1 T, U_a = 6 kV, U_p = 16 kV, r = 5.5 mm.

and layers of the slow-wave system). The role of these factors in the modulation cannot be evaluated in a study of the characteristics of the end current because the end current exists only when both U_a and the rf power are nonvanishing.

When we probe the magnetron with an electron beam we are also able to observe a modulation of the outer boundary of the beam, at the spatial period of the slow-wave system of the anode unit. Figure 5 shows a photograph of the fluorescent shield in bombardment by the electron beam, taken with B = 0.1 T, U_a = 6 kV, and U_p = 16 kV. When there is an input microwave signal azimuthal inhomogeneities are visible at the outer boundary; these disappear at $P_{in} = 0$. Figure 6 shows the $I = I(\varphi)$ curve obtained by microphotometry of the photograph in Fig. 5 at r = 5.5 mm.

The results obtained with electron probing show that there can be an azimuthal modulation of the space charge under the influence of the microwave field of the slow-wave system.

The data on the azimuthal distribution of the end current agree with information in the literature[5] on the modulation of the ion current to the cathode in an M-type amplifier and, we believe, show that azimuthal inhomogeneities are characteristic of the space charge in both generators and amplifiers with crossed fields operating at a high microwave level.

We record the $I = I(r)$ characteristics for the radial distribution of the glow intensity at fixed values of the coordinate φ. Figure 7 shows the $I = I(r)$ curves obtained near the maximum ($\varphi = 70°$) and the minimum ($\varphi = 120°$) of the $I = I(\varphi)$ curve measured at B = 0.12 T and U_a = 12.8 kV. We see that the light reaches its greatest intensity I_m at the hub of the electron cloud near the cathode. The smooth nature of the $I = I(r)$ curve near the cathode could be due to saturation of the fluorescent shield during bombardment by a dense electron current. As r is increased near the synchronization radius r_s the value of I falls abruptly to the value I_1, which varies slightly over the range $4.5 \leq r \leq 6$–6.5 mm. Near the anode the intensity reaches a maximum.

We can explain some features of these end-current characteristics on the basis of the motion of electrons in the interaction region of the experimental device. The radial component of the electric field causes the electron stream to drift around the axis. The motion of electrons to the anode in a magnetron occurs under the influence of the azimuthal component of the microwave field, which reaches a maximum near the central gap of the resonator. At low microwave amplitudes, the electrons, which are displaced toward the anode near one of the slits, continue to rotate around the cathode, and there is no significant change in their radial position until the neighboring gap is reached. There they are again displaced toward the anode. The process continues until the electrons reach the anode surface. As the microwave intensity is increased, a point is reached at which a large number of the electrons from the region between the boundary of the hub and the anode manage to reach the anode while they are moving near one gap. Under these conditions we would expect a deep modulation of the space charge above the boundary of the hub of the electron cloud.

The maximum of the end current on the $I = I(r)$ characteristics could be a consequence of the high space-charge density near the anode, due to either the existence of an additional emission source at the anode or the incidence on this region of some of the electrons which are not intercepted by the preceding layer.

Fig. 5. Photograph of the image on the fluorescent shield in bombardment by the probing electron beam. B = 0.1 T, U_a = 6 kV, r = 16 kV.

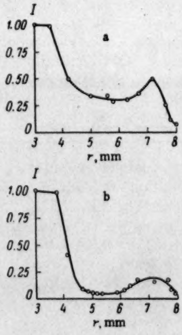

Fig. 7. The $I = I(r)$ characteristics for the radial distribution of the intensity of the glow on the fluorescent shield in bombardment by the end current. B = 0.12 T, U_a = 12.8 kV. a) φ = 70°; b) 120°.

On the basis of this analysis of the end-current characteristics of a cold-cathode magnetron we have thus determined the part of the working region in which secondary-emission multiplication of electrons occurs under the influence of the input microwave signal, we have detected an azimuthal modulation of the space charge at the spatial period of the slow-wave system, and we have obtained new information about the radial distribution of the end current, which can be attributed to the existence of a maximum in the space-charge density near the anode surface as well as near the cathode.

Excitation collisions between magnesium ions and inert gas atoms

V. L. Ovchinnikov, O. B. Shpenik, and I. P. Zapesochnyi

Problems Laboratory for the Physics of Electron Collisions,
Uzhgorod State University

(Submitted March 12, 1973; resubmitted July 10, 1973)
Zh. Tekh. Fiz., 44, 612-616 (March 1974)

Excitation processes are studied in collisions of Mg$^+$ ions with inert gas atoms over the energy range from threshold to 2500 eV and the spectral range 2200-6600 Å. The excitation processes in collisions of Mg$^+$ with He, Ar, Kr, and Xe atoms are different from those in collisions of Mg$^+$ with Ne atoms, because of the different natures of the partners. A "competition" between two energetically close inelastic channels of the reaction Mg$^+$–Ne leads to an oscillation of the total cross sections for excitation of the spectral lines.

There has been comparatively little previous study of excitation processes in ion–atom collisions. The work that has been carried out has been concerned primarily with excitation processes in collisions of alkali metal ions and inert gas ions with inert gas atoms,[1-4] of alkali metal ions with alkali metal atoms, and of alkali metal ions and alkali earth ions with cadmium atoms.[6] Valuable information has been obtained about the probabilities for the reactions to proceed through various channels and about the excitation of the interacting particles.

We report here on a study of excitation processes in low-energy collisions of Mg$^+$ ions with inert gas atoms. These experiments represent the beginning of a systematic study of the excitation of energy levels in collisions of alkali earth ions with He, Ne, Ar, Kr, Xe atoms in the energy range from threshold to 2.5 keV and over a broad spectral range.

The experiments are carried on by an optical method, through detection of the emission of the excited particles produced in the collisions. The experimental apparatus, which is like that described in ref. 6, consists of an ion source with an ion-optics system, a collision chamber with a gas-injection device, the spectral instrument, and a unit for photoelectric detection of the radiation.

The magnesium-ion source, which operates under conditions corresponding to a low-voltage discharge, and the ion-optics system, which includes a 127° cylindrical electrostatic selector and focusing lenses, provide a magnesium-ion current up to 1 μA in the collision chamber with a beam cross section of 1 × 3 mm over the energy range 50-2500 eV. The collision chamber is filled with spectrally pure inert gas from a special glass injection system. The pressure in the chamber is held constant by means of a precision needle valve and is measured by a thermocouple (LT-2) and vacuum gauges (LM-2) (the appropriate corrections are incorporated[7]). The radiation generated during the collisions is directed by a quartz optical system to the entrance slit of a monochromator (ZMR-3 or MDR-2), placed at a right angle with respect to the beam; the radiation is detected at the exit from this system by a photomultiplier (FÉU-18A or FÉU-79). The output signal from the photomultiplier is processed by narrow-band amplification and phase detection. The ion beam (or light flux) is modulated by feeding rectangular blanking pulses to one of the electrodes of the ion-optics system.

The absolute values of the excitation cross sections are determined by a photoelectric comparison of the intensity of the spectral lines excited in the ion–atom collisions with the intensities of reference He and Ne lines excited by electron impact. Account is taken of the spectral sensitivity of the entire detection system. The reference lines are λ 3448, λ 3889, λ 4713, λ 4922 Å He I and λ 3520, λ 5852 Å Ne I, whose effective electron-excitation cross sections have been measured repeatedly.[8,9] This simple method is convenient because it allows us to determine the excitation cross sections in collisions of Mg$^+$ ions with all partners with the same error: 60-80%.

The excitation functions and effective excitation cross sections of the spectral lines are measured under conditions ensuring single collisions: at gas pressures of $7 \cdot 10^{-3}$ torr and below in the collision chamber and at all values of the magnesium-ion beam current achievable. Measures were taken to suppress the production of secondary electrons at the point at which the radiation is detected.

The emission spectrum recorded in the optical range 2200-6600 Å in collisions of Mg$^+$ ions with He, Ar, Kr, and Xe atoms consists of the Mg I and Mg II lines alone. The spectrum for Mg$^+$–Ne collisions is more complicated: In addition to the Mg I and Mg II lines there are lines of neon atoms and ions (Ne I and Ne II). The most intense are the spectral lines of Mg II: the resonant doublet at λλ 2795, 2803 Å and the lines from the first excited S and F levels at λλ 2928, 2936 Å, and λ 4481 Å, respectively. The resonant line λ 2852 Å and the triplet lines λλ 5167, 5173, 5184 Å and λλ 3829, 3832, 3838 Å are excited in the Mg I spectrum. The Mg$^+$–Ne collisions reveal certain Ne I lines which are emitted in transitions between $2s^22p^53s$ and $2s^22p^53p$ electronic configurations: λλ 5852, 6143, 6402, 6506 Å. There are also Ne II lines: λ 3547 and λ 3237 Å.

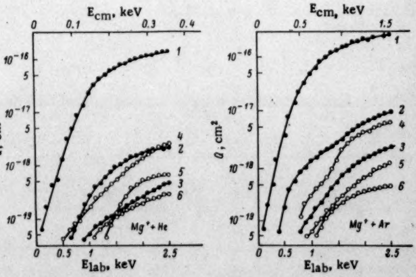

Fig. 1. Cross sections for the excitation of spectral lines in Mg$^+$ –He and Mg$^+$–Ar collisions as functions of the energy. 1) λλ 2795; 2803 Å Mg II; 2) λλ 2928, 2936 Å Mg II; 3) λ 4481 Å Mg II; 4) λ 2852 Å Mg I; 5) λλ 3829, 3832, 2828 Å Mg I; 6) λλ 5167, 5173, 5184 Å Mg I.

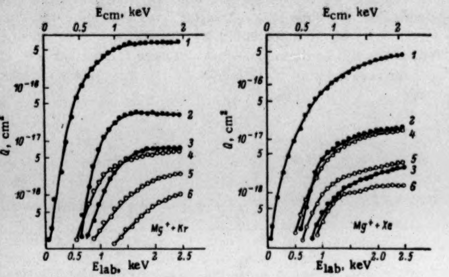

Fig. 2. Excitation cross sections for the spectral lines in Mg⁺−Kr and Mg⁺−Xe collisions as functions of the energy. 1) λλ 2795, 2803 Å Mg II; 2) λλ 2928, 2936 Å Mg II; 3) λ 4481 Å Mg II; 4) λ 2852 Å Mg I; 5) λλ 3829, 3832, 3838 Å Mg I; 6) λλ 5167, 5173, 5184 Å Mg I.

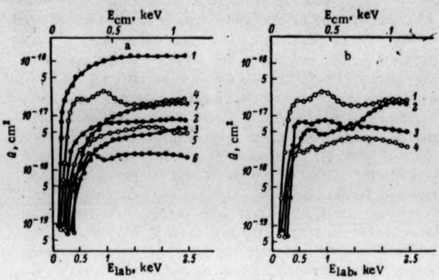

Fig. 3. Excitation cross sections for the spectral lines in Mg⁺−Ne collisions as a function of the energy. a: 1) λλ 2795, 2803 Å Mg II; 2) λλ 2928, 2936 Å Mg II; 3) λ 4481 Å Mg II; 4) λ 2852 Å Mg I; 5) λλ 2795/32/38 Å Mg I; 6) λ 6506 Å Ne I; 7) λ 3237 Å Ne II. b: 1) λ 2852 Å Mg I; 2) λ 5852 Å Ne, I; 3) photoexcitation cross section for the lines λ 6143, λ 6506, λ 6402 Å Ne I; 4) λλ 5167, 5173, 5184 Å Mg I.

We have studied the excitation functions and measured the effective excitation cross sections of all these spectral lines; the results are shown in Figs. 1-3. These results are obtained by averaging over the results of at least five separate measurements. The excitation functions for essentially all lines observed in Mg^+-He, Mg^+-Ar, Mg^+-Kr, and Mg^+-Xe collisions (Figs. 1 and 2) are monotonically increasing curves having indistinct experimental thresholds far above the kinematic thresholds (by a factor of from 2 to 30). There is a tendency for the excitation cross sections to increase from He to Ar, Kr, and Xe. For the Mg^+-Ne reaction there is a clearly defined threshold with a rapid increase in the cross sections near the threshold and a high efficiency for charge exchange of Mg^+ ions into excited states. Furthermore, the excitation curves for several of the lines display an oscillatory structure (Fig. 3).

It is difficult to analyze unambiguously these results, lacking information of any type about the levels of the quasimolecule formed by the Mg^+ ion and the inert gas atom during the collision. Nevertheless, a qualitative interpretation can be based on the ratios of the energy balances for the excitation of the particles in collision of these partners. This approach is equivalent to analyzing the position of the quasimolecule levels at infinite separation of the nuclei. We say that the "ground level" is that of the Mg^+A quasimolecule (where A represents an inert gas atom) and the "excited levels" are those of $Mg^{+*}A$, Mg^*A^+, Mg^+A^*, etc. Each of these symbols actually represents a group of levels corresponding to excitation to various states of the starred particle.

Since the $Mg^{+*}(3^2P_{1/2,\ 3/2})$ level is the lowest-lying level for any A, it must be excited most efficiently. It is therefore completely plausible to find the effective cross section for the resonant doublet Mg II (λλ 2795/2803 Å) to be the highest in all the gases. A gradual decrease in the energy of the Mg^*A^+ levels from He to Xe should lead to an increase in the excitation efficiency of the Mg I lines, in agreement with experiment. We can apparently attribute the absence from the emission spectrum (except for that corresponding to Mg^+-Ne collisions) of lines corresponding to the target atom to the circumstance that the Mg^+A^* levels accessible to study are the highest-lying of the excited levels of the quasimolecule, so their population is energetically the least favorable.[1)]

The monotonic nature of the excitation functions for Mg^+-He, Ar, Kr, and Xe collisions and the pronounced "retardation" of the experimental thresholds in comparison with the kinematic thresholds apparently indicate a "quasiadiabatic" nature of the interaction of these partners. Analysis of the results shows that most of the curves can be described between the threshold and 2-2.5 keV by[10]

$$Q(v) = K \exp - \frac{l \Delta E}{4\hbar v},$$

where K is a constant which is a function of the nature of the process, ħ is Planck's constant, l is the interaction radius of the particles for the "adiabatic parameter," ΔE is the energy defect of the process, and v is the velocity of the incident ion.

For example, for Mg^+-Xe collisions and for the λλ 2795, 2803 Å Mg II lines we have $\Delta El = 11.3$ eV · Å and $K = 10^{-14}$ cm²; for Mg^+-Ar, for the λλ 2928, 2936 Å lines we have $\Delta El = 14.4$ eV · Å and $K = 4.8 \cdot 10^{-16}$ cm²; and for Mg^+-He, for the λλ 5167, 5173, 5184 Å Mg I lines we have $\Delta El = 137$ eV · Å and $K = -1.3 \cdot 10^{-17}$ cm². We can assume that in this case the population of the excited levels near the threshold appears by means of tunnel transitions.[11] The pronounced discrepancy between the experimental and theoretical excitation thresholds is evidently due to the low probability for tunneling, as a consequence of which the excitation cross sections for levels near the threshold are vanishingly small, while the thresholds we have detected are governed by the sensitivity of the detection system. We see from Figs. 1-3 that the experimental excitation thresholds for all lines are governed by the energies at which the effective cross sections reach values of the order of (3-5) · 10^{-21} cm².

Excitation in collisions of Mg^+ ions with neon atoms is apparently due to a completely different interaction between the colliding particles. The clearly defined experimental thresholds and the rapid increase in intensity near the threshold indicate that in this case we are dealing with a Landau–Zener mechanism for population of the excited levels. This circumstance is also apparently responsible for the effective population of various excited levels: $Mg^{+*}Ne$, $Mg^{+}Ne^{*}$, and $Mg^{+}Ne^{+*}$, especially $Mg^{*}Ne^{+}$. The oscillatory structure of the excitation functions for certain lines (Fig. 3) could be a consequence of the interaction of energetically close excited levels of $Mg^{*}Ne^{+}$ and $Mg^{+}Ne^{*}$ (ref. 2). Such an interaction apparently occurs between the $Mg^{*}(3^1P_1)\,Ne^{+}$ level and the group of nearby $Mg^{+}Ne^{*}$ levels ($2p^5 3p\, ^3D_3$, $^3D_2{}^1$, D_2) and between the $Mg^{*}(4^3S_1)\,Ne^{+}$ and $Mg^{+}Ne^{*}$ ($2p^5 3p\, ^1S_0$) levels. The energy differences between the positions of these levels at infinity are 0.29–0.37 and 0.07 eV, respectively. This hypothesis is supported by the observation that the excitation functions for the spectral lines from these levels oscillate out of phase; their excitation cross sections are approximately equal (see Fig. 3b, curves 1 and 3 and curves 2 and 4). On the other hand, the spectral lines from energetically isolated levels do not exhibit such a structure (curves 1–3, 5, 7 in Fig. 3a).

We note in conclusion that the existence of two or more energetically close levels of a quasimolecule at infinite separation of the nuclei is not, however, a sufficient condition for the appearance of oscillations in the total cross sections, as can be seen from our results. For example, there are many such excited levels of the quasimolecules $Mg^{+}-He$, $Mg^{+}-Ar$, $Mg^{+}-Kr$, and $Mg^{+}-Xe$, but we do not observe oscillations of the corresponding excitation functions (Figs. 1 and 2). All this indicates the complexity of the mechanism for the interaction for heavy particles and again emphasizes the need for further experimental study of collisions with a wider variety of partners.

---

[1] We have not studied the most intense resonant lines of the inert gas atoms because of the limited spectral range.

Surface-ionization determination of the electron affinities of silver and gold

É. Ya. Zandberg, A. G. Kamenev,

and V. I. Paleev

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 44, 617-624 (March 1974)

A surface-ionization method is used to find the electron affinity S, based on a comparison of the temperature dependences of the thermionic and negative-ion currents from inhomogeneous emitters (absolute method). The sources of systematic error in the determination of S by this method, due to either assumptions incorporated in the method itself or secondary processes involving the formation of negative ions which accompany surface ionization, are discussed. The values of S for silver and gold determined by the absolute method are S(Ag) = 1.38 ± 0.10 V and S(Au) = 2.34 ± 0.10 V.

The photodetachment of electrons from negative ions (PD) has recently been used to determine the electron affinities of several elements: gold and platinum, from the threshold energy of the photons, and copper and silver, from an analysis of the energy spectra of the detached electrons.[1-3] The values found for S(Cu, Ag, Au) are significantly lower than the values found previously by surface-ionization (SI) methods.[4-6] The results are compared in Table 1.

In principle, the optical methods for determining S are more accurate than the SI methods. However, the discrepancies between the values of S determined by the PD and SI methods exceed the stated experimental errors. In an effort to explain these discrepancies, Hotop[2] has suggested that the thermodynamic equilibrium between the emitter and the adsorbed film of particles to be ionized (which is a necessary condition for the use of the SI methods) is in fact not established, that the method of determining the difference[4] $S_x - S_0$ is not valid in those cases in which the negative-ion currents are compared for elements differing markedly in chemical properties, and that the polycrystalline nature of the emitters used in the SI method plays an important role.

If the arguments of ref. 2 are valid, the SI methods used to determine the values of S for many elements are not suitable for this purpose. We have therefore analyzed the errors incorporated in the method by which S is determined by means of surface ionization, analyzed possible experimental errors, and carried out new measurements of S(Ag, Au) by an absolute SI method.

ANALYSIS OF THE ABSOLUTE METHOD FOR DETERMINING S WHEN POLYCRYSTALLINE EMITTERS ARE USED

The absolute method for determining S is based on a comparison of the temperature dependences of the thermionic and negative-ion currents from a given part of the emitting surface.[8]

According to the Saha–Langmuir equation, the negative-ion current in ionization of atoms on homogeneous metals under ordinary conditions $e(\varphi - S) \gg kT$ is[8]

$$I_n = \frac{1-R_-}{1-R_0} A_- s e \nu \exp\left[\frac{e(S - \varphi + \sqrt{e\mathcal{E}})}{kT}\right]; \qquad (1)$$

where R_- and R_0 are the reflection coefficients for negative ions and neutrals, respectively. at the potential barrier at the emitter surface; A_- is the ratio of statistical sums corresponding to negative-ion states, Q_-, to those corresponding to neutrals, Q_0; s is the emitting surface area; e is the ion charge; ν is the number of ionizable atoms per square centimeter of emitter surface area per second; T is the temperature; φ is the emitter work function; $\mathcal{E}$ is the electric field at the emitter surface; and k is the Boltzmann constant.

We assume that there is no question regarding the applicability of the Saha–Langmuir equation in determining the electron affinity S of atoms in the case in which the emitters are metallic: The values of S for several elements (Cl, Br, I, F, S, and H), including some chemically active elements, that have been found by SI methods agree with the more accurate values found by PD methods.[8] The applicability of SI methods in determinations of atomic ionization potentials V has been demonstrated: The values of V found by SI methods, even for rare-earth atoms, have been verified by spectroscopic determinations.[8] Finally, studies of the energy distribution of atomic ions yield direct information about the establishment of a thermal equilibrium between adsorbed atoms and metallic emitters.[7,8]

All the surface-ionization experiments which have been carried out show that the ratios $(1-R_+)/(1-R_0)$ and $(1-R_-)/(1-R_0)$ are approximately equal to unity and are independent of T. For the case of Ag and Au atoms on a tungsten surface it has been shown experimentally[9] that $R_0 = 0$. In principle, the coefficients R_+ and R_- must be smaller than R_0, because of the effects of image forces in the case of charged particles.[10] Accordingly, $R_- = 0$ for Ag and Au, so that Eq. (1) is simplified.

The thermionic current from a homogeneous emitter is given by the Richardson–Dushman equation:

$$I_e = A_0 T^2 (1 - \overline{R}_e) s \exp\left[\frac{-e(\varphi - \sqrt{e\mathcal{E}})}{kT}\right], \qquad (2)$$

where $A_0 = 120$ A/(cm^2 · deg^2) is a universal constant, and $\overline{R}_e$ is the coefficient for the reflection of thermionic electrons from the emitter surface averaged over the initial velocities. This reflection coefficient is a function of T.

When $R_- = R_0 = 0$, and in the approximation in which the values of $\overline{R}_e$ and the statistical-sum ratios A_- are independent of T, we find the equation usually used to determine S:

TABLE 1

No.	Element	S, V	Ref.	Measurement method
1	Cu	1.5±0.5	[4]	SI. Comparison of the negative-ion currents of two elements. The difference S(I) - S(Cu) is measured; it is assumed that S(I) = 3.07 V
2	Cu	1.78±0.16	[5]	SI. Comparison of the currents of positive and negative ions of two elements. The difference S(Cu) − S(Ag) is measured; it is assumed that S(Ag) = 1.90 ± 0.15 V
3	Cu	1.226±0.010	[1, 2]	PD. Determination from the electron energy spectrum
4	Ag	2.0±0.2	[4]	SI as in No. 1
5	Ag	1.90±0.15	[6]	SI. The negative-ion current is compared with the thermionic current
6	Ag	1.303±0.010	[1, 2]	PD. Determination from the electron energy spectrum
7	Au	2.8±0.1	[4]	SI as in No. 1
8	Au	2.3086±0.0007	[1, 3]	PD. Determination from the threshold photon energy

$$S = -\frac{k}{e}\frac{d}{d\left(\frac{1}{T}\right)}\left(\ln\frac{I_e}{I_n T^2}\right). \qquad (3)$$

However, the value A_- can be a function of T, since $Q_- = f(T)$ and $Q_0 = f(T)$. The only excited levels E of ions and atoms which are pertinent for surface ionization are those whose energies are comparable to kT, since the excitation source is simply the thermal energy of the emitter. The excited levels of neutrals and positive atomic ions are known accurately[11,12] and can always be taken into account (for Cu, Ag, and Au atoms there are no levels having energies near kT, and for these elements the values of Q_0 are independent of T). Whether levels having $E \approx kT$ exist for negative ions is usually not known. If they do exist, neglect of the functional dependence $Q_-(T)$ must lead to a measured value S' which is lower than the actual value S: Since $Q_-(T)$ increase with increasing T, we find from Eqs. (1) and (2) that

$$-\frac{k}{e}\frac{d}{d\left(\frac{1}{T}\right)}\ln\frac{I_e}{I_n T^2} = S - \Delta = S', \qquad (4)$$

where Δ is a positive quantity.

According to refs. 1-3, there are no excited levels near kT for the Au^- and Ag^- ions.

If the emitter is polycrystalline and consists of a set of areas s_i having work functions φ_i, we have the following equations under ordinary conditions $e(\varphi_{i\,\min} - S) \gg kT$, i.e., when the contact fields of the spots are compensated by the external field $\mathcal{E}$ at the emitter surface:

$$I_n = A_- e\nu \exp\left[\frac{e\left(S + \sqrt{e\mathcal{E}}\right)}{kT}\right]\sum_i s_i \exp\left(-\frac{e\varphi_i}{kT}\right), \qquad (5)$$

$$I_e = A_0 T^2 \exp\left[\frac{e\sqrt{e\mathcal{E}}}{kT}\right]\sum_i s_i\left(1 - \bar{R}_{ie}\right)\exp\left(-\frac{e\varphi_i}{kT}\right). \qquad (6)$$

It follows from Eqs. (5) and (6) that with $\bar{R}_{ie} = \bar{R}_e$ and $\bar{R}_e$ independent of T over the appropriate temperature range Eq. (3) can be used to determine S even in the case of polycrystalline emitters. Whether the conditions $\bar{R}_i = \bar{R}_e$ and $\bar{R}_e(T) = \text{const}$ hold can be determined by determining S from Eq. (3) for some element for which the value of S is well-known, e.g., for iodine.

In Eq. (3) it is assumed that the flux of ionizable particles, ν, is not affected by a change in the emitter temperature. If the vapor of the element contains molecules in addition to atoms, the condition $\nu(T) = \text{const}$ is not satisfied if the degree of molecular dissociation at the emitter is smaller than unity and is a significant function of the emitter temperature. In this case the electron affinities determined from Eq. (3) for elements whose vapor contains molecules are actually certain values S' lower than the actual values S.

Accordingly, even in the case of homogeneous and polycrystalline emitters, a determination of S by an absolute SI method can lead to values S' which are too low. Accordingly, if the SI method yields values S' > S, the fault lies not with assumptions incorporated in the SI method itself, but with systematic experimental errors. In an effort to ascertain these errors we have used an absolute SI method to determine S(Ag, Au).

DETERMINATION OF S(Ag, Au) BY AN ABSOLUTE SI METHOD

a. Apparatus. A metal spectrometer with a water-cooled ion-source chamber is used.[12] The resolution at half-height of the lines is ~ 150.

Figure 1 shows the arrangement of the ion source. The emitter is a polycrystalline wire 1 of W or Mo, 200 μ

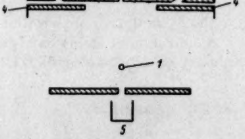

Fig. 1. Arrangement of the ion source and the thermionic-electron collectors.

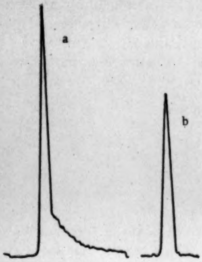

Fig. 2. Shape of the I$^-$ lines in ionization of KI on a tungsten wire. T, °K: a) 2450; b) 2150.

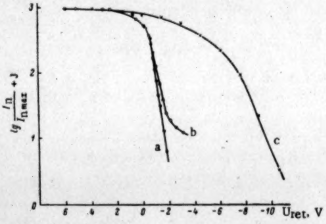

Fig. 3. Retardation curves for I$^-$ ions. a) Ions formed by SI(T = 2150°K); b) total flux of ions due to SI and conversion (T = 2450°K); c) conversion ions distinguished from the total current at T = 2450°K. The absolute values of the maximum conversion current constitute a few percent of the maximum total current.

in diameter. The wire is held in a fixed position with respect to the entrance slit of the mass analyzer at all temperatures by means of a weight system for suspending the wires and holding them under tension. The gold or silver is placed in molybdenum ampoules 3 with external heating jackets enclosed in heat shields. The atomic fluxes from the evaporators can be cut off by baffles 4.

The thermionic electrons are collected by collectors 5-7 (collector 7 can be placed in the position of one of the evaporators, while movable collector 6 can be removed). Electron collector 6 should be used to measure the values of I_e from the same part of the wire as that from which the ion current is drawn. However, simultaneous measurements of I_e at the three collectors (5-7) showed that the Richardson work function φ_R^* has the same value when any of these collectors is used. Operation of the evaporator does not affect the value of φ_R^* found through the use of any of these collectors. This result indicates that the wires have only a slight coverage of ionizable atoms at the flux densities used. Since the same values of φ_R^* are found when any of the three collectors is used, the grain size on the polycrystalline wires used is small in comparison with the size of the surface region from which the thermionic electrons are collected. This circumstance was not checked in previous measurements[6] of S(Ag) by an absolute method involving the use of thermionic collector 7 (Fig. 1).

The pressure of residual gas and vapor is ~ $5 \cdot 10^{-7}$ torr under working conditions.

The wire temperature is measured by an optical micropyrometer; account is taken of the light absorption in the glass port. The temperature of the tungsten wires is varied over the range 2450-2100°K, and that of the molybdenum wires is varied over the range 2200-1850°K.

The potential differences accelerating the ions and electrons are 800-1000 V, corresponding to fields $\mathscr{E} \approx 10^4$ V/cm at the wire surface. This field is sufficient to compensate for the contact fields of the spots and to produce a saturation current; these fields $\mathscr{E}$ are considerably weaker than those which would cause field emission.

The ion collector is an open-type ion-electron multiplier, operated in the circuit of ref. 13 and having a gain of ~ $1 \cdot 10^4$. The sensitivity of the collector of the mass analyzer in a measurement of the ion current is ~ $1 \cdot 10^{-17}$ A/div of the scale of the indicating device. A plane energy-analyzing grid is placed in front of the ion collector; this analyzer gives the ion distribution with respect to the normal component of the initial translational velocity (the ion retardation curves[8]).

b. Measurements of S of iodine. To test the assumptions used in the derivation of Eq. (3) and to determine the accuracy with which the values of S are determined by the absolute SI method we have studied iodine, for which approximately equal values have been found for the electron affinity in experiments by different methods: S(I) = 3.063 ± 0.003 V (ref. 14), S(I) = 3.076 ± 0.005 V (refs. 15, 16), and S (I) = 3.04 ± 0.05 V (ref. 17). Furthermore, iodine is used as a reference element in ref. 4 in the determinations of S(Cu, Ag, Au).

The I atoms are produced by placing the salt KI in ampoule 3 (Fig. 1), as in ref. 4; the molecules of this salt dissociate completely on clean W or Mo surfaces.[8] At the selected flux of molecules from the evaporator, ν, the values of φ_R^* do not change when any of the thermionic-electron collectors are used to measure I_e.

The I$^-$ lines recorded for various values of T of the tungsten and molybdenum wires show that at high T the lines have tails on the high-mass side. Figure 2 shows the shape of the I$^+$ lines at two temperatures, while Fig. 3 shows the retardation curves for the I$^-$ ions. Figures 2 and 3 show that the I$^-$ lines at high T are composite, i.e., they are formed not only by ions resulting from surface ionization, but also by ions resulting from the conversion

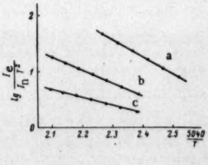

Fig. 4. The function log (I_e/I_nT^2) = f(5040/T) for I(a), Au(b), and Ag(c).

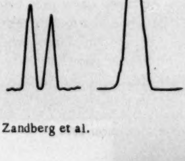

Fig. 5. Shape of the isotopic lines of Ag (a) and Au (b) at T = 2450°K.

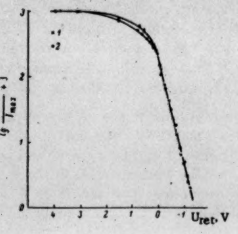

Fig. 6. Superimposed retardation curves for Ag^+ ions (1) and Ag^- ions (2) at T = 2200°K.

of positive I^+ ions into negative I^- ions at the emitter surface. The I^+ ions are produced during the ionization of I atoms in the volume between the emitter and accelerating electrode 2 (Fig. 1) by thermionic electrons which are accelerated by the field. The mechanism for the formation of conversion ions was discussed in ref. 18, and the distortions which they cause in the mass spectra of negative ions in the case of a surface-ionization ion source have been discussed in ref. 19. The results of this group of experiments show that the conversion-ion currents become appreciable at tungsten-wire temperatures $T \gtrsim 2250$°K and at molybdenum-wire temperatures $T \gtrsim 2050$°K. Accordingly, we have measured the values of S(I) at values of T for which there is essentially no conversion current. Operation at lower emitter temperatures also significantly reduces the I^- background current and thereby improves the accuracy with which S(I) is determined (the background current of I^- ions, measured when the flow of KI molecules is cut off, can be different when this flow is turned on, and the difference can increase with the emitter temperature).

Figure 4a shows a typical curve of the functional dependences

$$\lg\left(\frac{I_e}{I_n T^2}\right) = f\left(\frac{5040}{T}\right)$$

obtained for iodine. From many series of determinations of S(I) from such curves, using tungsten and molybdenum wires, we find S(I) = 3.08 ± 0.07 V, where the error is the rms error. From the good agreement of these values with those found[14-16] by PD methods we conclude that the systematic errors due to the use of polycrystalline emitters and the assumptions of the method do not exceed a few hundredths of a volt. The SI method has a larger random error than the PD method, primarily because of its greater sensitivity to the error in the determination of the emitter temperature.

c. Measurements of S(Ag, Au). Studies of the shape of the Ag^- and Au^- lines in the mass spectra at various emitter temperatures show that these lines do not contain conversion ions, nor are there measurable background Ag^- or Au^- currents. The reason lies in the circumstance that the vapor pressures of these elements are lower than that of I in a system with identical emitter temperatures. Figure 5 shows typical Ag^- and Au^- lines, while Fig. 6 shows the superposition of the retardation curves for the Ag^- and Ag^+ ions. The equal slopes of the linear regions of these retardation curves, which imply an identical ion temperature, and the approximate equality of this temperature to the emitter temperatures constitute evidence that the Ag^- ions, like the Ag^+ ions, are formed by surface ionization.

Typical functional dependences

$$\lg\left(\frac{I_e}{I_n T^2}\right) = f\left(\frac{5040}{T}\right)$$

for Ag and Au are shown in Fig. 4.

Repeated determinations of S(Ag, Au) on various W and Mo wires revealed S(Ag) = 1.38 ± 0.10 V and S(Au) = 2.34 ± 0.10 V, where the error is the rms error. These values agree well with those found by the PD methods (Table 1), but the errors are larger.

CONCLUSION

These measurements of S for I, Ag, and Au show that SI methods give the correct values of S for these elements, but special experiments must be carried out to determine the mechanism for the formation of the negative ions which are detected. Such determinations were carried out in ref. 7 but not in earlier experiments.[4,6]

If we make the natural assumption that in the comparison of the currents of Cu^-, Ag^-, and Au^- ions with the current of I^- ions in ref. 4 some of the I^- ions were of conversion origin, we find an explanation for the high values of S(Cu, Ag, Au) found in ref. 4 and the correct values of the differences S(Ag) − S(Au), etc. [The I^- conversion current contribution to the total I^- current leads to values S'(I) which are lower than the actual values S(I).] Accordingly, the errors in the differences S(I) − S(Ag, Au, Cu) are apparently not due to differences in the chemical properties of elements of groups I and VII, as was suggested in refs. 2 and 3.

Differences in the chemical properties of elements can play a role in the determination of S by methods in which the SI currents are compared only if these elements react with the emitter at a rate which is a function of the emitter temperature or if the atoms of these elements diffuse into the interior of the emitter and have different activation energies for diffusion. In such cases a change in T will change the resultant flux density of ionizable particles to the emitter surface. Reactions between the ionizable atoms on the emitter surface can be neglected because of the low surface coverage under these experimental conditions. Some information about the coverage of the emitter surface comes from the value of its work function; thus, in a determination of S it is desirable to monitor the work function, even though it does not appear in the equation from which S is determined.

These measurements of S(Ag) and S(Au) have shown, in complete agreement with the theory for surface ionization of atoms on polycrystalline emitters,[8] that the inhomogeneity of the emitter with respect to the work function due to its polycrystalline nature has essentially no effect on the measured values of S.

For small values of S all the SI methods require high densities of particle fluxes; in this case the secondary

TABLE 2

Element X	$S(Ag) - S(X)$, V	Ref.	$S(X)$, V
Si	0.06±0.02	[7]	1.24±0.02
Ge	0.16±0.03		1.14±0.03
Sn	0.14±0.06	[6]	1.16±0.06
Pb	0.25±0.08		1.05±0.08
Sb	0.40±0.07	[6]	0.90±0.07
Bi	0.14±0.06		1.16±0.06
Cu	0.12±0.06	[5]	1.18±0.06

processes affecting the measured values of S become more important. Surface-ionization methods can apparently be used at $S \ngtr 1$ V. In this case the method of a twofold comparison of the currents of positive ions[6] is less sensitive to experimental conditions than is the absolute method or the method in which the functional dependences of the negative-ion currents of two elements are compared.

In conclusion we list in Table 2 the differences S(Ag) − S(X) measured by the twofold comparison method[6] for the atoms of seven elements X (refs. 5-7) and the values of S(X) calculated on the basis of the value of S(Ag) = 1.30 ± 0.01 V from refs. 1, 2, rounded to the nearest hundredth of a volt.

The value S(Cu) = 1.18 ± 0.06 V agrees well with the value S(Cu) = 1.226 ± 0.010 V obtained by the PD method,[1,2] and the value S(Si) = 1.24 ± 0.02 V is approximately equal to the value determined for this quantity by the PD method in ref. 20. The values of S have not yet been determined by the PD method for the other methods in Table 2.

The authors thank N. I. Ionov for discussion.

Effect of ion microfields on emission of an arc cathode

A. M. Dorodnov, V. B. Davydov, A. V. Kozyrev, and Ya. A. Pomelov
N. E. Bauman Moscow Technical College

(Submitted June 19, 1973)
Zh. Tekh. Fiz., 44, 625-631 (March 1974)

A refined model is proposed for the cathode fall on the basis of the individual-zone method. This refinement treats the effect of the microfields of individual ions on the emission characteristics of an arc cathode. Calculations using this model give the additional emission of electrons per individual ion as a function of the parameters of the cathode surface.

In explaining the experimental current densities of arc cathodes and in constructing theoretical models for such cathodes[1,2] it is usually assumed that the emission of electrons from the cathode obeys the Richardson–Schottky law and that the electric field at the cathode surface is given by the McKeown equation. However, study of thermionic tungsten cathodes at low pressures has shown[3,4] that under these conditions the emission is anomalous and does not satisfy the traditional model. A significantly anomalous emission has also been observed from graphite cathodes, even at atmospheric pressure.[5]

One promising approach to improving the classical emission equations in the presence of plasma is to take account of the microfields of individual ions.

In general, the field at the cathode calculated from the Poisson equation through the McKeown equation, E_k, cannot be used in the equations for thermionic, field, and thermionic-field emission, because this procedure only gives the average field: Because of the microfields of ions, the local field at the cathode, E, can differ considerably from E_k. Since the current density j_e in all the emission equations is an exponential function of the field, the contribution of stronger fields turns out to be larger, thereby increasing the emission current. This effect is particularly pronounced when $E \gg E_k$. Accordingly, the averaging must be carried out, not over the field, but over the current, and the nature of the change in the local field at the cathode must be taken into account.

Two basic methods have been proposed to solve this problem.

1. First, there is the statistical approach, first developed by Ecker and Müller.[6]

In this method, the ions in the cathode sheath are assumed to be stochastically independent and Markovian chains are used to calculate the probability density W(E) for the existence of a field E at a given point on the cathode. Then the emission equation is averaged over this probability density:

$$j_e = \int_0^\infty j(E)\, W(E)\, dE. \tag{1}$$

This approach has been applied to the Fowler–Nordheim law for field emission;[6] the result is a significant increase in the emission current (an order of magnitude).

Second, there is the method of individual zones. In this method, some "average" ion is chosen, and the additional charge emitted from the cathode in an individual zone during the transit of the ion through this zone, Q_e, is determined.

The choice of an "average ion" is equivalent to averaging the additional contribution from each ion to the cathode emission, $Q_e(\mathbf{v}, \mathbf{r})$, over the ion distribution function at the cathode surface, $f_i(\mathbf{v}, \mathbf{r})$:

$$\bar{Q}_e = \frac{1}{n_i} \int\limits_{(\mathbf{r})} \int\limits_{(\mathbf{v})} Q_e(\mathbf{v}, \mathbf{r})\, f_i(\mathbf{v}, \mathbf{r})\, d\mathbf{r}\, d\mathbf{v}. \tag{2}$$

In Eq. (2) the integration is carried out over μ space.

By assuming a monoenergetic ion flux through the cathode we can evaluate integral (2). In this case the ion distribution function is represented by a δ function, whose normalized form is

$$f_i = n_i \delta(\mathbf{v} - \mathbf{v}_i). \tag{3}$$

Here, $\mathbf{v}_i$ is the average ion velocity and n_i is the ion density.

Then the equation for $\bar{Q}_e$ is

$$\bar{Q}_e = \int\limits_{(\mathbf{r})} \int\limits_{(\mathbf{v})} Q_e(\mathbf{v}, \mathbf{r})\, n_i \delta(\mathbf{v} - \mathbf{v}_i)\, d\mathbf{r}\, d\mathbf{v} = Q(\mathbf{v}_i), \tag{4}$$

and the emission equation (e.g., for the case of a Richardson–Schottky law) becomes

$$j_e = j_{ep} + j_i \frac{Q_e}{e}. \tag{5}$$

The first term in Eq. (5) is given by the Richardson–Schottky emission equation,

$$j_{ep} = A T_k^2 \exp\left(-\frac{e\varphi_k - e\sqrt{eE_k}}{kT_k}\right), \tag{6}$$

and j_i is the ion current density at the cathode.

The method of individual zones was worked out by Kisliuk[7] and Bauer.[8] Kisliuk[7] solved the problem of electron emission due to tunneling, taking account of the effect of the field of an individual ion approaching the cathode. Kisliuk showed that the increase in the emission can become important only when the field near the cathode is strong, $E_k > 3 \cdot 10^7$ V/cm, e.g., in breakdown of a discharge gap.

Bauer reduced the problem to one of determining the lowering of the potential barrier at the metal–plasma interface due to the distortion caused by an ion approaching the cathode; then the additional electron emission is calculated on the basis of the law for thermionic-field emission. The results found show that at cathode temperatures

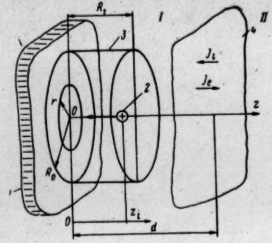

Fig. 1. Model for the individual zone of an ion. I) Collisionless zone; II) ionization zone; 1) cathode; 2) approaching ion; 3) individual zone; 4) boundary of the collisionless zone.

of T_k = 3000-3500°K and at fields near the cathode of $E_k = 0.5 \cdot 10^6 - 5 \cdot 10^7$ V/cm, up to four additional electrons can be emitted per ion approaching the cathode. It should be pointed out, however, that the model proposed by Bauer is imperfect. In analyzing the lowering of the potential barrier Bauer neglects the effect of the right-hand barrier formed by the ion (Fig. 2); it is of fundamental importance to take this effect into account when the ion is close to the cathode because this effect can influence the final results. It is precisely because of this circumstance that the choice of a distance for neutralization of the ion from the cathode surface is of fundamental importance in Bauer's calculations. Several simplifying assumptions introduced in the analyzis of the barrier shape[8] can also affect the calculated results.

In this work we use an improved model for the cathode region to develop the individual-zone method for the case of Richardson–Schottky emission. The following structure of the cathode sheath is proposed for taking account of the effects of the ion microfields on the emission (Fig. 1). Adjacent to the plane and smooth cathode surface is collisionless zone I of thickness d, containing a positive space charge; this zone produces an electric field at the cathode whose average value is E_k and which does not have a radial component. There is a potential drop U_k over the thickness of the collisionless zone. Ions of charge q and mass M formed in the necessary density in the quasineutral ionization zone (II) move toward the cathode; as they approach it, they are neutralized at the neutralization distance R_n. We adopt a cylindrical coordinate system (r, θ, z) with origin at the cathode surface. The z axis is normal to the cathode and passes through the center of the approaching ion, whose instantaneous distance from the surface is z_i.

Using the familiar image method we find the following shape for the barrier at the interface of the metal and the medium for this case:

$$U(z,\ r,\ z_i,\ E_k,\ q) = E_k z + \frac{e}{4z} + \frac{q}{\sqrt{(z_i - z)^2 + r^2}} - \frac{q}{\sqrt{(z_i + z)^2 + r^2}}. \tag{7}$$

In the asymptotic cases $z_i \to \infty$, $r \to \infty$, $z_i \to 0$, this barrier becomes the classical Schottky barrier,

$$U = E_k z + \frac{e}{4z}. \tag{8}$$

Figure 2 shows the shape of the potential barrier for various positions of the ion. We see from Fig. 2 that the lowering of the potential barrier is a function of the position of the ion: When the ion is close to the cathode the left-hand barrier is so low that the right-hand barrier begins to play the decisive role in the emission. In principle, Eq. (7) can be used to find the lowering of the potential barrier, ΔU, as a function of r, z_i, and E_k:

$$\Delta U(r,\ z_i,\ E_k,\ q) = \min_{z \geqslant 0} U(z,\ r,\ z_i,\ E_k,\ q). \tag{9}$$

From this functional dependence we can in turn determine the emission, taking account of the individual field of the ion,

$$j(r,\ z_i,\ E_k,\ q) = A T_k^2 \exp\left(-\frac{e\varphi_k}{kT_k}\right) \exp\left[\frac{e\Delta U(r,\ z_i,\ E_k,\ q)}{kT_k}\right] \tag{10}$$

and we can determine the additional electron current per ion at a fixed ion distance z_i,

$$I_e(z_i,\ E_k,\ q) = 2\pi \int_0^{R_0} [j(r,\ z_i,\ E_k,\ q) - j_{eP}]\, r\,dr. \tag{11}$$

Here, R_0 is the characteristic dimension of the individual zone (Fig. 1). The quantity R_0 is subject to a restriction which follows from the condition for the applicability of the individual-zone method:

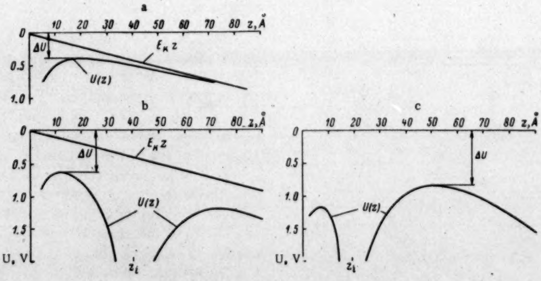

Fig. 2. Potential barriers at the cathode surface for various ion positions. $E_k = 10^6$ V/cm, β = 1, r = 0. a) $z_i \to \infty$ and $z_i = 0$; b) z_i = 40 Å; c) z_i = 19 Å.

$$R_0 \leqslant \min(d,\ \bar{n}_i^{-1/3}) \qquad (12)$$

The thickness of the space-charge zone is determined from the Langmuir–Boguslavskii equation,

$$d = \sqrt{\frac{\left(\frac{2q}{M}\right)^{1/2} U^{3/2}}{9\pi j_i}}, \qquad (13)$$

and the average ion density n_i is determined from the Poisson equation,

$$E_k = 4\pi q \int_0^d n_i dz = 4\pi \bar{n}_i dq. \qquad (14)$$

The electric field at the cathode surface, E_k, is related to the ion current density j_i by the McOwen equation:

$$E_k^2 = 16\pi\left(\frac{M}{2q}\right)^{1/2} U_k^{1/2} j_i. \qquad (15)$$

The relation describing the motion of the ion, $z_i = z_i(t)$, for the motion in the field of space charge near the cathode is, according to ref. 4,

$$z_i = d - \frac{\pi}{3}\frac{2q}{M} j_i t^3. \qquad (16)$$

Substituting this relation into Eq. (11) and integrating $I_e[z_i(t), E_k, q]$ over the time required for the ion to move from R_1 [R_1 must satisfy condition (12)] to R_n, we find that the additional charge emitted per ion within its individual zone is

$$Q_e = 2\pi \int_{t_1}^{t_2} dt \int_0^{R_0} \{j[r,\ z_i(t),\ E_k,\ q] - j_{eP}\} r dr, \qquad (17)$$

where $z_i(t_1) = R_1$ and $z_i(t_2) = R_n$.

We carry out calculations by this procedure in terms of the dimensionless variables

$$u = \frac{U}{\sqrt{eE_k}};\ \xi = \frac{z}{\frac{1}{2}\sqrt{\frac{e}{E_k}}};\ \nu_i = \frac{z_i}{\frac{1}{2}\sqrt{\frac{e}{E_k}}};\ \rho = \frac{r}{\frac{1}{2}\sqrt{\frac{e}{E_k}}};\ \mu = \frac{d}{\frac{1}{2}\sqrt{\frac{e}{E_k}}}, \qquad (18)$$

which we can use to eliminate E_k from (7):

$$u(\xi,\ \rho,\ \nu_i,\ \beta) = \frac{1}{2}\xi + \frac{1}{2\xi} + \frac{2\beta}{\sqrt{(\nu_i - \xi)^2 + \rho^2}} - \frac{2\beta}{\sqrt{(\nu_i + \xi)^2 + \rho^2}}. \qquad (19)$$

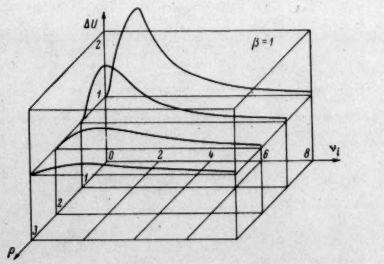

Fig. 3. The functional dependence $\Delta U = \Delta U(\rho,\ \nu_i,\ \beta)|_{\beta=1}$.

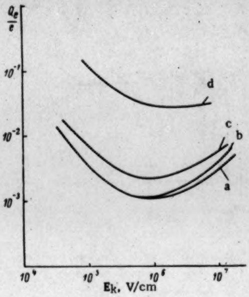

Fig. 4. Electron yield Q_e/e as a function of E_k at T_k = 3000°K. $\beta = 1$. a) $\rho_0 = 10$, $\rho_1 = 10$, $\rho_2 = 0$; b) $\rho_0 = 10$, $\rho_1 = 10$, $\rho_2 = \eta$; c) $\rho_0 = \mu$, $\rho_1 = \mu$, $\rho_2 = 0$, d) $\rho_0 = \mu$, $\rho_1 = \mu$, $\rho_2 = 0$.

Here, $\beta = q/e$. Then numerical methods are used to find the stationary points of the function $u(\xi,\ \rho,\ \nu_i,\ \beta)$ through the use of the condition $\partial u(\xi,\ \rho,\ \nu_i,\ \beta)/(\partial\xi) = 0$; then we find the minima and the value of expression (19) at the minima in the region $\xi > 0$ for fixed values of the parameters β, ρ, and ν_i. The result of this procedure for $\beta = 1$ (singly charged ions) is the function

$$\Delta u|_{\beta=1} \equiv \left.\frac{\Delta U}{\sqrt{eE_k}}\right|_{q=e} = \Delta u(\rho,\ \nu_i,\ \beta)|_{\beta=1}, \qquad (20)$$

shown in Fig. 3. The maximum value of the function $\Delta u(\rho,\ \nu_i,\ \beta)|_{\beta=1}$, equal to 2.39, is reached at $\rho = 0$ and at the value of ν_i corresponding to the ion position at which the left-hand and right-hand barriers are of the same height. Using (15) and (18), we can rewrite integral (17):

$$Q_e = \pi\left(\frac{M}{2\beta}\right)^{1/4}\left(\frac{e}{3}\right)^{3/4}\frac{U_k^{1/4}}{E_k^{11/4}} A T_k^2 \exp\left(-\frac{e\varphi_k}{kT_k}\right)\int_{\rho_2}^{\rho_1}\frac{d\nu_i}{(\mu - \nu_i)^{2/3}}$$
$$\times \int_0^{\rho_0}\left\{\exp\left[\frac{e\sqrt{eE_k}\,\Delta u(\rho,\ \nu_i,\ \beta)}{kT_k}\right] - \exp\left(\frac{e\sqrt{eE_k}}{kT_k}\right)\right\}\rho d\rho, \qquad (21)$$

where

$$\rho_0 = \frac{R_0}{\frac{1}{2}\sqrt{\frac{e}{E_k}}};\ \rho_1 = \frac{R_1}{\frac{1}{2}\sqrt{\frac{e}{E_k}}};\ \rho_2 = \frac{R_n}{\frac{1}{2}\sqrt{\frac{e}{E_k}}} = \eta.$$

Equation (21) was integrated numerically. Figures 4 and 5 show some of the calculated results, for $\beta = 1$, U_k = 5 V, φ_k = 4.5 V, M = 40 · 1.67 · 10^{-27} kg (argon), and for T_k and E_k over the ranges T_k = 2800–3500°K and E_k = 10^4–1.5 · 10^7 V/cm. For comparison, Fig. 5 shows curves plotted from Bauer's results.[8] As mentioned above, the lowering of the potential barrier Δu tends toward the classical Schottky correction (Δu → 1) as $\nu_i \to 0$. Comparison with the analogous case of Bauer ($\nu_i \to 0$, Δu → ∞) shows that the singularity at Δu as $\nu_i \to 0$ makes the result of the evaluation of integral (21) strongly dependent on the method used to truncate it. In ref. 8 the integral is truncated at the ion-neutralization distance R_n = 8.5 Å, so even a slight error in the choice of R_n (there is no reliable experimental information on R_n) can lead to a significant distortion

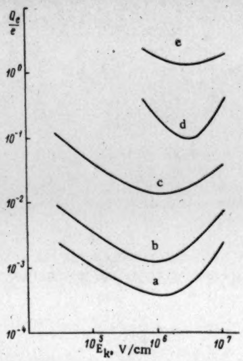

Fig. 5. Electron yield Q_e/e as a function of E_k for $\rho_0 = 10$, $\rho_1 = 10$, and $\rho_2 = 0$. T_k, °K: a) 2800; b) 3000; c) 3500. Curves d and e are plotted from Bauer's results[8] for 3000 and 3500°K, respectively, $\beta = 1$.

of the final results (curves d and e in Fig. 5). The elimination of the singularity in the lowering of the potential barrier Δu as $\nu_l \to 0$ in our model means that the calculated results are only weakly dependent on this neutralization distance. Accordingly, the integration to $\rho_2 = 0$ ($R_n = 0$) does not significantly affect the value of Q_e (curves a and b in Fig. 4). We note that this circumstance is not the consequence of any additional assumption, but the result of taking account of the effect of the right-hand barrier.

Variation of the radial dimension of the individual zone, ρ_0, has little effect on Q_e (curve c in Fig. 4), while variation of the axial dimension ρ_1 has a stronger effect (curve d in Fig. 4).

Using these results we can easily find an upper estimate on the electron yield Q_e/e per ion for the case in which multiply charged ions move toward the cathode. Using (19) and (21), we find

$$\Delta u(\rho, \nu_l, \beta) \leqslant \beta \Delta u(\rho, \nu_l, \beta)|_{\beta=1}, \tag{22}$$

$$\frac{Q_e}{e} \leqslant \frac{\beta^{10/3}}{e}[Q_e(E_{\text{eff}})|_{\beta=1} + j_{eP}(E_{\text{eff}})\pi R_0^2 \Delta t|_{q=e}] - j_{eP}(E_k)\pi R_0^2 \Delta t. \tag{23}$$

Here, $E_{\text{eff}} = \beta^2 E_k$, $\Delta t = t_2 - t_1$, and $\Delta t|_{q=e} = t_2|_{q=e} - t_1|_{q=e}$. The quantity $Q_e(E_{\text{eff}})_{\beta=1}$ is the value of expression (21) evaluated at $\beta = 1$ and E_{eff}, $j_{eP}(E_{\text{eff}})$, and $j_{eP}(E_k)$ are the values of expression (6) calculated for fields of E_{eff} and E_k, respectively, at the cathode.

The electron yield Q_e/e is a function of the motion of the ion in the individual zone. In the same manner we can find an upper estimate for all possible trajectories of singly charged ions:

$$\frac{Q_e}{e} < \frac{\pi R_0^2}{e} \Delta t [j_{eP}(E'_{\text{eff}}) - j_{eP}(E_k)], \tag{24}$$

where $E'_{\text{eff}} = 5.7E_k$, and the quantities $j_{eP}(E'_{\text{eff}})$ and $j_{eP}(E_k)$ are calculated as in the previous case.

We see from (23) and (24) that in order to explain the anomalous emission by the individual-zone method we must take account of effects which increase the time the ion spends in the individual zone (e.g., charge exchange, reflection of ions, etc.).

Simulation of ion scattering on diatomic molecules

M. L. Aleksandrov, N. S. Pliss, and A. P. Shcherbakov

Special Construction Bureau for Analytic Instrument Construction,
Academy of Sciences of the USSR, Leningrad

(Submitted April 26, 1973; resubmitted July 27, 1973
Zh. Tekh. Fiz., 44, 632-634 (March 1974)

A method is proposed for calculating the classical deflection function $\Theta(b)$, averaged over all molecular orientations, for the scattering of ions or atoms by diatomic molecules in the kiloelectron-volt range; a modified Firsov potential is used for the interatomic interaction. Analytic expressions approximating Ar^+-N_2 and U^+-N_2 are constructed for the Θ (b) pairs. The calculated functional dependence is recommended for use in statistical simulation of the scattering of ions by diatomic residual gas molecules in mass spectrometers.

INTRODUCTION

The method of statistical simulation is a versatile analytic tool for studying the scattering of ions by residual gas molecules in a mass spectrometer and is used in instrument design.[1] An important element in the method is simulation of the initial conditions for the ion motion after the scattering; it is convenient to use for this purpose the functional dependence $\Theta = \Theta(b)$, i.e., that of the center-of-mass scattering angle on the impact parameter b, which is assumed to be a random quantity with a distribution density

$$p(b)=\begin{cases} cb, & b\in(b_1, b_2),\\ 0, & b\overline{\in}(b_1, b_2),\end{cases}$$

where c is a normalization constant, and b_1 and b_2 are governed by the range of Θ which is most important in studying scattering in mass spectrometers: $0.017 < \Theta < 0.350$ rad.

We report here an attempt to determine the Θ(b) functional dependence for the scattering of ions by diatomic molecules over the energy range 4-16 keV. Classical mechanics can be used for these energies and angles. The effect of inelastic energy loss on the angular distribution of scattered particles is neglected because it is small in comparison with the ion energy.

CALCULATION OF THE ANGLE THROUGH WHICH IONS ARE SCATTERED BY DIATOMIC MOLECULES

Scattering of ions in this energy range is governed by short-range repulsive forces. Following ref. 2, to describe this interaction we can use a modified Firsov potential, written in the atomic system of units (in which we have $\hbar = m_e = e^2 = 1$):

$$V(r)=\frac{Z_1Z_2}{r}\chi(r), \tag{1}$$

where Z_1 and Z_2 are the charges of the atomic nuclei, and

$$\chi(r)=\left[a\exp\left(-\frac{\alpha}{A}r\right)+b\exp\left(-\frac{\beta}{A}r\right)\right]^2$$

is the shielding function, where $a = 0.7111$, $b = 0.2889$, $\alpha = 0.1750$, $\beta = 1.6625$, and $A = 0.8853/(Z_1^{1/2} + Z_2^{1/2})^{2/3}$.

A feature of the scattering of ions by residual gas molecules like N_2 and O_2 is the anisotropy of their interaction with the diatomic molecules. To describe this interaction we use a two-center representation of the potential, i.e., we write the potential for the interaction with a molecule of species AB as

$$\tilde{V}(r)=V(r_{AC})+V(r_{BC}),$$

where r is the distance between the ion of species C and the center of gravity of the AB molecule, r_{AC} and r_{BC} are the interatomic distances, and V(r) is the potential given by Eq. (1).

In small-angle scattering of particles by a spherically symmetric potential the function Θ(b) is described approximately by[3]

$$\Theta(b)=\frac{\Delta p}{p}=-\frac{b}{E}\int_b^\infty\frac{dV}{dr}\frac{dr}{\sqrt{r^2-b^2}}=-\frac{b}{E}P(b), \tag{2}$$

where E is the energy of the relative motion, Δp is the transverse momentum, and p is the momentum of the particle after the scattering.

For the two-center potential $\tilde{V}(r)$ and for scattering through small angles we assume, in accordance with ref. 4, that the momentum Δp, which governs the deflection angle of the particle, is equal to the sum of the momenta obtained in the interaction of the ion with each atom of the molecule on an essentially rectilinear trajectory. Since the relative velocity of the colliding particles is high we can assume that the molecular orientation remains the same throughout the collision. This orientation is specified by the direction of the axis of the diatomic molecule by means of the polar angle ψ (the polar axis is chosen to be the direction along the relative velocity) and by the azimuthal angle φ.

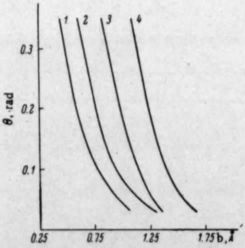

Fig. 1. The functions Θ (b). 1) Ar^+-Si, 12 keV (ref. 2); 2) Ar^+-N_2, 12 keV; 3) U^+-Si, 16 keV (ref. 2); 4) U^+-N_2, 16 keV.

Then using Eq. (7) from ref. 4, we find the following expression for Θ for a fixed orientation of the molecule:

$$\Theta(b, \Psi, \varphi) = \frac{1}{E}[b_1^2 P^2(b_1) + b_2^2 P^2(b_2)$$

$$+ 2(b^2 - r_0^2 \sin^2\Psi) P(b_1) P(b_2)]^{1/2} = \frac{\Phi(b, \Psi, \varphi)}{E}.$$

Here, $b_i^2 = b^2 + 2(-1)^i b r_0 \sin\Psi \sin\varphi + r_0^2 \sin^2\Psi$ $(i = 1, 2)$, $2r_0$ is the internuclear distance in the molecule, b is the impact parameter, measured from the center of gravity of the molecule, and $P(b_i)$ is found from the integral in (2), where potential (1) is used as V(r).

Assuming the distribution of the unit vector which specifies the orientation of the molecule to be homogeneous over a sphere of unit radius, we can find the scattering angle averaged over all possible molecular orientations:

$$\Theta(b) = \frac{1}{4\pi E} \int_0^\pi \sin\Psi d\Psi \int_0^{2\pi} \Phi(b, \Psi, \varphi)\, d\varphi. \quad (3)$$

Since the potential used here is universal, Eq. (3) can be used for a computer calculation of the classical deflection function Θ(b) for any system of a monatomic ion and diatomic molecule or atom and diatomic molecule for various energies E.

EXAMPLE

As an example we calculate the functions Θ(b) for the Ar^+-N_2 pair (curve 2 in Fig. 1, for an ion energy of 12 keV) and the U^+-N_2 pair (curve 4, for an ion energy of 16 keV) for Θ in the range from 0.017 to 0.350 rad. Shown for comparison in this figure are the deflection functions obtained on the basis of the calculations of Nikulin[2] for a single-center modified Firsov potential for the same ions (curve 1 for Ar^+ and curve 3 for U^+). These curves are plotted for the same energies, but the target is an Si atom, which has the same mass as the N_2 molecule, and the nuclear charge of this atom is equal to the total charge of the nitrogen nucleus.

We see from this figure that account of the two centers leads to stronger scatter at a given impact parameter and thus to an increase in the total scattering cross section.

It should be noted that this method for calculating the scattering of ions by diatomic molecules can also be used for scattering involving a single-center potential; for this purpose the internuclear distance $2r_0$ should be set equal to zero. The results found in this case agree within 8% with the results of ref. 2; the discrepancy is maximal for large angles, due to the approximate nature of Eq. (2), but it essentially vanishes at small angles.

To simulate the initial conditions for the motion of the ion after the scattering it is necessary to know the analytic function Θ(b), which makes it possible to calculate the scattering angle for any random value of b. Using an expansion in terms of Laguerre functions to approximate these curves, and restricting the expansion to the second order, we find the following analytic expressions:

$$\Theta = \frac{1}{E} e^{-4.3b}(102.2 - 38.7b + 11.7b^2)$$

for the Ur^+-N_2;

$$\Theta = \frac{1}{E} e^{-3.2b}(20.1 - 15.1b + 5.3b^2)$$

for the Ar^+-N_2.

In these equations the impact parameter b is given in angstroms, the energy of the relative motion, E, is given in kiloelectron volts, and the angle Θ is given in radians. The error of this approximation does not exceed 3%.

CONCLUSIONS

A method has been proposed for a computer calculation of the classical deflection function Θ(b) in the kiloelectron-volt energy range for any pair consisting of a monatomic ion and diatomic molecule or atom and diatomic molecule.

The analytic approximations obtained for the function Θ(b) for certain pairs are convenient for simulating scattering of ions by residual gas molecules in mass spectrometers over the entire energy range considered.

Rate for evaporation of a liquid into vacuum

A. P. Andreev and M. A. Gurevich
M. I. Kalinin Leningrad Polytechnical Institute

(Submitted March 28, 1973; resubmitted June 28, 1973)
Zh. Tekh. Fiz., 44, 635-643 (March 1974)

A method is described for determining the evaporation coefficient of a liquid, and experimental results are reported. Photography and a thermocouple technique are used to measure the diameter and temperature, respectively, of drops of methanol, ethanol, and n-propanol evaporated into vacuum. A residual gas pressure of about $5 \cdot 10^{-3}$ torr is maintained in the chamber by condensing the vapor on the walls of the vessel by means of liquid nitrogen. Heat is supplied to the drop by radiation. In each experiment the temperature and rate of decrease in the diameter of a drop remain approximately constant (the drop diameter changes from 2 to 1 mm). The temperature ranges studied are from −96 to −56°C for methanol, from −86 to −36°C for ethanol, and from −65 to −13°C for n-propanol. The evaporation coefficient is calculated from the measured temperature and evaporation rate by means of the Knudsen–Hertz–Langmuir equation. At the lowest temperatures the evaporation coefficients for the alcohols, α, are found to be about an order of magnitude higher than the values given in the literature for higher temperatures. The evaporation rate increases with increasing temperature for all three alcohols, but the evaporation coefficient decreases. Over these temperature ranges the evaporation coefficients decrease from 0.4 to 0.2 for methanol, from 0.6 to 0.15 for ethanol, and from 0.5 to 0.1 for n-propanol. Empirical equations are found for the temperature dependence of the evaporation coefficient for these alcohols:

$$\alpha = A \exp\left[-\frac{(T-T_{\mathrm{me}})^3}{C}\right] + B.$$

Here, T_{me} is the melting point of the corresponding alcohol, and A, B, and C are constants for each alcohol. This equation describes the results found in the present work as well as experimental data reported elsewhere.

INTRODUCTION

To the best of our knowledge, there is no generally accepted method for calculating the evaporation coefficient of a liquid as a function of the temperature, and the experimental data available for most substances cover only a narrow temperature range.[1,2] Our purpose here is to measure the evaporation coefficients of three alcohols at comparatively low temperatures and to use the results, along with data in the literature, to draw conclusions about the functional dependence of the evaporation coefficient on temperature.

The evaporation rate is usually calculated from the Knudsen–Hertz–Langmuir equation

$$i = \frac{\alpha v_{\mathrm{av}}}{4}(c_s - c_0) \tag{1}$$

or if the vapor can be treated as an ideal gas, from

$$i = \alpha \sqrt{\frac{M}{2\pi R T_s}}(P_s - P_0). \tag{2}$$

Here, i is the mass flux of vapor from a unit area of the evaporation surface, α is the evaporation coefficient, v_{av} is the average thermal velocity of the vapor molecules, c_s and P_s are respectively the density and pressure of the saturated vapor at the surface temperature, c_0 and P_0 are the density and pressure of the vapor at a distance on the order of a mean free path from the evaporation surface, T_s is the absolute temperature of the evaporation surface, M is the molecular weight of the substance, and R is the universal gas constant.

These equations are best thought of as defining the concept of the "evaporation coefficient."

As a rule, the evaporation coefficient of the liquid is determined by measuring the evaporation rate, the temperature of the evaporation surface, and the vapor pressure near it. Either this vapor is held constant by continuous evacuation of the working chamber or its gradual increase is taken into account; here the equation for α incorporates the difference between two pressures, P_s and P_0, which are approximately equal. The measured values of P_0 are generally somewhat uncertain, especially when low pressures ($1 \cdot 10^{-3}$–$5 \cdot 10^{-1}$ torr) must be measured. Reliable measurements of P_0 are not required if $P_0 \ll P_s$,

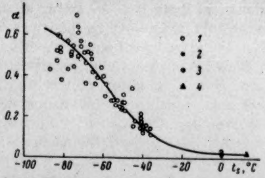

Fig. 3. Evaporation coefficient of ethanol as a function of the temperature. 1) This work; 2) ref. 9; 3) ref. 11; 4) ref. 10.

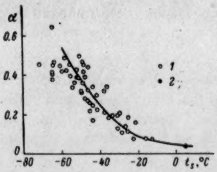

Fig. 4. Evaporation coefficient of n-propanol as a function of the temperature. 1) This work; 2) ref. 9.

Over a time not exceeding 10% of the total evaporation time, the drop cools to a certain temperature governed by the illumination and the properties of the liquid; for the rest of the time (until the drop diameter falls to almost half its initial value), its temperature varies only slightly, by 2-3°C. This change in surface temperature can lead to a change of 15-25% in the evaporation rate of these alcohols, according to Eq. (2). Within approximately the same error the functional dependence of the drop diameter on the time is linear.

The decrease in the diameter of a spherical drop is related to the mass flux from a unit area of the surface, i, by

$$i=\frac{1}{\pi\delta^2}\frac{dm}{d\tau}=\frac{1}{2}\rho_s\frac{d\delta}{d\tau}. \qquad (5)$$

Here, m is the mass of the drop, δ is its diameter, ρ_s is the liquid density, and τ is the time.

From the $T_s \equiv T_s(\tau)$ curves we distinguish a region over which the temperature does not change by more than 2-3°C; averaging over this region, we assign it the value of $\Delta\delta/(\Delta\tau) \approx \overline{[d\delta/(d\tau)]}$ obtained for the same time interval.

The evaporation coefficient is calculated from an equation found by substituting Eq. (5) into Eq. (2):

$$\alpha=\frac{\rho_s\frac{d\delta}{d\tau}}{2\sqrt{\frac{M}{2\pi RT_s}}P_s\left(1-\frac{P_0}{P_s}\right)}. \qquad (6)$$

In our case $P_0 \ll P_s$.

The liquid density ρ_s and the saturation vapor pressure P_s are taken from refs. 3-5. Where information is not available on the working temperatures we determine the density by a linear extrapolation and we determine P_s through an extrapolation by the Cox–Antoine method. (The P_s extrapolation is carried out at −67 to −96°C for methanol and from −43 to −65°C for n-propanol; the values of P_s for ethanol are known over the entire temperature range).

The resulting evaporation coefficients are shown in Figs. 2-4, along with the values of α for these alcohols which we have found in the literature.

The results found from measurements of the evaporation rate and calculation of the evaporation coefficient are tabulated at the end of this paper.

CHECK OF THE RELIABILITY OF THE EXPERIMENT

Judging from the reviews in refs. 2, 6, and 8, we conclude that two fundamental errors are the most dangerous in a measurement of the evaporation coefficient. One is a discrepancy between the measured temperature and the surface temperature.

In our experiments much of the heat is supplied to the drop along the leads of the thermocouple, which absorbs radiation from the lamp. It could be argued that the indications of the thermocouple depend on the position of the junction within the drop (on the immersion depth L) and on the heat flux passing through the thermocouple.

We assume that in the experimental functional dependence $d\delta/(d\tau) = F(T)$

$$T=T_s+\Phi\left[\left(\frac{Q}{Q_\Sigma}\right)_1,\ \left(\frac{L}{r}\right)_1\right].$$

Here, r is the drop radius, L/r is the relative immersion depth of the junction of the thermocouple in the drop, and Q/Q_Σ is the relative energy supplied through the thermocouple.

Let us change Q/Q_Σ abruptly. (For this purpose we insert the end of a copper wire 0.35 mm in diameter into the drop; the wire is held at a certain distance from the thermocouple. At the given radiation densities the result would be a severalfold change in the evaporation rate and a simultaneous change in the detector temperature T.) Now we have

$$\frac{d\alpha}{d\tau}=F(T)=F\left\{T_s+\Phi\left[\left(\frac{Q}{Q_\Sigma}\right)_2,\ \left(\frac{L}{r}\right)_1\right]\right\}.$$

It turns out that for any T

$$F\left\{T_s+\Phi\left[\left(\frac{Q}{Q_\Sigma}\right)_1,\ \left(\frac{L}{r}\right)_1\right]\right\}=F\left\{T_s+\Phi\left[\left(\frac{Q}{Q_\Sigma}\right)_2,\ \left(\frac{L}{r}\right)_1\right]\right\}.$$

It should be noted that the equality of evaporation rates necessarily implies the equality of the surface-evaporation temperatures T_s. Hence,

$$\Phi\left[\left(\frac{Q}{Q_\Sigma}\right)_1,\ \left(\frac{L}{r}\right)_1\right]=\Phi\left[\left(\frac{Q}{Q_\Sigma}\right)_2,\ \left(\frac{L}{r}\right)_1\right];$$

i.e., the error in the temperature measurement is not a function of the relative heat flux through the thermocouple.

In an analogous manner we show that the error in the temperature measurement is not a function of the depth to which the junction of the thermocouple is immersed in the liquid. The results are shown in Fig. 5. Since it would but this condition would at first glance seem impossible to satisfy, since superheating by even a few degrees can cause boiling.

However, the condition $P_0 \ll P_s$ can be satisfied for several liquids at a relatively low temperature, and boiling can be prevented if the liquid is evaporated as drops. Let us consider the pressure acting on the surface of a spherical drop in evaporation into vacuum, P_Σ:

$$P_\Sigma = P_e + P_\sigma = P_s\frac{\alpha}{2} + \frac{2\sigma}{r}. \qquad (3)$$

Here, P_e is the "reactive" pressure due to the evaporation (its relationship to P_s is demonstrated, e.g., in ref. 2), P_σ is the Laplace pressure, σ is the surface tension of the liquid, and r is the drop radius.

Boiling will evidently not occur if

$$P_s < P_\Sigma = \frac{2\sigma}{r\left(1 - \frac{\alpha}{2}\right)}. \qquad (4)$$

For example, a drop of ethanol 1 mm in radius must evaporate into vacuum without boiling at $t_s < -40°C$, corresponding to a saturation vapor pressure of $P_s \approx 0.4$ torr.

Condition (4) is of course not a necessary condition; it is also necessary to take account of the size of the vaporization centers. In our experiments we do not observe boiling even at P_s slightly higher than P_Σ.

EXPERIMENTAL APPARATUS AND PROCEDURE

The experimental apparatus is shown in Fig. 1.

Chamber 3, 4.5 liters in volume, is evacuated by a mechanical pump through a liquid-nitrogen trap to a residual pressure no higher than $5 \cdot 10^{-3}$ torr (the pressure is measured by a thermocouple vacuum gauge). Then isolating glass 5 is pressed against the end of inlet device 1.

Liquid drops with an initial diameter of about 2 mm are formed in the volume (0.15 cm^3) isolated by glass cap 5 and the end of Teflon bushing 12. In this volume there is a glass arm 15, mounted on the end of the bushing to which the junction of thermocouple 13 is attached. A syringe needle 2 is inserted through an axial aperture in the bushing, and the piston forces the liquid onto the arm (the end of the arm is 0.5-0.7 mm in diameter).

The rotation axis of plug 10, with two Teflon gaskets, is 2.5 mm away from the axis of bushing 12. Accordingly, by removing the syringe needle from the axial aperture and rotating the plug through 180°, it is possible to insert pin 9 in place of the needle. In this manner, the volume containing the drop is completely isolated.

The cap is linked through Teflon coupling 14 with shaft 16, which transmits the force to advance or withdraw the cap from spring-loaded release 7. After the cap is withdrawn, drops begin to evaporate; a low pressure is maintained in the chamber through the condensation of the liquid vapor on the walls of vessel 4, previously filled with liquid nitrogen. However, there must be no air at atmospheric pressure in the volume isolated by the cap, for this air could increase the pressure of uncondensed gas in the chamber by an order of magnitude. Degradation of the vacuum is avoided by evacuating intermediate chamber 11 through the axial aperture of the bushing after each loading of the syringe. To prevent liquid in syringe reservoir 8 from being withdrawn, the needle of the syringe is inserted into the rear of the bushing. After the evacuation is completed, and the cap is pressed into place, the syringe needle is removed from the bushing, and a small amount of emerging liquid saturates the intermediate chamber; atmospheric air does not penetrate into the chamber because plug 10 isolates it from the atmosphere.

During the evaporation the changes in the drop size are detected by photography in transmitted light. The drop temperature is measured by a Chromel–Alumel thermocouple with a lead diameter of 0.1 mm which is inserted into the drop; the temperature is recorded on an ÉPP-09 potentiometric recorder. The measurements of the drop temperature and size are synchronized by shorting the input to the potentiometer during the recording of each frame; this procedure produces time markers.

The energy required to evacuate the drop is supplied by radiation from the motion-picture projection lamp which is also used for the photography. The radiation density can be altered by varying the current through the lamp; for high radiation densities a short-focus lens is used inside the vacuum chamber. The total range of radiation densities is (0.25-200) $\cdot 10^{-2}$ W/cm^2.

The experimental results are used to construct functional dependences of the diameter of the observed projection of the drop on the time. (During the adjustment of the system the drop is suspended so that its maximum and minimum diameters lie in the observed plane throughout the evaporation.)

EXPERIMENTAL RESULTS

We have studied the evaporation of drops of methanol, ethanol, and n-propanol. We use analytically pure liquids, except that in several cases we use rectified ethanol and incorporate the appropriate correction.

Since the drop is initially at a temperature at which condition (4) does not hold, the cap is not withdrawn abruptly, but in two stages. First, the compression force is reduced, the vapor escapes into the vacuum chamber, and the drop rapidly cools, evaporating. After 1-2 sec, the drop has cooled to a point at which condition (4) is satisfied, and the cap is withdrawn completely.

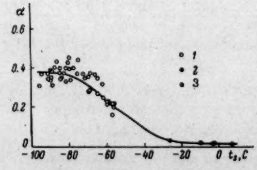

Fig. 2. Evaporation coefficient of methanol as a function of the temperature. 1) This work; 2) refs. 9, 12; 3) ref. 12.

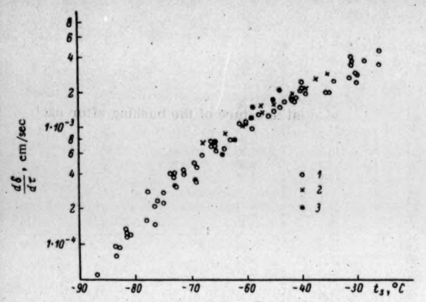

Fig. 5. Diagram used to check for a systematic error in the temperature measurement. Measured rates of change of the diameter of an ethanol drop: 1) basic series of measurements (the junction of the thermocouple is in the upper part of the drop); 2) series in which a copper wire is inserted; 3) series in which the thermocouple junction is in the lower part of the drop.

be difficult to assume that the systematic error in the temperature measurement, Φ, is actually not a function of these factors, we conclude that this error is smaller than the measurement error; thus, the experimental dependence is the dependence on the actual temperature of the drop surface:

$$\frac{d\delta}{d\tau}=F(T_s).$$

Intense mixing apparently prevents any important inhomogeneity of the temperature field in the drop; we have observed on several occasions that dust particles reaching the drop move rapidly.

The second dangerous possibility of error arises because the effect of the diffusive resistance to vapor transport and thus of inverse condensation is frequently neglected. Under quasisteady-state conditions the rate of the phase transition itself is actually equal to the rate at which vapor is withdrawn through a layer of a foreign gas. According to the scheme described by Fuks,[6] molecules are exchanged without hindrance between the surface of the drop and a sphere of radius (r + Δ), while in vacuum (Δ is a length on the order of the mean free path), and far from the drop surface, Fick's law operates.

TABLE 1

	A	*B*	*C*
Methanol	0.36 (1 ± 0.13)	0.017	$1.1\cdot10^5$
Ethanol	0.65 (1 ± 0.12)	0.020	$2.5\cdot10^5$
n-Propanol	0.96 (1 ± 0.21)	0.035	$4.2\cdot10^5$

Since the vapor pressure at the absorbing surface under our experimental conditions is much lower than the saturation vapor pressure in the temperature range studied, we find, in the approximation of spherical symmetry,

$$I=\frac{I_{\text{vac}}}{1+\xi};\;\xi=\frac{v_{\text{av}}\alpha r^2}{4D}\left(\frac{1}{r+\Delta}-\frac{1}{b}\right). \tag{7}$$

Here I is the mass flux of vapor from the drop surface, I_{vac} is the mass flux of vapor into absolute vacuum, b is the radius of the absorption sphere, and D is the diffusion coefficient. Obviously, the measured evaporation rate will be closer to the evaporation rate into vacuum, the lower ξ is in comparison with unity.

In planning the experiments we estimate the values of ξ, calculating the diffusion coefficient and the mean free path (used instead of Δ) from the equations for the hard-sphere model. We assume the evaporation coefficient to be equal to unity, and we neglect 1/b in comparison with 1/(r + Δ) (these simplifications can only lead to values of ξ which are too high). Estimates show that under these experimental conditions ξ < 0.10.

Evidence that the diffusive resistance is negligible comes from the circumstance that the measured evaporation rates of the drop do not exceed 5% of the rates which can be achieved by diffusion under the corresponding conditions. Incidentally, in all these estimates we neglect the Stefan flux from the evaporation surface, which would

evidently lead to an underestimate of the rate at which vapor is removed.

To check our estimate of the effects of the diffusive resistance we carry out a series of experiments involving the evaporation of ethanol drops at a much higher pressure of uncondensed gas: $P_g = (1.5\text{–}3.7)\cdot 10^{-1}$ torr. Under these conditions we have $\Delta \approx l \ll r$, and Eq. (7) reduces to

$$I = \frac{I_{\text{vac}}}{1 + \frac{r v_{\text{av}} \alpha}{4D}} = \frac{I_{\text{vac}}}{1 + \frac{v_{\text{av.}} \alpha \, (\overline{rP_g})}{4\,(DP_g)}}. \tag{8}$$

We calculate the value of DP_g from the standard gas-kinetic equation,[7] and we determine the time average of rP_g from experiment. Since the radius r decreases as time elapses, while P_g increases because of inleakage, the product rP_g varies little as a function of the time.

From the values α calculated from the results of the basic series of experiments, we can calculate the value of I_{vac} on the basis of the observed rate I. The satisfactory agreement (within the experimental error) of the results calculated from Eq. (8) with the experimental results carried out in the kinetic region verifies that this equation can be used to calculate the evaporation rate under conditions representing a transition stage between the kinetic and diffusive regimes. Unfortunately, we were not able to compare the equations given in ref. 6, since they all reduce to form (8) under our experimental conditions.

GENERALIZATION OF THE EXPERIMENTAL RESULTS

We have selected empirical equations which satisfactorily describe (see Figs. 2-4) the evaporation rate as a function of the temperature T_s for the three alcohols:

$$\alpha = A \exp\left[-\frac{(T_s - T_{me})^3}{C}\right] + B. \qquad (9)$$

Here T_{me} is the melting point of the alcohol. The values of A, B, and C (constant for each alcohol) are shown in Table 1. The confidence interval is calculated for a confidence level of 0.68.

This equation describes our results and the other experimental results available in the literature.

The functional dependence of the evaporation coefficient on the temperature described by Tables 2-4 does not agree with theoretical predictions with which we are familiar.[1,8] Apparently, the nature of the functional dependence of the evaporation coefficient on the temperature can be explained on the basis of associations of molecules in both in the liquid and vapor.

The authors thank graduate students V. K. Popov, V. E. Loshkarev, and B. I. Izrailev for participation in various stages of this work.

Multiple reflection of light in a shock tube

V. D. Mironov and V. I. Selyakov
Moscow Engineering-Physics Institute

(Submitted March 21, 1973; resubmitted August 6, 1973)
Zh. Tekh. Fiz., 44, 644-648 (March 1974)

A method is proposed for distinguishing the emission from a hot gas from multiply reflected light in a shock tube; the method is based on the measurement of the intensity of the multiply reflected light before the shock wave arrives in the field of view of the detector.

The emission method is one of the most versatile and widespread diagnostic tools for shock-tube experiments. When this method is used in the visible or IR regions the experimenter is confronted with a peculiar phenomenon: Before the incident shock wave arrives in the field of view of the detector the detector records a monotonically increasing emission signal whose level can be a significant fraction of the total intensity. This effect has been attributed to multiple reflection of light at the walls of the shock tube.[1-3] When the shock tube passes through the field of vision of the optical system the sum of the direct emission (the useful signal) and the multiply reflected light is recorded. This multiple reflection not only interferes with measurements of absolute emission intensities, but also distorts the functional dependence of the emission intensity on the time and thus ultimately leads to errors in the measurement of relaxation times.[1] Instrumental methods for eliminating multiple reflection have not always been successful, especially in shock tubes with narrow cross section.

In principle, it is possible to calculate the contribution of multiple reflection to the measured intensity. This calculation requires knowledge of the reflection characteristic of the walls of the shock tube as well as the magnitude of the reflection coefficient. These properties are strongly influenced by the magnitude and shape of the microscopic surface irregularities, the material, the method used to deposit the protective coating, etc. The use of standard samples to determine the reflection properties can thus lead to large errors; on the other hand, it is generally impossible to measure the reflection properties of the experimental apparatus under operating conditions.

We note, however, that the multiply reflected light observed before the arrival of the shock waves carries information about the reflection of light at the walls of the shock tube, so it may be possible to determine the multiple-reflection contribution to the detected emission of the gas volume behind the shock front (ordinarily called the "piston") by measuring the intensity of the multiply reflected light before the arrival of the shock wave. This method is based on the assumption of similarity in the distribution of the emission intensity with respect to the cross sections of the piston. In particular, for tubes having a circular cross section the intensity of the emission of a unit volume can be written as $I(\xi, r) = I(\xi)\varphi(r)$, where ξ is the coordinate along the tube axis; the origin of this coordinate is at the shock front, and the coordinate is measured opposite the flow. Also, $\varphi(r)$ is the radial distribution, which is not a function of ξ. We also assume that the conditions governing the light reflection are constant along the tube channel.

We denote by $i^{\omega}(x)$ the intensity of multiply reflected light detected before the arrival of the shock wave; here x is the position of the shock front with respect to the optical axis of the detector (Fig. 1). As the piston passes into the field of view of the optical device a total intensity $J(\xi)$ is recorded; this intensity consists of the actual (desired) intensity $J^{act}(\xi)$ and the intensity of multiply reflected light, which we denote in this case by $i^e(\xi)$. The time coordinate of the oscillogram is converted to the linear coordinate used here through the use of the known velocity of the shock wave, $x = U_s t$. Times before the arrival of the shock wave are assigned negative values.

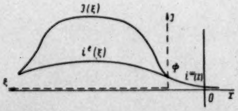

Fig. 1. Intensity of emission from the piston and that of multiply reflected light in the fixed (laboratory) coordinate system (x, J) and in the moving coordinate system (ξ, J) fixed at the shock front Φ. The motion is from left to right. The optical axis of the detector is at x = 0.

CASE OF A PISTON WHICH IS HOMOGENEOUS WITH RESPECT TO ITS LENGTH

Let us consider the case in which $J(\xi) = \text{const}$. Assume that a piston of length l is arranged as shown in Fig. 2. The contribution to the multiple reflection of light (detected by the detector along with the direct emission) from the part of the piston to the left of the axis is assumed to be the multiple reflection of light from the entire piston at $x = 0$, minus the contribution of the rear of the piston $\xi > x_0$. This latter contribution is in turn assumed to be given by the negative value of the multiple reflection of light, again of the entire piston at $x = x_0 - l$, etc. The contribution of the right-hand side of the piston is taken into account similarly. As a result we find

$$i^e(\xi)|_{\xi=x_0} = 2\sum_{n=0}^{\infty} i^{\omega}(-nl) - \sum_{n=0}^{\infty} i^{\omega}(x_0-(n+1)l) - \sum_{n=0}^{\infty} i^{\omega}(-x_0-nl). \tag{1}$$

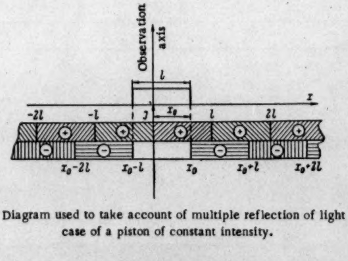

Fig. 2. Diagram used to take account of multiple reflection of light in the case of a piston of constant intensity.

In writing the last term in Eq. (1) we have taken account of the symmetry of the reflection properties of the channel walls with respect to the optical axis.

Using Eq. (1) and the measured intensity of the "early" emission i^{ω} as a function of the distance of the shock front from the optical axis, x, we calculate the intensity of the multiple reflection of light for any position of the piston with respect to the detector. Since i^{ω} falls off quite rapidly with increasing x, it is sufficient to retain only the first few terms in the summation in Eq. (1).

PISTON WHICH IS INHOMOGENEOUS WITH RESPECT TO ITS LENGTH

Since the magnitude of the multiple reflection of light is a linear function of the actual emission intensity of the piston, in analyzing multiple reflection in the channel of the shock tube we can introduce the transfer coefficient k(x), defined as the ratio of the detected intensity of multiple reflection of light of an infinitesimally thin layer, whose position with respect to the optical axis is given by the coordinate x, to the actual emission intensity of this layer:

$$k(x)=\lim_{\Delta\xi\to 0}\frac{i^{\omega}(x)}{J_{\text{act}}(x)\,\Delta\xi(x)}. \tag{2}$$

This transfer coefficient automatically takes account of the geometric conditions of detection; for a given experimental apparatus the geometry is a function of x alone, so that no additional information is required about the nature of the reflection or the magnitude of the reflection coefficient. The transfer coefficient has the symmetry property

$$k(x)=k(-x).$$

Using the transfer coefficient we can describe multiple reflection by the following equations: For the case in which the piston has not reached the observation zone, and the coordinate of the optical axis in the moving system is x < 0,

$$i^{\omega}(x)=\int_0^l k(x-\xi)\{J(\xi)-i^e(\xi)\}\,d\xi \tag{3}$$

for the case in which the piston is at the optical axis, $l \geq x \geq 0$,

$$i^e(x)=\int_0^l k(x-\xi)\{J(\xi)-i^e(\xi)\}\,d\xi, \tag{4}$$

where $J = J^{\text{act}} + i^e$ is the detected intensity.

Equations (3) and (4) constitute a system of Fredholm equations of the first and second kinds with unknown functions i^e and k. Since the kernels and the free terms are bounded and continuous, we can use the trapezoidal equation to replace integral equations (3) and (4) by the system of algebraic equations

$$i^{\omega}(x_p)=\sum_{q=1}^{N}k(x_p-x_q)\{J(x_q)-i^e(x_q)\}\,\Delta x, \tag{5}$$

$$i^e(x_r)=\sum_{q=1}^{N}k(x_r-x_q)\{J(x_q)-i^e(x_q)\}\,\Delta x, \tag{6}$$

where $\Delta x = l/N$; p = 1, 2, ..., ∞; r, q = 1, 2, ..., N; $x_p < 0$; and x_q, $x_r > 0$. We also assume that the transfer coefficient is essentially constant over the piston length l at a certain distance L. In this case we can write the intensity of the multiple reflection of light as

$$i^{\omega}(-L)=k(-L)\int_0^l \{J(\xi)-i^e(\xi)\}\,d\xi.$$

We can use this assumption to limit the number of equations in (5).

We solve system (5), (6) by the method of successive approximations, specifying a trial function $i_0^e(x)$. When values of the trial function $i_0^e(x)$ at the points $x = x_q$ are substituted in, Eq. (5) converts into a system of linear equations in the transfer coefficients. The determinant of this system is diagonal and nonvanishing. Solving system (5) we find the first approximation for the values of transfer coefficient $k_1(x)$. Then we substitute the values found for $k_1(x)$ into system (6) and find the first approximation for the intensity of the multiply reflected light within the piston, i_1^e. We again substitute this value into system (5), find the next approximation for the values of the transfer coefficient, etc.

It can be shown that the values found for $k_s(x)$ and $i_s^e(x)$ by the method of successive approximations reduce to certain limiting functions $\bar{k}(x)$ and $\bar{i^e}(x)$ which are the solutions of system (5), (6) if

$$\frac{J_{\max}^{\text{act}}\Delta x}{J_{\min}^{\text{act}}\Delta x}\,\frac{\sum_q k_q\Delta x}{1-\sum_q k_q\Delta x}<1, \tag{7}$$

where $J_{\max}^{\text{act}}$ and $J_{\min}^{\text{act}}$ are the maximum and minimum values of the actual intensity of the piston emission found from the trapezoid equation in writing system (5)-(6).

We note that, when criterion (7) holds, the solution of (5), (6) is unique and is a continuous function of the initial conditions.

As a rule, the value of $J_{\max}^{\text{act}}\Delta x$ is relatively independent of the choice of partition, while $J_{\min}^{\text{act}}\Delta x$ is strongly dependent on this choice. Accordingly, the partition must be quite coarse in order for criterion (7) to hold. Estimates of the error involved in replacing the system of integral equations by the system of algebraic equations[4,5] show that for partitions satisfying criterion (7) the error associated with this replacement remains completely satisfactory. Accordingly, the error involved in separating the measured radiation intensity into the actual intensity and the intensity of multiply reflected light is governed primarily by the errors in the measurement of $J_{\text{act}}^{\min}$.

Using Eqs. (5) and (6) we can show that the errors are related by

$$\max|\Delta i^e|<\frac{J_{\text{act}}^{\max}\Delta x}{J_{\text{act}}^{\min}\Delta x}\left\{1-\left(1+\frac{J_{\max}^{\text{act}}\Delta x}{J_{\min}^{\text{act}}\Delta x}\right)\sum_q k_q\Delta x\right\}^{-1}\max|\Delta i^{\omega}|. \tag{8}$$

Inequality (8) gives a mathematically rigorous estimate of the maximum possible error in the determination of i^e. When we take into account the actual relationship between the intensity of multiply reflected light and the transfer coefficients, we can show

$$|\Delta i^{e}| \sim \frac{J_{\max}^{\text{act}}\Delta x}{J_{\min}^{\text{act}}\Delta x}|\Delta i^{\omega}|. \tag{9}$$

Using these estimates, we can determine the error involved in distinguishing the actual intensity from the measured intensity, provided that we know the experimental error in the intensity of multiply reflected light measured before the arrival of the shock wave. In the case of relative measurements, there are basically two factors which contribute to the error in the determination of i^{ω}: noise in the light detector and the error in the recording. When there is a good signal-to-noise ratio, the error in the determination of i^{ω} can be greatly reduced by separately recording the intensity of the multiply reflected light before the arrival of the shock wave, using an amplification providing the largest possible reflection of the indicating device.

We have used this method to determine the contribution of multiple reflection of light to the emission in a study of the vibrational relaxation of carbon monoxide heated in an incident shock wave. Concrete calculations show that the left side of (7) turns out to be approximately equal to unity when the partition used provides the necessary accuracy in the replacement of the integral equations by algebraic equations. Accordingly, the convergence rate of the successive approximations is a strong function of the choice of the initial approximation i_0^e. It turns out that the best initial approximation is the function $i_0^e(\xi)$, constructed in the approximation of a constant-intensity piston. This initial approximation will evidently be convenient in other cases also. Figure 3 shows an oscillogram of the radiation in the fundamental band of CO at $\lambda = 4.7\ \mu$, obtained in a shock tube 57 mm in diameter. On this oscillogram we see the emission detected before the arrival of the shock wave (region I). The time at which the shock wave arrives is recorded by a piezoelectric transducer at the optical axis of the detection system. The "0" shows the initial approximation i_0^e, found under the assumption of a piston of constant intensity. In this case the third approximation of the intensity of multiply reflected light turns out to lie between the first and second and is not shown in this figure.

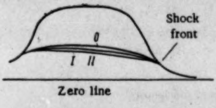

Fig. 3. Diagram used to determine the contribution of multiple reflection of light to the emission intensity.

CONCLUSION

These results demonstrate the applicability of this method, based on a measurement of the intensity of multiply reflected light before the arrival of the shock wave, for determining the contribution of multiply reflected light to the detected emission of the gas behind a shock front. When this method is used, it is a simple matter to evaluate the intensity of the multiply reflected light when the change in the radiation intensity over the length of the piston can be neglected. For an accurate account of the contribution of multiply reflected light, the method of successive approximations must be used to solve system (5)-(6). In the first case the calculations are elementary. This algorithm for an accurate determination of the contribution of multiply reflected light to the measured intensity can be easily adapted for computer calculations.

In conclusion the authors thank E. P. Fetisov and A. I. Lukovnikov for useful comments and for discussion of this work.

Brief communications

Nonlinear instability of a helicon packet in an anisotropic plasma

Ya. N. Istomin and V. I. Karpman

Institute of Terrestrial Magnetism, the Ionosphere,
and Radio-Wave Propagation,
Academy of Sciences of the USSR, Moscow

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 44, 649-651 (March 1974)

The instability region of a nonlinear quasimonochromatic packet of helicons ("whistlers") in a plasma with a loss cone is wider than that predicted by linear theory.

As is shown in ref. 1, the evolution of a quasimonochromatic wave packet of whistlers propagating parallel to the magnetic field in a collisionless plasma is described in the adiabatic approximation by

$$\frac{\partial h}{\partial t} - aF(h)\frac{\partial h}{\partial z} = 0, \tag{1}$$

where $h = B/B_0$ is the ratio of the slowly varying magnetic field of the wave, B, to the constant external field B_0, and the function F(h) is governed by the interaction of the wave with resonant particles (having velocities sufficiently close to the resonant velocity $v_R = (\omega - \omega_c)/k$, where ω is the wave frequency, ω_c is the gyrofrequency, and k is the wave number). Instead of writing the general expression for F(h) found in ref. 1 [for our purposes the most important feature of this function is that $F(h) > 0$], we turn to a more detailed examination of the constant a, whose sign determines the evolution of the packet:[1]

$$a = \frac{64}{3\pi^2}\gamma_L\tau_m W_T^{1/2}\frac{\int\limits_0^\infty f_0'(W)\,W^{5/2}dW}{\int\limits_0^\infty f_0'(W)\,W^3 dW}. \tag{2}$$

Here,

$$\gamma_L = \frac{\pi^2\omega_p^2\omega}{k^2c^2}\left(1 - \frac{\omega}{\omega_c}\right)\int\limits_0^\infty f_0'(W)\,W^3 dW \tag{3}$$

is the growth rate of the wave in the linear approximation, where

$$f_0'(W) = \left(\frac{\partial f}{\partial u} + \frac{\omega_c}{kW}\frac{\partial f}{\partial W}\right)_{u=v_R}, \tag{4}$$

$f(u, W)$ is the distribution function unperturbed by the wave, u is the longitudinal component of the particle velocity, W is its transverse component, and τ_m is the characteristic nonlinear oscillation period of the longitudinal velocity u about its resonant value v_R: $\tau_m = (k\omega_c h_m W_T)^{-1/2}$, where h_m is the maximum relative amplitude in the packet, and W_T is the average transverse thermal velocity of the electrons.

It follows from Eq. (1) that the evolution of a packet having a length considerably exceeding $v_R\tau_m$ (the criterion for the adiabatic approximation) proceeds in such a way that the maximum packet amplitude does not change (h_m = const), while its spatial width increases if $a > 0$ or decreases if $a < 0$. The constancy of the maximum packet amplitude corresponds to a familiar feature of the quasilinear theory of monochromatic waves: The amplitude of a plane wave no longer changes when the distribution function in the resonant region becomes ergodic.[1)]

In connection with the question of whether the packet spreads or contracts as a function of the sign of a, we note that this effect is due to the difference between the average motion of resonant particles in the field of the packet and in an incident plane wave. The spreading of the packet is actually a manifestation, in the nonlinear "quasiergodic" stage, of the effect of the instability, while a reduction in the packet width corresponds to resonant cyclotron damping.

We see from Eq. (2) that if the ratio of the integrals on the right side is positive, the sign of a is the same as the sign of the growth rate in the linear approximation, γ_L, i.e., the packet is unstable (or stable) in a plasma which is unstable (or stable) in the linear approximation. This situation is realized, e.g., in an anisotropic plasma having a bi-Maxwellian distribution (i.e., having difference longitudinal and transverse temperatures), so that the instability condition for such a plasma found in the linear approximation in ref. 3 also holds for nonlinear packets.

Here we show that there can be cases in which the region of the nonlinear instability is generally broader than in the linear approximation. As a simple example we consider a plasma with a loss cone, which has an unperturbed distribution function of the form

$$f(u, W) = n\left[\Gamma(j+1)\,\pi^{3/2}W_T^{2j+2}u_T\right]^{-1}W^{2j}\exp\left(-\frac{u^2}{u_T^2} - \frac{W^2}{W_T^2}\right). \tag{5}$$

Substituting (5) into (4) and (2), we find

$$a = \frac{64}{3\pi^2}\gamma_L\tau_m\frac{\Gamma\left(j+\frac{3}{4}\right)\left[j/\left(j+\frac{3}{4}\right)-\beta\right]}{\Gamma(j+1)\left[j/(j+1)-\beta\right]}, \tag{6}$$

where

$$\beta = 1 - \frac{W_T}{u_T}\left(1 - \frac{\omega}{\omega_c}\right). \tag{7}$$

The instability condition in the linear approximation ($\gamma_L > 0$) is

$$\frac{\omega}{\omega_c} < \rho_L \equiv \left(1 - \frac{u_T}{W_T}\right) + \frac{u_T}{W_T}\frac{j}{j+1}. \tag{8}$$

The condition for a nonlinear instability ($a > 0$), on the other hand, is seen from (6) to correspond to a broader range:

$$\frac{\omega}{\omega_c} < \rho_{NL} \equiv \left(1 - \frac{u_T}{W_T}\right) + \frac{u_T}{W_T}\frac{j}{j + \frac{3}{4}}. \tag{9}$$

Accordingly, in the frequency range $\rho_L < \omega/\omega_c < \rho_{NL}$, which lies in the linear-stability region, the packet retains its nonlinear instability.

As another characteristic example we consider the distribution function

$$f(V^2, \alpha) = \text{const}\,\frac{\sin^{2j}\alpha}{E^n}, \tag{10}$$

which is frequently used to describe the "hot-electron" component in the magnetospheric plasma [$\alpha = \arctan W/u$ is the pitch angle and $E = m(u^2 + W^2)/2$ is the kinetic energy]. In this case we have

$$\rho_L = \frac{j(j+2)}{(j+1)(j+n+1)}; \quad \rho_{NL} = \frac{j\left(j + \frac{7}{4}\right)}{\left(j + \frac{3}{4}\right)(j+n+1)}$$

and, as above, $\rho_{NL} \geq \rho_L$; these parameters are equal at $j = 0$.

We note in conclusion that, despite the close analogy mentioned in the footnote between the nonlinear theory of the resonant interaction of a wave with particles for whistlers and plasmons, the nonlinear-instability region is broader than the linear region only for whistlers, since, as is evident from (2), this broadening is due to the additional integrals over the transverse velocities.

The authors thank D. R. Shklyar for useful discussion.

---

[1] The quasilinear theory of monochromatic waves for whistlers is very reminiscent in both form and results of the corresponding theory for monochromatic longitudinal waves in an isotropic plasma. For a more detailed discussion of this point the reader is referred to the literature cited in ref. 1. The adiabatic theory for the evolution of a quasimonochromatic packet of plasma waves, which also leads to Eq. (1), is discussed in ref. 2.

Optimization of the paraxial asymptotic electric field in electron-optical systems

V. E. Ginzburg and V. N. Danilov
Institute of Radio Engineering and Electronics,
Academy of Sciences of the USSR, Moscow

(Submitted February 17, 1973; resubmitted July 20, 1973)
Zh. Tekh. Fiz., 44, 651-655 (March 1974)

A simple and fairly accurate paraxial asymptotic form is developed for the electric field inside and outside a dense electron beam; this is used in the analysis of paraxial axisymmetric electron-optical systems. It is possible to treat a strong inhomogeneity current density in a cross section, marked aberrations, and the intersection of electron trajectories, taking account of space-charge forces.

The development of calculational techniques makes timely the problem of computer design of optimum electron-optical systems (EOS). Requirements imposed on the trajectories and the electrodes must be satisfied simultaneously. First, trajectories must produce the required beam. As a rule the trajectories of the beam electrons must be similar although in many cases, as in the use of electrostatic lenses to shape electron beams with a weak inhomogeneity of the current density over the cross section, intersections of trajectories are unavoidable because of aberrations. The electrodes in turn must be technically feasible and the interelectrode distances must satisfy electrical strength requirements. Since computer design involves calculating a large number of variations, the calculational technique on which it is based, besides being accurate, must use a short calculational time per variation.

At the present time the electrodes of an EOS are synthesized for given beam characteristics on the basis of paraxial expansions of the field and beam parameters in powers of the transverse coordinate.[1-4] Paraxial expansions assume that the current density is only slightly nonuniform over the cross section of the beam, and are special cases of asymptotic expansions in powers of a small geometric parameter ε, which characterizes the narrowness of the beam, and a parameter ν which characterizes the narrowness of the band occupied by the electrodes.[5]

$$\varphi=\sum \varepsilon^k \varphi_k(r,\ z),\ \psi=\sum \nu^k \psi_k(r,\ z). \tag{1}$$

Here φ is the electric potential inside the beam, ψ is the potential outside the beam, and r and z are cylindrical coordinates. The coefficients φ_k allow a non-power-law radial dependence corresponding to a strong nonuniformity of the current density. The parameter ν is generally much larger than ε since the band of definition of the external field is several times broader than the band occupied by beam. Generally speaking, the errors of the expansions are commensurate if the series for ψ contains more terms than the series for φ.

Synthesized electrodes generally turn out to be complex; in practice electrodes are constructed from cylindrical and conical surfaces. Computer simulations to analyze beam perturbations due to the simplification of electrode shapes are much more time consuming than synthesis. The present paper seeks the simplest asymptotic approximation permitting the synthesis and analysis of an axisymmetric EOS with adequate accuracy. The corresponding approximations for a plane-symmetric EOS are similar and will not be presented.

An estimate is made of the electric forces acting outside the cathode region of an electron gun,[6] including a triode,[7] in electrostatic lenses,[8] and in systems with electron retardation.[9] The forces determined by the fourth derivative of the potential on the U_z axis are commesurate with the forces due to the space charge ρ; outside the beam these forces exceed the forces corresponding to the expansions.

$$\varphi=U-\frac{1}{4}U''r^2+\frac{1}{64}U^{\mathrm{IV}}r^4+4\pi\int\limits_0^r\frac{dr}{r}\int\limits_0^r\rho r dr, \tag{2}$$

$$\psi=U-\frac{1}{4}U''r^2+\frac{1}{64}U^{\mathrm{IV}}r^4-\frac{1}{2304}U^{\mathrm{VI}}r^6+\Pi+B\ln\frac{r}{r_{\mathrm{B}}}, \tag{3}$$

$$B=2\frac{I_{\mathrm{B}}}{v},\ 2\pi\int\limits_0^r\rho r dr=\frac{I}{v},\ \Pi=\frac{2}{v}\int\limits_0^{r_{\mathrm{B}}}I\frac{dr}{r},\ v=\sqrt{\frac{2e}{m}U}.$$

Here the family of trajectories is given in parametric form $r = r(z, I_0)$. The parameter I_0 is equivalent to the parameter r_H, the radial coordinate of an electron with a given trajectory at the entrance to the system, and represents the current flowing in the system through a circle of radius r_H. The subscript B denotes quantities referring to the beam boundary. It is convenient to have the parameter I_0 change by the same amount from trajectory to trajectory. If the trajectories do not intersect, the trajectory parameter I_0 in any cross section of the beam corresponds to the current I flowing through a circle whose radius is equal to the radial coordinate of the electron. If there are intersections I_0 remains a trajectory parameter equivalent to r_H. For machine calculations it is convenient to number the trajectories, e.g., from 1 to 10, and to take account of the change in space-charge forces by the exchange of I_0 values between intersecting trajectories. Then I_0 and I will correspond. The following assumption is made to evaluate the integrals in Eqs. (2) and (3). In each cross section of an annulus whose inner and outer radii are determined by the radial coordinates of electrons with adjacent trajectories there is a uniformly distributed current equal to the difference in the values of I_0 for these trajectories.

Expansions (2) and (3) contain terms related both to the charges on the electrodes, including those induced by the beam, and to the space-charge density ρ. We limit ourselves to terms larger than or commesurate with the first approximation for the space charge potential. The ratios of the orders of magnitude of the forces, confirming the validity of approximations (2) and (3) for the systems named above, are shown in Fig. 1 for the case of a single electrostatic lens.[8] The transformation to dimensionless quantities normalized to unity for the EOS's named above separates out the small parameters in Eqs. (2) and (3): ε in front of r in (2), ν in front of r in (3), and ε^2 in front

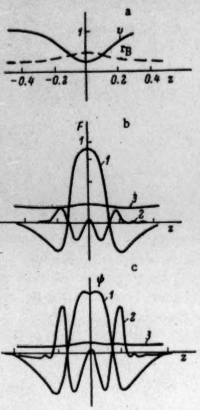

Fig. 1. Ratios of orders of magnitude of forces in an electrostatic lens shaping a beam with a perveance of 0.78 $\mu A/V^{3/2}$. a) Distribution of potential U along the axis of the lens and along the boundary trajectory of an electron r_B; b) forces F acting on a boundary electron of the beam determined by (1) the second derivative of the potential, (2) the fourth derivative, and (3) the space charge; c) contribution of these forces to the potential distribution outside the beam.

of ρ and I. Thus, in comparison with the asymptotic forms[5] the space charge terms are displaced to higher approximations. The modified paraxial equation for a family of electron trajectories $r(z, I_0)$, within the framework of the same asymptotic accuracy, has the form

$$2r''\left(U-\frac{r^2}{4}U''-G_1\right)(1+r'^2)^{-1}+r'\left(U'-\frac{1}{4}r^2U'''+G_2\right)+\frac{r}{2}U''-\frac{r^3}{16}U^{IV}+G_3=\frac{2I}{rv};\ r'=\frac{\partial r}{\partial z}. \quad (4)$$

The terms G_1, G_2, and G_3 describe the effect of the magnetic field

$$G_1=\frac{m}{e}\frac{v_\theta^2}{2},\ G_2=\frac{v_\theta}{c}H_r,\ G_3=\frac{v_\theta}{c}\left(H_z-\frac{mcv_\theta}{er}\right),$$
$$v_\theta=\frac{e}{mc}\left(A_\theta-A_{\theta k}\frac{r_k}{r}\right),\ A_\theta=\frac{r}{2}H-\frac{r^3}{16}H'',\ H_z=\frac{1}{r}\frac{\partial(rA_\theta)}{\partial r},$$
$$H_r=-\frac{\partial A_\theta}{\partial z}.$$

Here H is the intensity of the magnetic field, A_θ is the azimuthal component of the vector potential, v_θ is the azimuthal component of the electron velocity, e and m are the charge and mass of the electron, c is the velocity of light, and the subscript k denotes quantities referring to the cathode.

We present below the results obtained by this method. The synthesis of an axisymmetric electrostatic lens shaping a beam with a perveance of 0.78 $\mu A/V^{3/2}$ is shown in Fig. 2. For this case

$$U=U_0(0.233+0.767\ \mathrm{th}\ 20z^2).$$

The running time on an M-220 computer is 30 sec. The same lens is calculated by an analytical method on a BÉSM-6 computer. The trajectories in the two cases agree within the accuracy of the curves. The spatial distribution of the potential for these cases is shown in Fig. 3. In the region where the potential gradients are large the equipotentials coincide within the accuracy of the curves, but in drift tubes the behavior of the equipotentials is somewhat different. This difference can be explained simply.

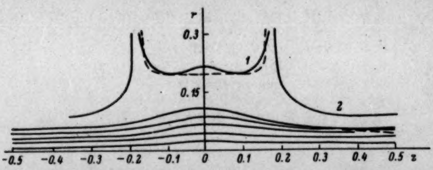

Fig. 2. Electrodes of an electrostatic lens, and electron trajectories. Open curves show a simplified electrode with zero potential, and the perturbed boundary trajectory, ψ: 1) 0; 2) $1U_0$.

If the potential on the axis is given by a polynomial of the sixth degree or less, expansions (2) and (3), neglecting space charge, yield an exact solution of Laplace's equation. Although the space charge forces are taken into account in the present problem they do not play a decisive role, as follows from Fig. 1. Near z = 0 the higher terms of the series for tanh $20z^2$ are small and as long as the series can be replaced by a sixth-degree polynomial Laplace's equation is solved exactly. In the drift tube region the higher terms of the series are important but there the potential gradients are small and therefore the trajectories through the whole lens are considered accurate over all.

Figure 2 shows that aberrations play an important role in the lens. They are still larger if the perveance is increased without decreasing the length of the lens. In principle the aberrations can be compensated by increasing the space-charge density of the beam from the axis to the boundary. Figure 4a shows the lens

$$\frac{U}{U_0}=0.44+0.56\ \mathrm{th}\ 16.7z^2-0.136e^{-23.4z^2},$$

shaping a beam with a perveance of 1.5 $\mu A/V^{3/2}$ and similar trajectories. The calculation was performed for 10 trajectories, five of which are shown in the figure. The current distribution over the cross section of the beam necessary for this is shown in Fig. 4b. Lenses with such a large nonuniformity of the current density cannot be synthesized by using an expansion in powers of the transverse coordinate.

To analyze the small perturbations in the potential on the axis we add the correction $\Delta(z)$ representing a su-

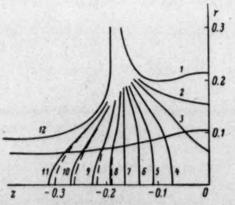

Fig. 3. Spatial distribution of potential for lens of Fig. 2. The solid curves are obtained by an analytic method using program KSI on a BÉSM-6 computer, and the open curves by our method. ψ: 1) 0, 2) 0.1, 3) 0.2, 4) 0.3, 5) 0.4, 6) 0.5, 7) 0.6, 8) 0.7, 9) 0.8, 10) 0.9, 11) 0.95, 12) $1U_0$.

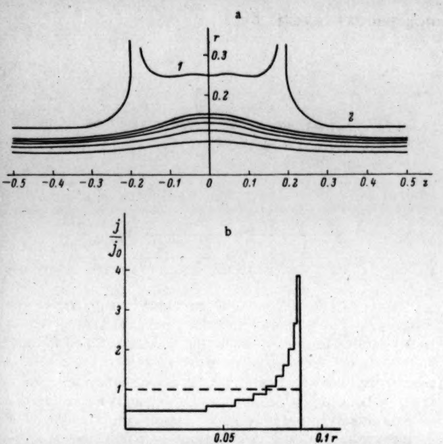

Fig. 4. a) Electrostatic lens shaping a beam with a perveance of 1.5 $\mu A/V^{3/2}$; ψ: 1) 0; 2) $1U_0$. b) Distribution of current density over the cross section of the beam entrance to a lens whose aberrations are compensated and through which the electron trajectories are similar.

perposition of functions e.g., $\Delta(z) = \sum_k A_k e^{\alpha k z^2}$. The coefficients in this expansion are chosen in such a way that the paraxial expansion of the harmonic field connected with this correction would lead to the given perturbation in the shape of the electrodes. To do this we specify 5-10 times as many points on the electrodes as there are coefficients to be determined and use the method of least squares to determine the coefficients A_k. This is a somewhat unusual application of the method of least squares since the analytic continuation of a function rather than the function itself is approximated.

By solving Eq. (4) and taking account of the field of the correction we find the perturbations of the trajectories. The perturbations of the trajectories arising from the perturbations of the space charge forces are hardly larger than the inaccuracies in plotting the graphs and can be ignored. Figure 2 shows the perturbation of the zero electrode to give it a more technological shape, and the perturbation of the boundary trajectory. For this case

$$\frac{U}{U_0} = 0.233 + 0.767\,\mathrm{th}\,20z^2 - 0.0388e^{-16z^2} + 0.0543e^{-28z^2} - 0.0307e^{-40z^2}.$$

The asymptotic form is generally valid outside the cathode region. In the immediate vicinity of the cathode the space charge forces are commensurate with the forces given by the second derivative of the potential, and taking account of higher derivatives gives a divergence. However, if the beam has a perveance of several units ($\mu A/V^{3/2}$) the forces given by higher approximations are small at distances from the cathode smaller than a quarter of its diameter. For a machine calculation the coefficient of the higher approximations, normally equal to unity but set equal to zero near the cathode, can vary smoothly from zero, corresponding to the model of a spherical diode, to unity for the asymptotic form. The determination of the zero electrode in the cathode region can be reduced to drawing a straight line from an edge point of the cathode at an angle of 67.5° with the boundary of the beam until it intersects the zero electrode given by (3). It should be noted that the model of a spherical diode is used in all the other methods of calculation in the cathode region.

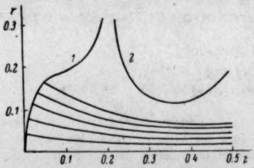

Fig. 5. Electrodes of a gun shaping a plane-symmetric beam, and the electron trajectories. ψ: 1) 0; 2) $1U_0$.

Figure 5 shows the results of the synthesis of a plane symmetric gun with a perveance per square of 1.8 $\mu A/V^{3/2}$

$$\frac{U}{U_0} = 0.92\,\mathrm{th}\,3.33x^{4/3}(1 + 1.6x + 3.32x^2).$$

The trajectories and perveance are in good agreement with numerical calculations.

Thus, the proposed procedure enables us to describe beams with a stronger transverse nonuniformity than is possible with the paraxial expansion,[2-4] and with intersecting trajectories. The solution of the external problem is so simplified that it appears possible to solve the analysis problem as a refinement of the synthesis problem. The solution of the external problem here does not require transforming to a curvilinear coordinate system and back; taking account of the contribution to the shape of the electrodes from the fourth and sixth derivatives of the axial potential does not require finding the extremely cumbersome higher expansions of the space-charge field. Aberrations are taken into account only through the presence of the term proportional to the fourth derivative of the axial potential. The expression for the external field does not contain the sources of nonuniformity arising in refs. 2-4 from representing the field in a nonharmonic coordinate system connected with the boundary trajectory which has a large curvature in the EOS considered.

In our opinion the asymptotic form described here is a necessary step away from classical electron optics; we go from the representation of the field in terms of the boundary trajectory of the beam to the representation of the beam trajectories in terms of the field parameters.

Long-wave cyclotron instability in a plasma in an inhomogeneous magnetic field

A. S. Kukushkin

(Submitted June 4, 1973)
Zh. Tekh. Fiz., 44, 655-658 (March 1974)

A differential equation is found for a long-wave-cyclotron instability in a plasma cylinder field. The eigenvalue problem for this equation with homogeneous boundary conditions is solved numerically. The inhomogeneity of the magnetic field reduces the growth rate.

INTRODUCTION

In a plasma with a nonequilibrium ion velocity distribution – a case typical of open confinement systems – ion instabilities can be excited at a frequency near the ion gyrofrequency or its harmonics. The linear theory for this instability in a plasma in a homogeneous magnetic field has been worked out in great detail (see, e.g., refs. 1, 2). In real systems, however, the field is always inhomogeneous. Since the instability is due to resonance effects (plasma waves and cyclotron rotation), the inhomogeneity of the field can be significant.

In most work on the cyclotron instability in an inhomogeneous magnetic field attention has been focused on the effect of an inhomogeneity along a line of force. However, in a plasma with the shape of a pancake (transverse dimension larger than the longitudinal dimension), the inhomogeneity across the magnetic field[19] is more important.

The exact integrodifferential equation for this case is rather complicated. However, for the long-wave case the ratio of the Larmor radius to the characteristic transverse dimension (23/957) becomes a small parameter. It can therefore be used for an expansion, as in ref. 3, and a second-order differential equation can be obtained. Below we derive the eigenvalue problem for this equation, with a homogeneous boundary condition at the surface of the plasma cylinder; we solve this problem numerically.

It turns out that even a pronounced inhomogeneity (an increment in the gyrofrequency which is much larger than the growth rate) does not provide complete stabilization; instead, it simply reduces the growth rate and changes the frequency of the long-wave instability.

OSCILLATION EQUATION

We consider a plasma cylinder of radius R_0 and homogeneous density in a magnetic field which is directed along the axis of the cylinder. We assume the magnetic lines of force to be straight, and that the functional dependence of the field on the radius $H_z = H_0[1-\rho(r/R_0)^2]$, where $\rho \ll 1$. We consider a perturbation in the electric potential like

$$\varphi = \psi(r)\, e^{-i\omega t + ikz + im\theta}$$

in the cylindrical coordinate system r, θ, z.

For simplicity we assume the electrons to be cold ($T_e = 0$). Then, using the method of ref. 3, and assuming $|(v_\perp/\omega_i)(d\psi/dr)| \ll 1$, we obtain the following equation for modes near the ion gyrofrequency, $\omega \approx \omega_i$:

$$\frac{1}{r}\frac{d}{dr}\left(r(1+A(r))\frac{d\psi}{dr}\right) - \frac{m^2}{r^2}(1-A(r))\psi - k^2\left(1-\frac{\omega_{0e}^2}{\omega^2}\right)\psi = 0, \quad (1)$$

where

$$A(r) = \frac{\omega_{0i}^2}{4\omega_i^2}\int_0^\infty v_\perp^3\, dv_\perp \int_{-\infty}^{\infty} dv_\parallel \frac{(\omega - kv_\parallel)\frac{1}{v_\perp}\frac{\partial f_0}{\partial v_\perp} + k\frac{\partial f_0}{\partial v_\parallel}}{\omega - \omega_j(r) - kv_\parallel}.$$

Here ω_j is the plasma frequency for particles of species j, ω_i is the ion gyrofrequency, and $f_0(v_\parallel, v_\perp)$ is the equilibrium ion distribution function. Since Eq. (1) holds only for long-wave modes, the effects of the nonmonotonic nature of the distribution of ions with respect to transverse velocity are inconsequential, and we can choose as f_0 an anisotropic Maxwell distribution with $T_\perp \gg T_\parallel$. To simplify the calculations we restrict the discussion to the case m = 0. Then Eq. (1) becomes

$$\frac{1}{r}\frac{d}{dr}\left(r(1+A(r))\frac{d\psi}{dr}\right) - k^2\left(1-\frac{\omega_{0e}^2}{\omega^2}\right)\psi = 0, \quad (2)$$

where

$$A(r) = \frac{\tau}{2}\frac{\omega_{0i}^2}{\omega_i^2}\left(1 + i\sqrt{\pi}\frac{\omega_i}{ku}\left(\frac{1}{\tau} + \frac{\omega-\omega_i(r)}{\omega_i}\right)W\left(\frac{\omega-\omega_i(r)}{\omega_i}\right)\right).$$

Here

$$\tau = \frac{T_\perp}{T_\parallel},\quad u = \sqrt{\frac{2T_\parallel}{m_i}},\quad \omega_i(r) = \omega_i\left(1-\rho\left(\frac{r}{R_0}\right)^2\right),$$

and

$$W(z) = e^{-z^2}\left(1 + \frac{2i}{\sqrt{\pi}}\int_0^z e^{t^2}dt\right)$$

is the probability integral of complex argument.

EIGENMODES

We supplement Eq. (2) with the boundary conditions

$$\psi(R_0) = 0,\ \psi(0) = 1 \quad (3)$$

and we seek the eigenvalues ω for this problem (the case Im $\omega > 0$ corresponds to an instability).

When $\rho = 0$ (a homogeneous field) and $|(\omega-\omega_i)/ku| \gg 1$ (a pronounced anisotropy of the temperatures) we can replace the function W(z) by its asymptotic representation $W(z) \approx (i/\sqrt{\pi})\,(1/z + 1/2z^3)$. Then the eigenfuntions of the problem are the Bessel functions $J_0(k[(1-\omega_{0e}^2/\omega^2)/(1+A)]^{1/2}r)$ and we find the following dispersion relation for ω:

$$\frac{k^2}{\mu^2}\left(1-\frac{\omega_{0e}^2}{\omega^2}\right) = -(1+A),$$

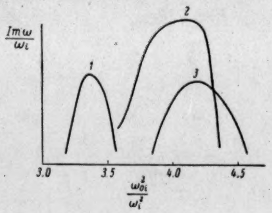

Fig. 1. Functional dependence of the growth rate on the plasma density in various fields. ρ: 1) 0.1; 2) 0; 3) −0.1.

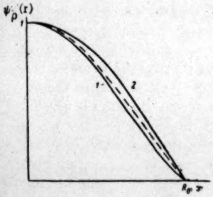

Fig. 2. Eigenfunctions $\psi_\rho(r)$ for various fields. The dashed curve shows the Bessel function $J_0(\mu r/R_0)$. ρ: 1) 0.1; 2) −0.1.

where μ is the first root of Bessel function $J_0(z)$. This equation (in different notation) is analyzed in ref. 4.

Here we consider the case $\rho \neq 0$. We cannot solve Eq. (2) analytically, so we are forced to find the eigenvalues ω for problem (2), (3) by a numerical method.

Figure 1 shows the functional dependence of the growth rates on the parameter ω_{0e}^2/ω_i^2 for the case

$$p \equiv \left(\frac{\mu}{R_0\omega_i}\right)^2 \frac{2T_\perp}{m_i} = 0.3, \; q \equiv \left(\frac{k}{\omega_i}\right)^2 \frac{2T_\perp}{m_i} = 0.1, \; \tau = 4 \cdot 10^3$$

and for various values of ρ. Here the real part of ω is approximately equal to the minimum value of the gyrofrequency in the plasma. This picture is qualitatively the same as that described by the results of ref. 5.

Figure 2 shows the eigenfunctions $\psi_\rho(r)$ for various values of ρ; we see that they are approximated by $\psi_0 \equiv J_0(\mu r/R_0)$. The quantity $1 + A(r)$ has no zeros at Im $r \geq 0$, Im $\omega \geq 0$, although these zeros move arbitrarily close to the real r axis as the parameter $\alpha = \sqrt{\tau/q}$ increases. However, in cases of practical interest, the value of α does not exceed the value $\alpha = 200$ assumed in our calculations.

Accordingly, the modes remain long-wave over plausible ranges of the parameters, even in an inhomogeneous field, so that the assumptions used in deriving Eq. (1) are valid and this formulation of the problem is internally consistent.

The good approximation of the eigenfunctions of problem (2), (3) by the Bessel functions, which are the basis functions for the expansion in ref. 5, confirms the validity of this expansion for long-wave perturbations.

We note that the transverse inhomogeneity of the field does not lead to complete stabilization; instead, it only causes a reduction in the growth rate for long-wave modes.

The author thanks V. V. Arsenin for suggesting this problem, and thanks Yu. N. Dnestrovskii for his interest.

Zh. Tekh. Fiz., 44, 658-660 (March 1974)

The formation of the return current is studied experimentally in an electron accelerator at energies up to 1 MeV and at currents up to 50 kA. The results agree with a model which only takes account of elementary processes. The velocity of the ionization front is measured in various gases at pressures of $5\cdot 10^{-2}$-10 torr.

The transmission of high-current relativistic beams through a neutral gas is of interest in several problems (e.g., heating plasmas, powerful microwave and x-ray sources, pumping gas and solid-state lasers, etc.) in which processes of beam energy transport are important. We report here a study of the transmission through a gas of a pulsed electron beam at an energy of 1.0 MeV, a current up to 50 kA, and a pulse length of $3\cdot 10^{-8}$ sec. The beam is produced by a high-current accelerator, which uses a cylindrical double shaping line and distilled water as a dielectric.[1]

We study the transmission of such a beam through a gas-filled metal chamber 300 cm long and 11 cm in diameter. To determine the energy lost by the beam we carry out calorimetric measurements of the beam energy at the entrance and exit of the plasma chamber. The difference between the corresponding calorimeter readings gives the energy lost by the beam as it travels through the gas. Figure 1 illustrates the efficiency of energy transport by a high-current relativistic beam as a function of the gas pressure in the chamber. We see that the optimum conditions for passage of the beam obtain at 0.5-2 torr.

It has been shown previously[2,3] that the transmission of a high-current relativistic beam through a plasma under conditions such that the current rise time t_r is much shorter than the skin time $t_r \ll t_d = 4\pi\sigma r^2/c^2$ (here σ is the plasma conductivity, r is the beam radius, and c is the speed of light) leads to the production of a return current, which tends to cancel the self-magnetic field of the beam. Figure 1 apparently shows that at pressures below 0.2 torr the return current is not sufficient to balance the self-magnetic field of the beam because of the low plasma density; the electron Larmor radius becomes smaller than the beam radius, thereby blocking the beam. As the pressure is raised above 4 torr one of the mechanisms that degrades the beam transport is scattering of electrons of the return current by ions and gas atoms. These transport conditions were studied previously.[1] Measurements of beam transport through a gas show that at pressures of 0.5-2 torr an electron beam can transport up to 80% of the energy over a length of 300 cm. The fraction of the energy lost is apparently due to the escape to the chamber walls of electrons accelerated in radial fields, due to the incomplete neutralization of the beam charge and scattering of electrons by the anode foil and gas atoms. It is also necessary to take account of the energy carried to the walls by particles accelerated in fields excited in collective interactions of the relativistic beam with the plasma. At low pressures the formation time of the return current and, thus, the characteristic time for neutralization of the self-magnetic field of the beam, can become comparable to the length of the current pulse (Fig. 2a), and again there would be a reduction of the energy characteristic of the beam. The formation time for the return current during the transmission of a relativistic beam through the gas is determined experimentally. The formation time for the return current is determined as a function of the pressure from signals taken from shunts detecting the electron-beam current I_m and the current flowing through the walls of the plasma chamber, $I_{wa} = I_m - I_{ret}$. Figure 2a,b, shows oscillograms of I_{wa}, which illustrate the formation of the return current in helium at various pressures. The experimental values of the return current formation time in various gases are shown along with the theoretical values in Table 1. The return current formation time is determined from

$$\frac{1}{t_b}\exp\left(\frac{t_b - t_n}{t_i}\right) = \frac{80}{p}\,\frac{1}{t_i\,(t_i + t_n)}\,\frac{1}{\beta}\,, \tag{1}$$

where t_b is the formation time of the return current, t_i

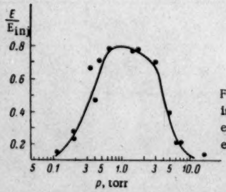

Fig. 1. Transport curve for a relativistic electron beam in air. The average beam current is 40 kA, and the energy is 0.6-0.7 MeV.

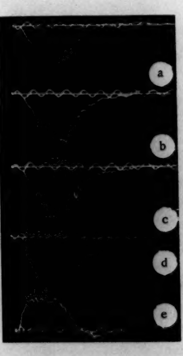

Fig. 2. Formation of the return current in helium. The beam current is 25 kA, and its energy is 0.8 MeV. The oscillograms shown here are proportional to the current flowing through the chamber wall, I_{wa}, for various gas pressures. p, torr: a) 10^{-1}; b) $1.7\cdot 10^{-1}$; c) $3.1\cdot 10^{-1}$; d) 1.3; e) beam-current pulse. The period of the time marker is 10^{-8} sec.

TABLE 1. Formation Time for the Return Current in Various Gases as a Function of the Pressure (electron energy of 0.8 MeV and current of 25 kA)

Gas	Pressure, torr				
	0.1	0.3	0.6	1.0	2.0
Hydrogen.	23.5	18.0	14.5	12.5	10.0
Helium	20.0	17.5	16.5	16.0	15.0
Neon	21.0	14.5	13.0	12.0	11.0
Argon	22.0	11.5	9.5	9.0	—
Air.	20.0	13.0	8.5	7.0	—
Air.	27.0 *	9.0 *	7.0 *	6.0 *	—

*Values of t_b calculated from Eq. (1).

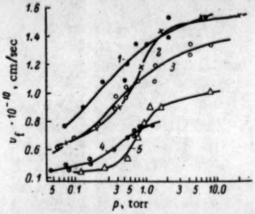

Fig. 3. Velocity of the ionization front as a function of the nature and pressure of the gas. Beam current of 25 kA and energy of 0.8 MeV. 1) Nitrogen; 2) argon; 3) hydrogen; 4) helium; 5) propane–butane mixture.

is the ionization time, t_n is the neutralization time, p is the gas pressure, and β is the velocity of the beam electrons.

This equation is derived under the approximation of a diffusion mechanism for the formation of the return current.[4] The agreement between the observed return current formation time and the theoretical time shows that elementary processes are predominant in the mechanism for the formation of plasma by the relativistic beam. A similar result was obtained in refs. 5-7.

An important characteristic of the transmission of a high-current relativistic beam through a gas is the velocity of the ionization front.[8] In our experiments we measure this velocity in the following manner: We place four loop-shaped pickups along the axis in the plasma chamber to detect the passage of the ionization front. The time intervals between the signals from the pickups are recorded on a six-trace oscilloscope with a time resolution better than $2 \cdot 10^{-10}$ sec; the velocity of the ionization front is calculated from these time intervals. The measured velocities of the ionization fronts in helium and nitrogen agree in order-of-magnitude with those calculated from the following equation:[9]

$$v_f = \sqrt{\frac{mc^3}{2\pi e j_0}}\, \nu_i \left(\gamma^{2/3} - 1\right)^{3/4}, \tag{2}$$

where $j_0 = env_0$ is the beam current density, ν_i is the ionization rate, γ is the relativistic factor, e is the electron charge, and m is the electron mass.

Figure 3 shows the measured velocities of the ionization front as a function of the pressure for various gases. We see that the front velocity does not exceed $1.6 \cdot 10^{10}$ cm/sec.

It was shown in refs. 9-11 that when a high-current relativistic beam is injected into a gas ions are captured and accelerated to a velocity $v_i = v_f$ in the potential well of depth $e\varphi \leqslant mc^2(\gamma - 1)$ at the ionization front. The efficiency of this mechanism is relatively low because the accelerated ions leave the potential well after they overtake the ionization front. Fainberg has proposed a method for increasing the efficiency of this acceleration through an increase in the velocity of the ionization front as it propagates through the plasma chamber. Under these conditions, the ions spend a considerable time in the accelerating field, so that the acceleration efficiency is increased. In our experiments we have studied the possibility of increasing the velocity of the ionization front by producing a pressure gradient along the chamber axis. Our measurements show that with a pressure changing from 0.2 torr at the front of the chamber to 1-2 torr at its end, the velocity of the ionization front increases by a factor of 1.4- 1.6, depending on the nature of the gas.

In conclusion the authors thank Ya. B. Fainberg for interest in this work, and E. A. Lemberg, N. P. Gadetskii, and V. D. Bondarenko for assistance in the experiments.

Radar sounding of sea ice

V. V. Bogorodskii and V. P. Tripol'nikov
Arctic and Antarctic Scientific-Research Institute, Leningrad
(Submitted July 31, 1973)
Zh. Tekh. Fiz., 44, 660-662 (March 1974)

The possible use of active radar methods to measure the thickness of sea ice has been suggested. Methods are available for measuring the thicknesses of floating ice covers.[1] Technical aspects of this problem have been examined.[2-5]

In the present work we discuss the results of an experiment on the radar sounding of sea ice from an aircraft. For this experiment we use a pulsed locator with the following parameters: carrier frequency, 100 MHz; pulse length 50 nsec; antenna directivity 6 dB; a locator potential of 140 dB.

The experiments are carried out near the SP-21 drifting station on pack ice more than 3 m thick, which is many years old; on pack ice ranging from 2 to 3 m in thickness, which is two years old; and on young ice 1-1.5 m thick. The results demonstrate directly feasibility of remote measurements of the thickness of ice formations of this type. Figure 1a shows oscillograms of the radar sounding of pack ice from an aircraft flying at an altitude of 100 m at a speed of 150 km/h; these oscillograms are taken in succession at an exposure time of 0.5 sec. A feature of the reflected pulses received on board the aircraft is the short lifetime of their stable image. The lifetime proper is governed by the speed of the aircraft. The level of the reflected signals recorded during the flight is governed by the state of the reflecting surfaces and the physical properties of the medium (ice). The signal reflected from the top of the ice is subjected to fluctuations due to irregularities in the relief and to variations in the matching of the snow cover with the upper layers of the ice. The same factors, along with scattering and absorption in the ice – factors which vary during horizontal motion over the ice – cause fluctuations in the signals reflected from the lower boundary of the ice. It should also be noted that the nature of the fluctuations is affected by the size of the "spot" irradiated by the radar.

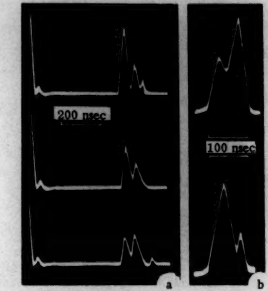

Fig. 1. Oscillograms obtained in the sounding of ice in the ocean. a) Pack ice with an average thickness of 5-6 m; b) superposition of the signals reflected from the top and bottom of young ice 1.5-1.7 m thick.

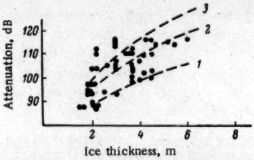

Fig. 2. Total attenuation of the signals reflected from the ice–water interface as a function of the ice thickness. 1) 1; 2) 3; 3) 5 dB/m.

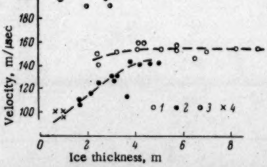

Fig. 3. Propagation velocity of the radar signal in the ice. 1) In pack ice without a snow cover; 2) for regions of pack ice covered by snow more than 0.5 m thick; 3) for pack ice with a porous texture; 4) in young ice 1-1.5 m thick at an air temperature of – 23 to – 25°C.

Signal fluctuations, although weaker, are found even in the sounding of fields of young ice, with level, almost smooth, surfaces. Measurements show that the total attenuation of signals reflected from the top of the ice varies from 90 to 120 dB when the aircraft is 100 m above packed ice. Of this fluctuation, the calculated geometric loss is 80 dB, and the (Fresnel) reflection loss is 10 dB for a dielectric constant of $\varepsilon' = 3.5$ for the ice. Accordingly, the loss due to scattering by the surface and the impedance mismatch of the media is 0-30 dB; for young ice, this latter loss is 0-10 dB. The total attenuation of the signals reflected from the bottom of the ice is on the same order of magnitude. The dashed curves in Fig. 2 show the calculated functional dependences of the total attenuation on the ice thickness at fixed values of the specific absorption in homogeneous ice with plane-parallel surfaces; the points show the experimental attenuations. This figure shows that the specific absorption does not exceed 1-5 dB/m in these experiments. Shown here is the entire range of signal amplitudes, without statistical characteristics. The fact that the signals shown in Fig. 1 are recorded at an exposure time of 0.5 sec and the fact that the aircraft moves 20 m during this time imply that it would be useful to use a statistical approach in analyzing the results. For this purpose it would be necessary to use a photodetection method with a short exposure time or to use some other rapid recording device.

There is another, extremely important, aspect of this problem: The thickness of the ice shown in Fig. 2 is calculated from the results of the sounding on the basis of the equation $h = v\tau/2$, where τ is the time interval between the reflected pulses and z is the propagation velocity of the signal in the ice.

The reliability of an interpretation of data from radar sounding of ice in the ocean is a function of the reliability of the signal-propagation velocity. The velocity of electromagnetic waves in ice in the ocean is governed by the relative amounts of liquid, solid, and gaseous phases (brine, crystalline ice, and air bubbles) in the ice. Accordingly, the propagation velocity of the radar signal can differ in ice formations of different ages and which were formed under different conditions. The velocity of vertical propagation of electromagnetic waves, averaged over the thickness, has been measured in regions of the ice fields along the flight path. These measurements show that the wave velocity in pack ice takes on different values over the same ice field. In regions devoid of a snow cover the propagation velocity averages 150 m/μsec (Fig. 3); in regions where the snow cover is more than 0.5 m thick, this velocity decreases with decreasing ice thickness. This fact can be explained by assuming that heat accumulates under snow-covered regions, so these regions are relatively rich in the liquid phase. Accordingly, the results of the radar sounding make the ice pack seem more homogeneous with respect to thickness than it actually is. Where the ice has a clearly defined porous structure, the propagation velocity is 190-200 m/μsec. The velocity of electromagnetic waves in young ice 1 m thick is 90-100 m/μsec at a stable air temperature of from −23 to −25°C. This velocity decrease is attributed to the greater salinity of young ice, since a high salinity is also a prerequisite for a relatively high content of liquid phase. The velocity of the radar signal in young ice is presumably governed significantly by the temperature conditions also. The velocity may be lower, the thinner the ice and the higher its temperature. Because of the fluctuations in the signal velocity in ice in the ocean, a correct interpretation of the results of radar mapping of the thickness requires a knowledge of the temperature conditions and a classification of the ice being probed.

Two-section solenoid with internal "equally-loaded" section; power as a function of the length of the internal section

G. S. Veisig, A.P. Doroshenko, and P. P. Rybin

Institute of Physics, Siberian Branch,
Academy of Sciences of the USSR, Krasnoyarsk

(Submitted July 3, 1973; resubmitted August 16, 1973)
Zh. Tekh. Fiz., 44, 662-666 (March 1974)

A two-section solenoid whose internal section is wound from a tape of varying width to provide the desired current density is analyzed. The turns of this internal section are not in mechanical contact with each other. The current-density distribution is specified in such a manner that the mechanical stress is the same, equal to the maximum tolerable, in all turns of the solenoid (except those of the external section). This distribution makes it possible to achieve strong magnetic fields. The outer radius of the internal section is shown to be a function of the length of this section; the functional dependence is found. The functional dependence of the power drawn by the entire solenoid on the length of the internal section is also found. There is a particular length of this section for which the power is a minimum. Upper and lower limits are found for this length.

The maximum solenoid field attainable with a material of limited strength is achieved by mechanically loading all the material of the solenoid to the maximum tolerable point[1] (we call such a solenoid an "equally loaded solenoid"). Since it is difficult to find the necessary current-density distribution j(r, z), we restrict the treatment below to a search for the values of j (r) which provide a uniform stress σ in the central plane of the solenoid, using the floating-turn model. In this case we have

$$\sigma = \frac{1}{10} H(r) j(r) r, \tag{1}$$

where H(r) is the magnetic field (in oersteds) at a point r between r_1 and r_2 [r_1 and r_2 are the inner and outer radii of the solenoid (in centimeters)], and σ and j(r) are given in dynes per square centimeter and amperes per square centimeter, respectively.

We approximate H(r) by

$$H(r) = \frac{4\pi\lambda}{10} \int_r^{r_2} j(r) \frac{k(r)}{\sqrt{k^2(r)+1}}\, dr, \tag{2}$$

where λ is the filling coefficient, and k(r) is equal to half the width of a layer of the solenoid winding divided by the radius of this layer. It should also be noted that Eq. (2) holds only for $k(r) \gg 1$. Then we can write Eq. (1) as

$$\sigma = r j(r) \frac{4\pi\lambda}{100} \int_r^{r_2} j(r) \frac{k(r)}{\sqrt{k^2(r)+1}}\, dr. \tag{3}$$

We are faced with the following problem: How do we vary j(r) in a real device in such a manner that it corresponds to Eq. (3) ? For this solenoid we adopt a wide tape of constant thickness, whose width 2b (r) we can vary at will. We note that b (r) = rk(r) and $j(r) = [j(r_1)k(r_1)r_1]/[rk(r)]$.

Substituting the latter expression into (3), we find an equation for k(r) as

$$k(r) = \frac{4\pi\lambda j^2(r_1) k^2(r_1) r_1^2}{100\sigma} \int_r^{r_2} \frac{dr}{r\sqrt{k^2(r)+1}}. \tag{4}$$

We then see that $k(r_2) = 0$. This result contradicts the condition $k(r) \gg 1$ and also leads to $j(r_2) = \infty$, which is meaningless. To avoid this difficulty, we assume the solenoid to be in an external field H_1 (i.e., we introduce an external section of the Bitter or Kolmov type; the structure of the latter is preferable, since it allows us to construct the solenoid from a single common tape).

Then Eq. (4) becomes

$$k(r) = \frac{j(r_1)\, k(r_1) r_1}{10\sigma} \left(\frac{4\pi\lambda j(r_1)\, k(r_1) r_1}{10} \int_r^{r_2} \frac{dr}{r\sqrt{k^2(r)+1}} + H_1 \right).$$

If we assume $\sigma = (1/10) r_1 j(r_1) H_0$ [$H_0 = H(r_1) + H_1$], we can rewrite the equation for k(r) as

$$k(r) = \frac{k(r_1)}{H_0} \left(\frac{4\pi\lambda\sigma k(r_1)}{H_0} \int_r^{r_2} \frac{dr}{r\sqrt{k^2(r)+1}} + H_1 \right). \tag{5}$$

Then we see that

$$k(r_2) = \frac{H_1}{H_0} k(r_1). \tag{6}$$

Differentiating the right and left sides of (5) with respect to r, we find a differential equation with separable variables[2] whose solution is

$$\ln\frac{r}{r_1} = \frac{H_0^2}{8\pi\sigma\lambda k^2(r_1)} \Big[k(r_1)\sqrt{k^2(r_1)+1} - k(r)\sqrt{k^2(r)+1} + \ln\frac{k(r_1)+\sqrt{k^2(r_1)+1}}{k(r)+\sqrt{k^2(r)+1}} \Big].$$

Then using (6) we find

$$\alpha = \left[\frac{k(r_1)+\sqrt{k^2(r_1)+1}}{hk(r_1)+\sqrt{h^2k^2(r_1)+1}} \right]^{\frac{\tau}{k^2(r_1)}} e^{\frac{\tau}{k^2(r_1)}\left[k(r_1)\sqrt{k^2(r_1)+1} - hk(r_1)\sqrt{h^2k^2(r_1)+1}\right]}, \tag{7}$$

where

$$\alpha = \frac{r^2}{r_1}, \quad h = \frac{H_1}{H_0}, \quad \tau = \frac{H_0^2}{8\pi\sigma\lambda}.$$

In Eq. (7), $k(r_1)$ and H_1 appear as independent variables. Analysis of their changes shows that α increases as $k(r_1)$ decreases, while α tends toward $\exp[(H_0^2 - H_1^2)/8\pi\sigma\lambda]$ as $k(r_1)$ becomes infinite. Similarly, α becomes infinite as H_1 tends toward zero, while α tends toward unity as H_1 tends toward H_0.

Let us consider the power drawn by the entire solenoid as a function of $k(r_1)$ and H_1. This power, W (watts), can be written as

$$W = \frac{400\pi\lambda\sigma^2 k^2(r_1)\rho}{H_0^2}\int_{r_1}^{r_2}\frac{dr}{k(r)} + \frac{H_1^2\rho}{G^2\lambda}r_2, \tag{8}$$

where ρ is the resistivity ($\Omega \cdot$ cm), G is the form factor of the external section,[3] and r_2 is both the external radius of the internal section and the internal radius of the external section.

In Eq. (8), as in Eq. (7), $k(r_1)$ and H_1 appear as independent variables. It is very important to ascertain the behavior of W as a function of $k(r_1)$ and H_1. For this purpose it is necessary to find the value of $k(r_1)$ at which W is a minimum, i.e., to find the best form factor for the entire solenoid.

We apply the mean-value theorem[4] to the integral in Eq. (8); then using Eq. (5) and performing some trivial transformations of Eq. (8), we find

$$W = wk(r_1)(r_2 - r_1) + Vr_2, \tag{9}$$

where

$$w = \frac{400\pi\sigma^2\lambda\rho}{H_0(H(\xi) + H_1)}\quad (r_1 \leqslant \xi \leqslant r_2),$$

$$V = \frac{H_1^2\rho}{G^2\lambda}.$$

Since $\lim_{k\to\infty}(k/\sqrt{k^2+1}) = 1$, we have $k(r_1) \sim \sqrt{k^2(r_1)+1}$ for $k(r_1) \gg 1$. Equation (7) can thus be rewritten as

$$\alpha = th^{-\frac{\tau}{k^2(r_1)}}, \tag{10}$$

where $t = \exp[(H_0^2 - H_1^2)/8\pi\sigma\lambda]$. Hence Eq. (9) becomes

$$W = r_1 wk(r_1)\left(th^{-\frac{\tau}{k^2(r_1)}} - 1\right) + r_1 Vth^{-\frac{\tau}{k^2(r_1)}}. \tag{11}$$

Analysis of Eq. (11) shows that $W = r_1 V$ at $H_1 = H_0$ (i.e., in this case only the external section draws power), and the power increases without bound as H_1 tends toward zero. This result again emphasizes the need for an additional section for our solenoid.

We now expand $h^{-\tau}/k^2(r_1)$ in a series in powers of $1/[k^2(r_1)]$:

$$h^{-\frac{\tau}{k^2(r_1)}} = \sum_{n=0}^{\infty}\frac{1}{n!}a^n\left(\frac{1}{k^2(r_1)}\right)^n,$$

where $a = \tau \ln h^{-1}$. Then Eq. (11) becomes

$$W(k(r_1)) = wr_1 k(r_1)(t-1) + r_1 Vt$$
$$+ r_1 wt\sum_{n=1}^{\infty}\frac{1}{n!}a^n\left(\frac{1}{k(r_1)}\right)^{2n-1} + r_1 Vt\sum_{n=1}^{\infty}\frac{1}{n!}a^n\left(\frac{1}{k(r_1)}\right)^{2n}.$$

Now it is easy to see that the function $W[k(r_1)]$ is analytic on the interval $(0, \infty)$, so it can be continued over the entire interval.[5]

TABLE 1

No.	H_0, kOe	σ, kg/mm^3	$k(r_1)$	α (common)	G

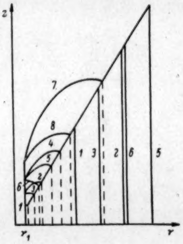

Fig. 1. Profiles of various solenoids (one fourth of a cross section is shown). The labels on the curves correspond to the boundaries between the internal and external sections; r_1 is the internal radius of the solenoids. The external sections are not shown for solenoids 4, 7, and 8 (because of their large size).

The first derivative of $W[k(r_1)]$ with respect to $k(r_1)$, $W'_{k(r_1)}[k(r_1)]$, is

$$W'(k(r_1)) = r_1 w(t-1) - r_1 wt\sum_{n=1}^{\infty}\frac{2n-1}{n!}a^n\left(\frac{1}{k(r_1)}\right)^{2n}$$
$$- r_1 Vt\sum_{n=1}^{\infty}\frac{2n}{n!}a^n\left(\frac{1}{k(r_1)}\right)^{2n+1}.$$

Then we see that $W'_{k(r_1)}(0) = -\infty$ and $W'_{k(r_1)}(\infty) = r_1 w(t-1)$, and the first derivative of $W[k(r_1)]$ with respect to $k(r_1)$ is everywhere positive on the interval $(0, \infty)$. It follows that the function $W[k(r_1)]$ has a minimum at the one point $k(r_1) = km$.

Since it is difficult to find km, we restrict the treatment here to a search for that interval (A, B) on which $W[k(r_1)]$ is close to the minimum, and near point A of which the function $W[k(r_1)]$ decreases (it increases at point B). We find the end points of this interval to be

$$A = \left(\frac{ta}{t-1}\right)^{1/3},$$

$$B = \frac{wA(th^{-\tau/A^2} - 1) + Vt(h^{-\tau/A^2} - 1)}{w(t-1)}.$$

Numerical evaluations of A, B, and $W[k(r_1)]$ show that the interval (A, B) lies between 2 and 6. Under these conditions, the solenoid is not too long, but the field is sufficiently homogeneous. If we turn our attention from the power to the form factor, we find that for fields no stronger than 700 kOe the form factor does not fall below 0.02, i.e., it remains high enough to allow us to proceed to engineering calculations.

Since all the calculations carried out analytically are approximate, of an accuracy inadequate for actual design, we have worked out a program for calculations on an M222 computer and carried out calculations for the following solenoids: a field of 250 kOe and a strength of 40 kg/mm^2; 350 kOe and strength of 40 and 60 kg/mm^2; 500 kOe and strengths of 60, 80, and 100 kg/mm^2; and 700 kOe and strengths of 100 and 120 kg/mm^2. We assume $k(r_2)$ to be equal to 1.5 [an assumption which always corresponds to the condition that $k(r_1)$ lie on the interval (A, B)], and we assume the external section to be a tape solenoid of trapezoidal cross section having $\alpha = 4.5$ (the ratio of the outer radius to the internal radius) and $k = 1.5$ ($G = 0.194$), mounted flush against the internal section. The field produced by the external section is $H_1 = 175$ kOe.

The calculated results are shown in Table 1, where, for convenience, the form factors are shown instead of the power.

Profiles of the solenoids are shown in Fig. 1.

Optical radiation from nanosecond discharges in dense gases

L. P. Babich

(Submitted September 4, 1972)
Zh. Tekh. Fiz., 44, 666-667 (March 1974)

An equation is derived for the photon yield of the optical radiation in the discrete spectrum of nanosecond-range gas discharges. It is shown that the familiar Legler equation gives a yield which is an order of magnitude too high. The conditions under which this yield is proportional to the electron density are found. Under these conditions, the development of ionization in nanosecond-range gas discharges can be studied by an optical method.

The optical radiation in the discrete spectrum is an important source of information about the space-time development of gas discharges.[1-3]

Because of the recent interest in nanosecond gas discharges, we feel it worthwhile to determine the applicability to such discharges of the familiar results on the discrete-spectrum yield[1,2] and to evaluate the possibility of studying the characteristics of these discharges by an optical method.

In a dense gas the discrete-spectrum photon yield per ionization event, Q, is given by the following equation, which takes "quenching" into account:[2]

$$Q=Q_0\left(\frac{E}{p}\right)\left(1+\frac{p}{p_0}\right)^{-1}, \tag{1}$$

where $p_0 = (n_1\sigma_q v_{rel}\,\tau^*)^{-1}$ is a constant for a given gas, and $Q_0(E/p) = \langle\sigma_{ex}v_e\rangle/\langle\sigma_i v_e\rangle$ is a function which decreases with increasing E/p. Here, n_1 is the density of the gas particles (the value of n_g at p = 1 torr and t = 0°C, $v_{rel} = \sqrt{2}vT$ is the average relative velocity of the gas particles, v_e is the electron velocity, τ^* is the lifetime of the excited state, σ_{ex} and σ_i are the cross sections for excitation and ionization by electron impact, and σ_q is the "quenching" cross section.

Introducing the average rates

$$\nu_{ex}=n_1\langle\sigma_{ex}v_e\rangle,\ \nu_i=n_1\langle\sigma_i v_e\rangle,\ \nu_q=n_1\sigma_q v_{rel},\ \nu^*=\tau^{*-1},$$

we can write

$$\frac{dn^*}{dt}=p\nu_{ex}n_e-\nu^*n^*-p\nu_q n^* \tag{2}$$

for the rate at which excited atoms are generated in the given state per unit volume,

$$\frac{dn_e}{dt}=p\nu_i n_e \tag{3}$$

for the rate of impact generation of electrons, and

$$\frac{dn_{\mathrm{m}}}{dt}=\nu^*n^* \tag{4}$$

for the rate of spontaneous emission of photons. Here we have assumed n^*, $n_e \ll n_g$.

A joint solution of Eqs. (2)-(4) with $dn^*/(dt) = 0$ leads to Eq. (1). However, in nanosecond discharges the equilibrium between the generation and decay of excited states is disrupted, since the discharge duration satisfies $t \leqslant \tau^*$, $(p\nu_q)^{-1}$, and the derivative on the left side of Eq. (2) can turn out to be larger than the last two terms on the right side.

Solving Eqs. (2)-(4) jointly for $dn^*/(dt) \neq 0$, we find

$$n_{\mathrm{m}}(t)=\frac{p\nu_{ex}\nu^*}{\nu^*+p(\nu_i+\nu_q)}\,n_e(0)\left\{\frac{\exp(p\nu_i t)-1}{p\nu_i}+\frac{\exp[-(\nu^*+p\nu_q)t]-1}{\nu^*+p\nu_q}\right\}. \tag{5}$$

With $(\nu^*+p\nu_q)t \gg 1$, $p\nu_i t \gg 1$, $p\nu_i \ll \nu^*+p\nu_q$, we find Eq. (1) from Eq. (5).

If $p\nu_i t \gg 1$ and

$$(\nu^*+p\nu_q)t\ll 1 \tag{6}$$

or

$$\exp(p\nu_i t)\gg\frac{p\nu_i}{\nu^*+p\nu_q}, \tag{6a}$$

then

$$Q=\frac{n_{\mathrm{m}}}{n_e}=\frac{\nu_{ex}}{\nu_i}\frac{\nu^*}{\nu^*+p(\nu_i+\nu_q)}=Q_0\left(\frac{E}{p}\right)\left[1+\frac{p}{p_1\left(\frac{E}{p}\right)}\right]^{-1}, \tag{7}$$

where $p_1(E/p) = p_0(1+\nu_i/\nu_q)^{-1}$ is a function of E/p.

Accordingly, when (6) or (6a) holds the proportionality is conserved between the photon yield from a unit volume of a discharge and the electron density at the given instant.

If we neglect electron diffusion,[4] we have $\nu_i = (\alpha/p)v_-$, where α is the first Townsend coefficient and v is the electron drift velocity; then p_1 and conditions (6) and (6a) become

$$p_1=p_0\left(1+\frac{p_0\alpha v_-}{p\nu^*}\right)^{-1}, \tag{8}$$

$$\left(1+\frac{p}{p_0}\right)\nu^*t\ll 1, \tag{9}$$

$$\left(1+\frac{p}{p_0}\right)\nu^*\exp(\alpha v_- t)\gg\alpha v_-. \tag{9a}$$

TABLE 1

	p_0, torr [1,2]	$\frac{\alpha}{p}$, cm^{-1}·torr^{-1} [6]	v_-, cm/sec	ν^*, sec^{-1} [2]	p_1, torr	$\frac{Q(7)}{Q_0}$	$\frac{Q(1)}{Q_0}$
N_2	60	0.455	$2.94 \cdot 10^7$	$2.86 \cdot 10^7$ [7],	2.1	$2.7 \cdot 10^{-3}$	$7.3 \cdot 10^{-2}$
				$5.56 \cdot 10^7$	3.9	$5.1 \cdot 10^{-3}$	
H_2	20	0.785	$3.85 \cdot 10^7$	$\sim 10^8$	1.4	$1.9 \cdot 10^{-3}$	$2.6 \cdot 10^{-2}$

Table 1 shows values found for $Q(7)/Q_0$ in N_2 for the transition $C^3\Pi_u \rightarrow B^3\Pi_g$ (the second positive system) and in H_2 for transitions from $2^1\Pi_u$ (the Werner series) in nanosecond range discharges with $E/p = 100$ V/(cm · torr) and $p = 760$ torr. Also shown here are the values of $Q(1)/Q_0$ calculated from Eq. (1). For v_- we used the results of a linear extrapolation of the data of ref. 5 into the region of large E/p (Table 1).

We see that the use of the equation for the photon yield of photons per ionization event based on the condition of an equilibrium between the generation and decay of excited states leads to a yield in the case of nanosecond discharges which is more than an order of magnitude higher.

The constancy of the photon yield per ionization event for a given value of E/p in nanosecond-range discharges allows us to use an optical method for studying the development of ionization in such discharges.

Plasma density in a magnetoplasma compressor

A. K. Vinogradova, V. P. Vinogradov, A. I. Morozov, and A. A. Sergeev

(Submitted August 15, 1973)
Zh. Tekh. Fiz., 44, 668-671 (March 1974)

The plasma density distribution is measured in the gap between the electrodes and at the focus in a magnetoplasma compressor by means of a Michelson interferometer with time resolution. The process is shown to be quasisteady-state; oscillations occur and are particularly intense when neutron emission is observed.

A magnetoplasma compressor is a coaxial system in which the plasma acceleration is accompanied by a radial contraction of the plasma.[1-4] We report here measurement of the plasma-density distribution in such a compressor having time resolution. The experimental results reported here have been obtained for the two compressors shown schematically in Fig. 1. The discharge is achieved in hydrogen at an initial pressure of 0.25-5 torr. Oscillograms of the voltage and the discharge current are shown in Fig. 2.

The plasma density is measured with a Michelson interferometer. The interference pattern is projected onto the slit of a camera operating in the streak mode. The slit is perpendicular to the axis of the compressor. When the interferometer and the camera are moved along the axis of the system, the radial distribution of the density can be measured in various cross sections along the z axis (Fig. 1). The light source is a modified He–Ne laser (LG-75), which can operate in either the continuous or pulsed modes. The maximum radiation density in the pulse, whose length is ~2 msec, is nearly the same (~25 mW) as in the continuous mode. The intensity of the laser light varies negligibly during the time which elapses during the events being studied. For a better use of the output power of the laser, the light beam is expanded by a cylindrical lens in the direction parallel to the camera slit. The interferograms are synchronized with oscillograms of the discharge current and voltage by means of a brief light flash from an IFK-20 lamp, which is triggered at the same time as the discharge. The resolving time, governed by the intensity of the illuminator and the sensitivity of the photographic film, is 0.5 μsec. The interferometer operates in either of two modes: In the first mode the mirrors are adjusted so that the interference field contains a large number of fringes (20-50), which are perpendicular to the slit of the streak camera. This mode is used primarily to obtain radial distribution of the plasma density. The second mode, in which there only one or two fringes, is used to obtain a clear picture of the density distribution (Fig. 3).

The fringe shift is measured on a Mir-12 microscope within 0.01 mm, corresponding to 0.05 of an interference fringe when the shift being measured is from 0.2 to two fringe widths. From the interferograms we select those which are most symmetric with respect to the axis, and we subject them to the Abel inversion. The radial distribution is averaged over several discharges for each cross section and for each time selected.

At a certain time on the interferograms we usually see an approximately identical shift of the fringes over the entire field of vision (8 cm). This shift is due to the appearance of low-density plasma between the external electrode and the chamber walls. In the analysis of the interferograms carried out to determine the plasma-density distribution near the axis of the instrument this fringe shift causes a small correction to the calculated plasma density and is usually subtracted as a background.

Interferograms are recorded inside the accelerating channel at three cross sections along the z axis; the density distributions are shown in Fig. 4. There is a general tendency for the density to increase with decreasing R and increasing z, in agreement with the assumed pattern of particle motion in the accelerating channel of a magnetoplasma compressor. Details of the distribution are still quite uncertain, and additional experiments are required for a more complete picture of the plasma flow. The dip in the density near the cathode evident from Fig. 4 can be attributed to a stronger magnetic field there,[2] which leads to a magnetization of the electrons, the appearance of a gradient in the electric field, and the acceleration of ions in this region. At the end of the cathode the magnetic field weakens, and the dip vanishes.

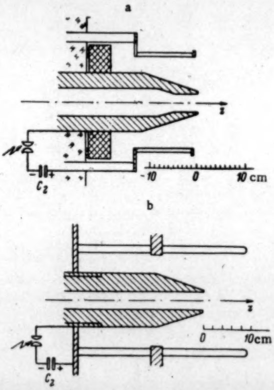

Fig. 1. Two versions of the compressor with rod anodes. a) MPK-1; b) MPK-2. The anode of MPK-1 is made from 28 rods; that of MPK-2 is made from 12 rods.

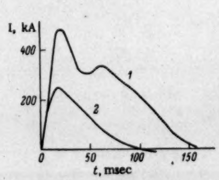

Fig. 2. Oscillograms of the discharge current. 1) MPK-1, U_0 = 3 kV, p_0 = 5 torr; 2) MPK-2, U_0 = 5 kV, p_0 = 0.25 torr.

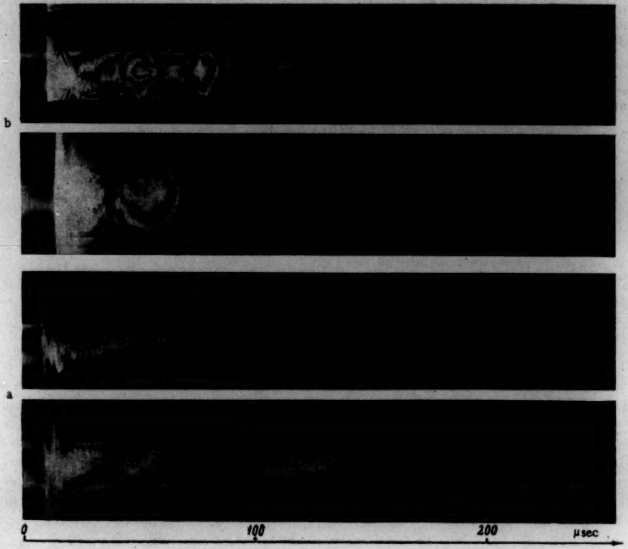

Fig. 3. Series of interferograms corresponding to the cross section z = 4 cm (1) and the cross section z = 10 cm (2) for the same (U_0 = 5 kV) initial voltage on the capacitor bank of the MPK-2, p_0, torr: a) 0.25; b) 2.

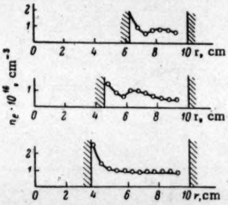

Fig. 4. Distribution of the plasma density in the accelerating channel of the MPK-1. p_0 = 5 torr, U_0 = 3 kV, t = 50 μsec. The electrodes are indicated by the hatching. z, cm: a) 10.5; b) 5.5; c) 2.5.

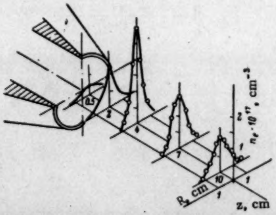

Fig. 5. Radial distribution of the plasma density in the compression zone of the MPK-2. p_0 = 0.25 torr U_0 = 5 kV, t = 40 μsec.

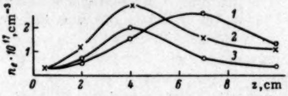

Fig. 6. Distribution of the plasma density along the axis of the MPK-2. U_0 = 5 kV, p_0 = 0.25 torr. t, μsec: 1) 30; 2) 40; 3) 60.

The radial distribution of the plasma density is shown in Fig. 5 for several cross sections beyond the end of the cathode (z > 0). While the average density in the gap is $\sim 10^{16}$ cm^{-3} (Fig. 4), it reaches a value of $\sim 4 \cdot 10^{17}$ cm^{-3} at the "focus," 4 cm from the end of the cathode. We see from Figs. 5 and 6 that the region of increased density has a radius of ~0.5 cm and a length of ~5 cm. Interestingly, the maximum density is a weak function of the initial gas pressure in the chamber. For example, as the initial pressure is increased from 0.25 to 2 torr, the maximum density at the z = 4 cm cross section does not change by more than a factor of 1.5-2. The plasma density at the compressor axis measured in discharges having different initial voltages on the capacitor bank (3, 4, and 5 kV) at times corresponding to a given discharge current turns out to be the same, within the spread in experimental values. This result is evidence for the quasisteady-state nature of the process i.e., it shows that the plasma properties in the compression zone are governed by the instantaneous value of the discharge current and are relatively weak functions of the time which has elapsed since the beginning of the discharge.

On almost all the interferograms we see that there are oscillations of the focus in the direction perpendicular to the axis of the compressor (radial oscillations), and there are periodic changes in the plasma density. Both types of oscillations are characterized by frequencies of 500 kHz and higher. As the initial gas density is increased, the oscillation amplitude decreases. At a very low initial voltage (3 kV), the frequency of the radial oscillations decreases (~ 200 kHz), while their amplitude increases significantly.

For several microseconds after the discharge current reaches its maximum the plasma oscillations at the focus are strongest and occur at the highest frequency. It is during this period that the focus is the source of neutron emission in operation with deuterium.[5]

In conclusion the authors thank P. E. Kovrov and L. G. Tokarev for assistance in the experiments.

Investigation of spatial distributions in a laser-produced plasma by Hα absorption

G. V. Ostrovskaya and N. A. Pobedonostseva
A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR

(Submitted July 16, 1973)
Zh. Tekh. Fiz., 44, 671-674 (March 1974)

In an earlier paper,[1] the parameters of a plasma produced by a laser in hydrogen were determined from the absorption of the Hα line. A laser spark in air was used as the continuum source. The operation of the two lasers (producing sparks in hydrogen and in air) is synchronized by one of the Q-switching prisms. The same prism is also used to obtain a time scan of the laser spark emission along the spectrograph slit. A homogeneous plasma is assumed in the first-order approximation. We then determine the average plasma parameters over the absorbing layer.

The present paper presents a detailed study of the spatial distribution of the parameters of a laser-produced plasma. The investigation is of interest both for the possibility of measuring plasma parameters by the absorption method and for developing a gasdynamic model of the expansion of the laser-produced plasma.

The apparatus described in ref. 1 is used to determine local plasma parameters. However, the time scan of the plasma emission is in the direction perpendicular to the spectrograph slit (Fig. 1a). The absorption spectrum obtained in this case corresponds to a particular time (the exposure time ≈ 60 nsec), while the spectral energy distribution determined from the height of the line corresponds to different regions of the plasma. An additional lens is also employed to image the air spark on the stop, after which the image is projected onto the spark in hydrogen. The stop allows us to observe the half-line from one side of the axis of symmetry of the spark during emission and to observe from the other side during absorption (Fig. 1b).

By taking these spectrograms at different distances from the axis, one can measure the values $\overline{kl}$ averaged over different cross sections (k is the absorption coefficient and l is the thickness of the illuminated layer). The radial distribution of the absorption coefficient can be obtained from $\overline{kl}$ by solving the Abel equation numerically using the Pierce method.[2] The radial distribution $k_{\lambda 0}(r/r_0)$ of the absorption coefficient at the center of the line is shown in Fig. 2 for a pressure of 3 atm. Measurements are performed at three times ($\tau = 0.8, 1.3, 1.7$ sec); however, in this figure, as in all the following figures, the experimental error is given only for the curves corresponding to $\tau = 0.8$ sec. As can be seen from the figure, the absorption coefficient is a maximum near the boundary of the illuminated zone and decreases towards the center of the plasma. As τ increases the distribution of the absorption coefficient becomes more uniform.

The values of $k_\lambda(r/r_0)$ are obtained for different distances from the center of the absorption line in similar fashion. This allows us to construct local profiles of the absorbed line. Figure 3 gives the local values of the linewidth Δλ. The local profiles of the absorbed line are used to determine the electron density N_e and the density of absorbing atoms N*; the atomic density N_0 is the normal state and the temperature T are calculated by assuming thermodynamic equilibrium.

The electron density is calculated from

$$N_e = 8 \cdot 10^{12} \left(\frac{\Delta\lambda}{\alpha_{1/2}}\right)^{3/2}, \tag{1}$$

where $\alpha_{1/2}$ is the half-width of the Stark profile calculated from Griem and Δλ is the experimental value of the absorption linewidth (in Å) measured at half-height.

T, deg	23000	17000	18800	18700	17000	14400	15700	16000	16000	12000	15100	15000

Note: (I) maximum value, (II) minimum, (III) average, (IV) integrated.

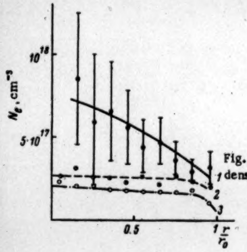

Fig. 4. Radial distribution of electron density.

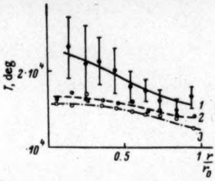

Fig. 6. Radial distribution of the temperature.

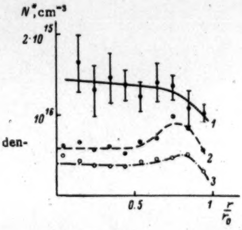

Fig. 5. Radial distribution of the density of absorbing atoms.

To determine N^*, N_0, and T we use the well-known equation relating $\int_0^\infty k_\nu d\nu$ to the density of absorbing atoms:

$$\int_0^\infty k_\nu d\nu = \frac{\pi e^2}{m_0 c} f_s N^* \left(1 - e^{-(\Delta E)/(kT)}\right), \tag{2}$$

and the Boltzmann and Saha equations. The radial distributions of N_e, N^*, and T calculated from these equations are shown in Figs. 4-6. It follows from these figures that within the limits of experimental error for N_e (≈30%), N^* (≈ 20%), and T (≈ 25%), the radial distribution of these quantities is fairly uniform.

The table gives the maximum, minimum, and average radial values of $k_{\lambda 0}$, Δλ, N_e, N^*, N_0 and T, and also the values of these parameters determined from the integrated (over the central cross section) profile of the Hα line (without using the Abel equation). Comparison of these data indicates that the plasma parameters determined from the absorption line profiles integrated over the cross section give a reasonable fit to the average radial values of these parameters.

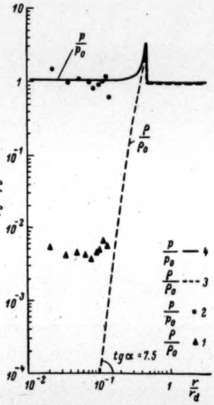

Fig. 7. Radial distribution of the density (1 is experimental and 2 theoretical) and the pressure (2 is experimental and 4 theoretical). The abscissa gives the distance from the center of the plasma with respect to the dynamic radius $r_d = (E_0/p_0)^{1/3}$ where E_0 is the energy released at the center (≈ 10^6 ergs).

The measured values of N_e, N_0, and T are used to calculate the radial density distribution of the gas $\rho = m_H (N_e + N_0)$ and the pressure $p = kT\,(2N_e + N_0)$. In Fig. 7, the radial distributions of ρ and p refer to the initial density ρ and pressure p_0 at time τ = 0.8 μsec. This figure also gives the radial distributions of ρ and p for a point explosion with a back pressure calculated according to Korobeinikov.[4] It is evident from the figure that the experimental values of the pressure give a good fit to the theoretical curve while the gas density distribution differs substantially from that given by point explosion theory.

Thus, in spite of the fact that point explosion theory gives a fairly good description of the propagation of a shock wave arising in the laser-produced breakdown of gases[5,6] and also of the density profile behind the shock front,[7] the theory does not provide an adequate description of the plasma parameters in the central regions, primarily because of the limited area of energy release during laser spark formation.

Two-omegatron study of the pumping characteristics of an NÉM-300 magnetic discharge pump for a mixture of gases

M. K. Bulgakov and V. G. Rogozinskii

(Submitted July 16, 1973)
Zh. Tekh. Fiz., 44, 674-767 (March 1974)

A two-omegatron method is used to study the pumping characteristics of an NÉM-300 magnetic-discharge pump as air and oxygen are admitted into the pump. The partial pumping rate of oxygen is shown to exceed that of nitrogen by a factor of 3-5. On the other hand, the pumping rate for a mixture of gases measured by a two-gauge method during the admission of air and oxygen is approximately equal to the calculated pumping rate for a given gas mixture. It follows from these results that measurement of the pumping rate by the two-omegatron method gives a more complete picture of the pumping process.

A qualitative picture of the pumping mechanism in a Penning cell, which is the pumping element in a magnetic-discharge pump, shows that the pumping of gases is affected by several factors, among which the composition of the gas being pumped and the pump memory are important. The effects of the components of the gas being pumped apparently are functions of their partial pressures and physical properties. These effects can be manifested in absorption of the gas being pumped on deposited titanium films and in the interaction of ions and gas with the cathode surface. For example, the presence of an argon impurity in the gas being pumped increases the rate at which titanium is sputtered and, thus, the rate at which the other gases are pumped.[1]

To study the pumping characteristics we use a system based on an ÉRA-300 apparatus, which consists of an NÉM-300 pump, in which one half of the electrode units have rectangular cells 20 × 40 mm in size while the other half have cells 20 × 60 mm in size,[2] and the measuring cap shown schematically in Fig. 1.

In the measurement procedure the complete spectrum of the gas mixture is recorded at each pressure by two IPDO-1 instruments, and the total pressure is measured by two VI-12 vacuum gauges. Before each measurement, a vacuum better than $3 \cdot 10^{-8}$ torr is established in the apparatus; the basic components of the residual gas spectrum under these conditions are H_2 (13.5%), N_2 + CO (67%), and Ar (6.%).

We study the pumping characteristics of the pump on the basis of a natural mixture of gases in air and on the basis of oxygen. Air flows into the pump through one of the leakage valves; the delay time between the pressure reading under the diaphgram and above the diaphgram in the range from $5 \cdot 10^{-8}$ to $5 \cdot 10^{-7}$ torr is 35-40 min, and at pressures above $5 \cdot 10^{-7}$ torr it is 15-20 min. The partial pressures and pumping rates are measured for the four basic components: H_2, CO + N_2, O_2, and Ar; account is taken of the sensitivity coefficient with respect to each gas. The pumping rate is calculated from

$$S_n = C\left(\frac{P_2}{P_1} - 1\right), \tag{1}$$

where C is the transmission of the diaphragm for the given gas, and P_1 and P_2 are the pressure below and above the diaphragm, respectively.

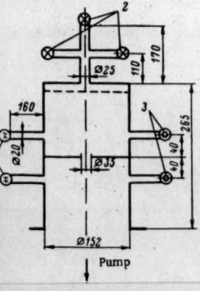

Fig. 1. The measuring cap. 1) RMO-4s pickup; 2) leakage valves for admitting the various gases; 3) IM-12 pickup.

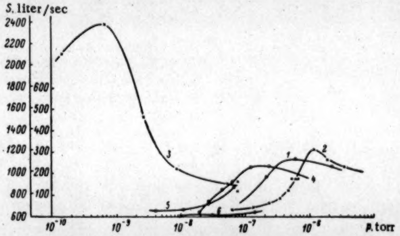

Fig. 2. Pumping rate as a function of the pressure during the admission of air. 1) Pumping rate calculated from the equation for a gaseous mixture; 2) pumping rate measured by the two-gauge method; 3) pumping rate for oxygen (scale of 600-2400 liter/sec); 4) pumping rate for nitrogen; 5) for hydrogen; 6) for argon.

We simultaneously measure the pumping rate for the gas mixture by the two-gauge method. For comparison, we calculate the pumping rate for a gaseous mixture from

$$S(\mathrm{cm}) = \frac{\sum_{i=1}^{n} s_i p_i \mu_i}{\sum_{i=1}^{n} r_i \mu_i \sum_{i=1}^{n} p_i}, \tag{2}$$

where s_i is the partial pumping rate of gas i, p_i is its partial pressure, μ_i is its molecular weight, and $r_i = p_i / \sum_{i=1}^{n} p_i$ is the relative pressure of the given gas in the mixture used in the measurement of the pumping rate. Using the procedure described above, we have carried out a series of measurements in which we supplied oxygen to one of the leakage valves. Figure 2 shows the pumping rates of the components as functions of the pressure in an air flow. We see from this figure that the pumping rate in terms of

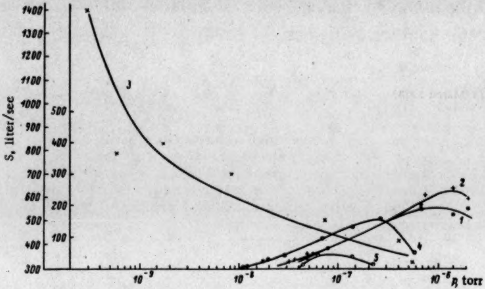

Fig. 3. Pumping rate as a function of the pressure for the admission of oxygen. 1) Pumping rate calculated from the equation for a gaseous mixture; 2) pumping rate measured by the two-gauge method; 3) pumping rate for oxygen (scale of 300-1400 liter/sec); 4) pumping rate for nitrogen; 5) for argon.

oxygen is much higher than that in terms of air. At pressures $3 \cdot 10^{-8}$-$5 \cdot 10^{-6}$ torr and at a pumping rate of 30-300 liter/sec in terms of air, the pumping rate in terms of oxygen is 2000-900 liter/sec at oxygen partial pressures in the range 10^{-10}-10^{-7} torr. The pumping rate calculated for the given mixture in accordance with Eq. (2) (curve 1) initially deviates slightly from the curve showing the pumping rate measured by the two-gauge method (curve 2), while in the range $8 \cdot 10^{-7}$-$3 \cdot 10^{-6}$ torr the two curves lie close together.

Figure 3 shows the pumping rates for the admission of oxygen. We see from these curves that the pumping rate in terms of oxygen is 1400-500 liter/sec over the pressure range $3 \cdot 10^{-10}$-10^{-7} torr. On the other hand, the pumping rate calculated on the basis of three components (O_2, N_2 + CO, Ar) is approximately equal to that measured by the two gauges in the pressure range $7 \cdot 10^{-8}$-$2 \cdot 10^{-6}$ torr.

The relative error in a measurement of the pumping rate is calculated from

$$\frac{\Delta s}{s} = \frac{2\frac{\Delta p_1}{p_1}}{1 - \frac{p_1}{p_2}}, \tag{3}$$

which is obtained from Eq. (1).

Including the relative error of about 10% of the IPDO-1 apparatus in calculating the pumping rates in terms of oxygen over the partial-pressure range from $3 \cdot 10^{-10}$ to $5 \cdot 10^{-7}$ torr, we find the relative error to be 20-25%.

It follows from the curves showing the partial pumping rates that the pumping rate in terms of oxygen for a mixture of oxygen and air is quite different from the pumping rate for nitrogen, especially at a low nitrogen partial pressure. When oxygen is admitted, its pumping rate is slightly lower than when air is admitted. These oxygen pumping rates with respect to the air pumping rates differ from the results reported in ref. 3, apparently because the pumping rate there was measured by a two-gauge method, in which no account was taken of the composition of the gas in the pump. It follows from Figs. 2 and 3 that the pumping rates calculated for a gas mixture are approximately equal to the values measured by the two-gauge method. Accordingly, the two-omegatron method gives a more complete picture of the nature of the pumping.

The high oxygen pumping rate can apparently be attributed to the high activity of oxygen in interactions with the titanium film.[4] It also follows from these results that the pumping of a gaseous mixture is affected by the mutual effects of all the components; this conclusion is based on the circumstance that the pumping rate for a gas mixture differs strongly from the pumping rates for such components as O_2, Ar, and H_2.

Possible use of the schlieren method to measure characteristics of turbulence

V. G. Ivanov
A. I. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 43, 677-679 (March 1973)

Analytical expressions are derived which relate measured values of the correlation function and the one-dimensional spectrum of schlieren screen brightness fluctuations to the correlation function and the one-dimensional and energy spectra of refractive index fluctuations of a turbulent medium.

In investigations of turbulent flow of a liquid, gas, or plasma, increasing attention has been paid in recent years to optical methods which compare favorably with contact methods as regards good spatial resolution, absence of perturbation of the test medium, and the possibility of measurement in hot and high-speed gas flow.

However, optical methods of measuring turbulence characteristics have not as yet been widely applied because the output signal of the optical system (the screen brightness) has a complex functional dependence on the refractive index of the turbulent flow. It is therefore important to establish the relation between statistical characteristics of the refractive-index fluctuations and those of screen brightness.

Attempts to solve this problem for the most effective optical method, the schlieren method, have not led to satisfactory results. For example, the integrodifferential equation obtained in ref. 1 cannot be used to determine the statistical characteristics of refractive index fluctuations of a turbulent medium from measured values of the correlation function of the schlieren screen brightness since this equation does not relate these characteristics in explicit form. Again, analysis has shown that the final result obtained in ref. 2 is incorrect, while the expressions derived in ref. 3 are valid only for the case of a Gaussian distribution function for the correlation of refractive index fluctuations, a situation which is very dubious in turbulent flow (see ref. 4).

Let $n(\mathbf{x})$ be the fluctuating, statistically homogeneous field of the refractive index lying between $x_3 - l$ and $x_3 + l$ and extending to infinity in the other two directions. To within a dimensional constant, the schlieren screen brightness is related to the refractive index of a turbulent flow, with the knife-edge parallel to the flow, by the following expression:

$$C(x_1, x_2) = \int_{x_3-l}^{x_3+l} \frac{\partial}{\partial x_2} n(x_1, x_2, x_3)\, dx_3.$$

It can be seen from this expression that the refractive index field is reflected in that of the screen brightness by means of an integrodifferential operator belonging to the class of operators examined in ref. 5, viz.

$$C(\mathbf{x}) = \int K(\mathbf{s})\, n(\mathbf{x} + \mathbf{s})\, dV(\mathbf{s}), \tag{1}$$

where

$$K(\mathbf{s}) = \begin{cases} -\delta(s_1)\,\delta'(s_2) & \text{for} \quad s_3 \leqslant l, \\ 0 & \text{for} \quad s_3 > l, \end{cases}$$

δ is the delta function and δ' is the derivative of the delta function.

In what follows, where not explicitly stated, the integration is carried out over all space.

We denote by $E(\mathbf{k})$ and $T(\mathbf{k})$ the spectra of refractive index fluctuations and those of schlieren screen brightness, respectively.

Then, as follows from ref. 5, the original field spectrum is related to that of the image field as follows:

$$T(\mathbf{k}) = S(\mathbf{k})\, E(\mathbf{k}), \tag{2}$$

where

$$S(\mathbf{k}) = \frac{1}{(2\pi)^3} \int \psi(\tau) \exp(-i\mathbf{k}\tau)\, dV(\tau),$$

$$\psi(\tau) = \int K(\mathbf{s} + \tau)\, K(\mathbf{s})\, dV(\mathbf{s}).$$

Relation (2) permits an analogy to be drawn between optical measurement of turbulence parameters for which representation of the output signal in the form of Eq. (1) holds, and the passage of random signals through linear electrical circuits. For instance, the kernel $K(\mathbf{s})$ which determines the properties of the measuring system corresponds to the generalized response of a linear system to a unit pulse, while the function $S(\mathbf{k})$ is a generalization, to within a constant multiplier, of the square of the transfer function of the linear system. Thus, the function $S(\mathbf{k})$ shows how fluctuations of various frequencies (wave numbers) are transmitted by a linear measuring system.

We now calculate the functions $\psi(\tau)$ and $S(\mathbf{k})$ pertaining to the schlieren method:

$$\psi(\tau) = \int_{-l}^{l-|\tau_3|} ds_3 \iint_{-\infty}^{+\infty} \delta(s_1)\,\delta'(s_2)\,\delta(s_1 + \tau_1)\,\delta'(s_2 + \tau_2)\, ds_1 ds_2$$

$$= -(2l - |\tau_3|)\,\delta(\tau_1)\,\delta''(\tau_2) \quad \text{for} \quad |\tau_3| \leqslant 2l;$$

$$S(\mathbf{k}) = -\frac{1}{(2\pi)^3} \iint_{-\infty}^{+\infty} \int_{-2l}^{2l} (2l - |\tau_3|)\,\delta(\tau_1)\,\delta''(\tau_2)$$

$$\exp(-ik_1\tau_1 - ik_2\tau_2 - ik_3\tau_3)\, d\tau_1 d\tau_2 d\tau_3$$

$$= \frac{k_2^2 l^2}{2\pi^3} \left(\frac{\sin k_3 l}{k_3 l}\right)^2 \text{for } |\tau_3| \leqslant 2l.$$

In the expression obtained for $S(\mathbf{k})$ the factor $[\sin k_3 l/(k_3 l)]^2$ results from the light rays passing through an optical nonuniformity of width $2l$, while the factor k_2^2 represents the sensitivity of the schlieren method to the first derivative of the refractive index.

From Eq. (2) we have

$$T(\mathbf{k}) = \frac{k_2^2 l^2}{2\pi^3} \left(\frac{\sin k_3 l}{k_3 l}\right)^2 E(\mathbf{k}).$$

Taking the Fourier transform of T(k), we obtain an expression for the correlation function $\beta(\xi)$ for screen brightness fluctuations:

$$\beta(\xi)=\frac{l^2}{2\pi^3}\int k_3^2\left(\frac{\sin k_3 l}{k_3 l}\right)^2 E(\mathbf{k})\exp(i\mathbf{k}\xi)\,dV(\mathbf{k}).$$

If the width of the nonuniformity is much larger than any characteristic scale of the turbulence, the function $[\sin k_3 l/(k_3 l)]^2$ can be replaced by the delta function; then

$$\beta(\xi_1,\ \xi_2)=\frac{2l}{\pi^2}\int_0^\infty\int_0^\infty k_3^2 E\left(\sqrt{k_1^2+k_2^2}\right)\exp(ik_1\xi_1+ik_2\xi_2)\,dk_1dk_2.$$

We introduce the polar coordinates

$$k_1=k\cos\varphi,\quad k_2=k\sin\varphi,\quad dk_1dk_2=kdkd\varphi.$$

Then, the correlation function for screen brightness fluctuations measured along the x_1 axis is

$$\beta(\xi_1)=\frac{2l}{\pi^2}\int_0^\infty k^3E(k)\int_{-\pi}^{\pi}\sin^2\varphi\exp(ik\xi_1\cos\varphi)\,d\varphi dk=\frac{4l}{\pi\xi_1}\int_0^\infty k^2E(k)\,J_1(k\xi_1)\,dk. \tag{3}$$

Taking the Mellin transform of this expression we obtain the relation between the three-dimensional spectrum of refractive index fluctuations E(k) and the correlation function for screen brightness fluctuations $\beta(\xi_1)$:

$$kE(k)=\frac{\pi}{4l}\int_0^\infty \xi_1^2\beta(\xi_1)\,J_1(k\xi_1)\,d\xi_1. \tag{4}$$

Hinze[4] gives the following relation between the three-dimensional spectrum E(k), the energy spectrum $E_n(k)$, and the one-dimensional spectrum $E(k_1)$ as measured by means of instrumentation:

$$E_n(k)=4\pi k^2E(k),$$

$$E(k_1)=\int_{k_1}^\infty\frac{E_n(k)}{k}\,dk.$$

Then the expressions relating the correlation function for schlieren screen brightness fluctuations to the energy and one-dimensional spectra of refractive index fluctuations in a turbulent medium are as follows:

$$\left\{\begin{aligned}&\xi_1\beta(\xi_1)=\frac{l}{\pi^2}\int_0^\infty E_n(k)\,J_1(k\xi_1)\,dk, &(5)\\ &\frac{E_n(k)}{k}=\frac{\pi^2}{l}\int_0^\infty \xi_1^2\beta(\xi_1)\,J_1(k\xi_1)\,d\xi_1, &(6)\end{aligned}\right.$$

$$\left\{\begin{aligned}&\beta(\xi_1)=\frac{l}{\pi^2}\int_0^\infty k_1E(k_1)\,J_0(k_1\xi_1)\,dk_1, &(7)\\ &E(k_1)=\frac{\pi^2}{l}\int_0^\infty \xi_1\beta(\xi_1)\,J_0(k_1\xi_1)\,d\xi_1. &(8)\end{aligned}\right.$$

Thus, by means of Eqs. (4), (6), and (8) we can numerically integrate measured values of the correlation function for screen brightness fluctuations and obtain the three-dimensional, energy, and one-dimensional spectra of refractive index fluctuations.

We now consider the expression for the correlation function for fluctuations of a scalar field for the case of homogeneous and isotropic turbulence proposed by Tatarskii:[4]

$$R(r)=\frac{\gamma^2}{2^{\nu-1}\Gamma(\nu)}\left(\frac{r}{r_0}\right)^\nu K_\nu\left(\frac{r}{r_0}\right),$$

where K_ν is a modified Bessel function; Γ is the gamma function; γ is the mean square magnitude of the fluctuations; r_0 is the characteristic scale of the turbulence, and ν is a parameter determining the form of the correlation function.

Then the one-dimensional spectrum of refractive index fluctuations will be

$$E(k_1)=\frac{2\gamma^2}{\sqrt{\pi}}\frac{\Gamma\left(\nu+\frac{1}{2}\right)}{\Gamma(\nu)}\frac{r_0}{[1+(k_1r_0)^2]^{\nu+1/2}}. \tag{9}$$

Substituting Eq. (9) into Eq. (7), we obtain

$$\beta(\xi_1)=\frac{l}{\pi^{3/2}}\frac{\gamma^2}{\Gamma(\nu)\,2^{\nu-3/2}}\frac{1}{r_0}\left(\frac{\xi_1}{r_0}\right)^{\nu-1/2}K_{\nu-1/2}\left(\frac{\xi_1}{r_0}\right), \tag{10}$$

and therefore the one-dimensional spectrum of schlieren screen brightness fluctuations measured along the x_1 axis is

$$T(k_1)=\frac{2l}{\pi^3}\frac{\gamma^2}{[1+(k_1r_0)^2]^\nu}, \tag{11}$$

i.e., in the high frequency (or high wave number) region the one-dimensional spectrum of refractive index fluctuations is related to the schlieren output signal spectrum as follows:

$$E(k_1)\sim\frac{T(k_1)}{k_1}\ \text{for}\ k_1r_0\gg 1. \tag{12}$$

The integral scale of the refractive index fluctuations is related to the length scale r_0 by the expression

$$\Lambda_n=\sqrt{\pi}\,\frac{\Gamma\left(\nu+\frac{1}{2}\right)}{\Gamma(\nu)}r_0. \tag{13}$$

Thus, if the one-dimensional spectrum of refractive index fluctuations can be approximated by Eq. (9), we can use Eqs. (10)-(13) and the relations $\beta(\xi_1)$ and $T(k_1)$ resulting from statistical processing of the schlieren output signals to find analytical expressions for the correlation function, and the one-dimensional and energy spectra of refractive index fluctuations, and we can also determine the integral scale Λ_n.

Since the refractive index for gases is usually a linear function of the density, in investigations of turbulent gas flows by the schlieren method we can use the analytical expressions derived here and the statistical characteristics of schlieren screen brightness fluctuations to find the statistical characteristics of the density fluctuations.

In conclusion the author thanks G. I. Mishin and S. N. Palkin for useful discussions.

Titanium-pump system for hydrogen

K. G. Mirzoev, V. G. Rogozinskii, and V. L. Ushkov

(Submitted July 16, 1973)
Zh. Tekh. Fiz., 44, 680-682 (March 1974)

A study is reported of a vacuum system used to pump 1000-1500 cm^3 · atm/h of hydrogen in continuous flow through the ion source of the injector of an I-100 linear proton accelerator. The vacuum system consists of two NÉM-1T pumps and a getter pump, whose pumping rate is 10^4 liter/sec at $1 \cdot 10^{-6}$ torr. The system operates stably at a flow rate of up to 500 cm^3 · atm/h and at pressure below $1 \cdot 10^{-5}$ torr. In pulsed supply of hydrogen through the source at a rate of 0.125 Hz, the pumping is achieved by two NÉM-1T pumps at an average pressure of $1.6 \cdot 10^{-6}$ torr. Information obtained from extensive use of the NÉM-1T pumps to pump hydrogen in the pulsed mode is reported.

The injector[1] of the I-100 linear proton accelerator initially operated with a continuous hydrogen flow of 1000-1500 cm^3 · atm/h through the ion source with a chamber pressure of $1\text{-}2 \cdot 10^{-5}$ torr, maintained by two high-vacuum oil-vapor VA-8-4 pumps with venetian-blind liquid-nitrogen traps. The penetration of oil vapor and its decomposition products into the chamber of the injector and into the resonator of the linear accelerator led to frequent high-voltage breakdowns, reducing the reliability of accelerator operation.

To study the possibility of oil-free pumping of the injector, we have studied a pumping system consisting of a titanium getter pump and two NÉM-1T magnetic-discharge pumps. On the basis of a GIN-5 pump[2] we design and construct a pump without an ionizer, so that we are able to increase the number of titanium evaporators to eight. The getter pump has been tested to $1 \cdot 10^{-5}$ torr by VN-2MG and VA-05-4 pumps with a nitrogen trap. After the body of the pump is heated to 70-80°C, and after the evaporators are outgassed, a limiting vacuum of $(1\text{-}2) \cdot 10^{-7}$ torr is achieved after 7-8 h of operation of the two evaporators, each of which is heated by ~ 1900 W. During this period the VA-05-4 pump operates continuously. The pumping rate in terms of hydrogen, measured by the two-gauge method, is about 10^4 liter/sec over the pressure range $1 \cdot 10^{-6}\text{-}2 \cdot 10^{-5}$ torr. Figure 1 shows the behavior of the partial pressures of CH_4, CO_2, CO + N_2, H_2 and Ar, obtained with an IPDO-1 device while the valve of the VA-05-4 device is off and with operation of one evaporator at a heater power of 1900 W. During these measurements the total pressure varies from $2 \cdot 10^{-7}$ to $(3\text{-}5) \cdot 10^{-6}$ torr. We see that the partial pressures of CH_4 and CO_2 increase rapidly initially and then reach nearly equilibrium values. This behavior is apparently due to the establishment of an equilibrium between the production and oxidation of methane involving the production of CO_2, which is pumped by the deposited titanium film.

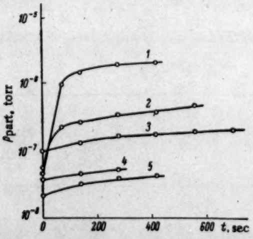

Fig. 1. Partial pressures of CH_4 (curve 1), CO_2 (2), H_2 (3), CO + N_2 (4), and Ar (5) during operation of the getter pump with one evaporator and a closed valve of the VA-05-4 device.

Vacuum system of the injector. 1) Hydrogen tank; 2) injection system and buret; 3) ion source; 4) accelerating tube and chamber of injector; 5) getter pump; 6) NÉM-1T No. 1; 7) NÉM-1T No. 2; 8) VA-05-4 oil-vapor pump; 9) DU-500 valve; 10) DU-160 valve; 11) DU-85 valve; 12) VN-7MG pump; 13) LM-2 and LT-2 gauges; 14) DU-85 ion trap.

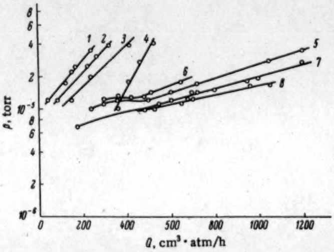

Fig. 3. Pressure in the injector as a function of the hydrogen flow rate with operation of one and two NÉM-1T pumps and getter-pump evaporators at various levels of heating power.$^{1-3}$ One NÉM-1T and one evaporator. W, watts: 1) 1530; 2) 1800; 3) 2000. 4, 5) One NÉM-1T and two evaporators. W, watts: 4) 1800; 5) 2200. 6-8) Two NÉM-1T's and two evaporators. W, watts: 6) 2000; 7) 2200; 8) 2400.

The pumping characteristics of the injector with the titanium pumps are studied on the apparatus shown schematically in Fig. 2. A preliminary evacuation to $1 \cdot 10^{-5}$ torr is achieved by VN-7MG and VA-05-4 pumps with a liquid-nitrogen trap. The hydrogen flow through the ion source is measured by a buret method, and the pressure is measured by an LM-2 ionization gauge in terms of the nitrogen equivalent. During the evacuation of the hydrogen two evaporators operate simultaneously with a heating power of 14-15 W per square centimeter of the initial surface of the evaporator. Under these conditions the chamber pressure does not exceed $(1\text{-}2) \cdot 10^{-5}$ torr, and the getter pump works for ~ 200 h before it is necessary to change evaporators. The results of tests of this pumping system are shown in Fig. 3. In operation of this system for 150 h at pressures above $1.5 \cdot 10^{-5}$ torr, pressure variations of $(2-6) \cdot 10^{-5}$ torr with a period of 3-5 min, lasting from 10 min to 3 h, are observed because of the argon instability. These variations arise and vanish either spontaneously or upon a change in the hydrogen flow rate. Accordingly, this pumping system can operate stably at pressures below $1 \cdot 10^{-5}$ torr, so that it is possible to evacuate a hydrogen flow of 500 $cm^3 \cdot atm/h$.

We have also designed and constructed an ion source with pulsed hydrogen injection[3] at a rate corresponding to the operating cycle of the accelerator; the hydrogen flow in the pulse is the same as for continuous flow, while the average hydrogen flow is 20-40 $cm^3 \cdot atm/h$. Under these conditions, two NÉM-1T magnetic-discharge pumps can be used for evacuation. The arrangement of the system is like that shown in Fig. 2; NÉM-1T No. 2 (7) replaces getter pump (5), while a TMN-200 turbomolecular pump replaces the VA-05-4 (8). This system has been used successfully for about five years.

The average pressure in the chamber during operation of the source, measured by an LM-2 gauge, is $\sim 1.6 \cdot 10^{-6}$ torr. The NÉM-1T pumps operate in continuous cycles of 1000-2000 h with stops for 150-200 h. Both pumps have operated more than $2 \cdot 10^4$ h before replacement, cleaning, and reassembly.

From the measured average volume of the craters in the cathodes of the pumps we determine the titanium flow rate and estimate the average efficiency of the titanium sputtering: 0.05-0.1 atom/ion.

An estimate of the saturation of the cathodes with hydrogen yields 0.02 atoms of H_2 per Ti atom, and the amount of H_2 absorbed by the Ti film is estimated to be 5% of the total amount of evacuated H_2. It follows that hydrogen is pumped primarily by the cathodes of the pumps, and, as is mentioned in ref. 4, as a result of the penetration of ions and diffusion of hydrogen into the titanium. Inspection of the cathode plates of the pumps shows that there are no cracks, deformations, or damaged regions on their surfaces, which would be characteristics of hydrogen saturation of the surface layer of titanium. The cathode plates may end up in this state because hydrogen manages to diffuse into the interior of the plate during the time between pulses in the case of pulsed injection, so it does not saturate the surface layer. As is shown in ref. 5, the coefficient for the penetration of hydrogen ions into titanium is reduced when the surface layer of titanium is saturated with hydrogen; then, after a pause, this coefficient resumes its original value.

The authors thank V. A. Teplyakov for discussion of the results and A. S. Nazarov and M. V. Kuznetsov for designing and constructing the getter pump.

Temperature dependence of trace diffusion coefficients of certain gases

A. É. Loiko, B. A. Ivakin, and P. E. Suetin
S. M. Kirov Ural Polytechnical Institute, Sverdlovsk

(Submitted May 21, 1973)
Zh. Tekh. Fiz., 44, 682-684 (March 1974)

The diffusion coefficients have been measured for 11 pairs of gases (He–D_2, H_2–Kr, Ar–Xe, Kr–Xe, H_2–CO_2, D_2–CO_2, He–CO_2, Ne–CO_2, Ar–CO_2, Kr–CO_2, and Xe–CO_2) as functions of the concentration over the temperature range 77-600°K.

There are several reasons for the interest in the trace diffusion coefficients of gases as functions of the temperature: First, the information currently available on the functional dependence on the concentration is clearly inadequate and is even partially contradictory. Second, measurements carried out with small gradients make it possible to study diffusion in "pure" form and to minimize the corrections due to the nonideal nature of the gases. Finally, the results found in measurements of the trace diffusion coefficients over a broad temperature range can provide a more accurate construction of the intermolecular potentials.

We have measured the trace diffusion coefficients for 11 pairs of gases. The experimental apparatus and procedure are described in detail elsewhere.[1–3] All the measurements are carried out at a concentration of 2.5% for the trace component. We estimate the experimental error to be ~0.9%.

The experimental diffusion coefficients for traces of the heavy and light components, converted to 1 atm in the standard manner, are shown in Tables 1 and 2. With a light-component trace the measurements are carried out at three temperatures: a low temperature, room temperature, and a high temperature. For the systems He–D_2, Ar–CO_2, and Kr–Xe, we find no functional dependence of the diffusion coefficient on the concentration within the experimental error.

Analysis of these results shows that the functional dependence of the diffusion coefficients on the concentration increases with increasing temperature and is responsible for a variation of 1-4% for all the pairs studied. The experimental results support the conclusions of the rigorous kinetic theory of low-density gases[4] regarding the weak functional dependence of the diffusion coefficients on the concentration.

The experimental results agree with the data of ref. 5 for systems of inert gases, within the experimental errors. For the He–CO_2 system there is a good agreement with the results of ref. 6. The functional dependence on the concentration for the He–CO_2 pair reported in ref. 7, however, is much stronger than that which follows from our results. We do not have information on the functional dependence of concentration for the other systems with which to compare our results.

Theoretical and mathematical physics

Charged-particle motion in a dipole magnetic field

L. G. Glikman

(Submitted June 5, 1973)
Zh. Tekh. Fiz., 44, 689-697 (April 1974)

Simple relations are found which characterize the features of charged-particle motion in the field of a magnetic dipole. In particular, the conditions necessary for penetration of a particle to the center of the magnetic dipole are refined and conditions are determined which are sufficient for a magnetic dipole to act as a mirror that reflects incident particles.

Numerous papers have been devoted to the study of charged-particle motion in the field of a magnetic dipole and some of the results are given in monographs.[1,2] An exact solution of the equations of motion for a charged-particle in such a field can only be found for the case in which the particle trajectory lies the median (equatorial) plane, which is an antisymmetry plane for the magnetic field. A detailed study of particle motion under arbitrary initial conditions requires numerical integration of the appropriate system of differential equations. However, important results can also be obtained by a qualitative study. In particular, by making use of the conservation laws for energy and generalized azimuthal momentum the allowed and forbidden regions of particle motion can be determined.[1]

A method similar to that proposed in ref. 3 and later used in refs. 4 and 5 is employed here for consideration of the features of particle motion. By means of this method one can study qualitatively some new features of charged-particle motion in the field of a magnetic dipole.

The Hamilton–Jacobi equation for this problem, written in the spherical coordinate system r, θ, ψ with its origin at the point which the magnetic dipole is located is

$$\left(\frac{\partial S}{\partial r}\right)^2+\frac{1}{r^2}\left(\frac{\partial S}{\partial \vartheta}\right)^2+\left(\frac{\frac{\partial S}{\partial \psi}}{r\sin\vartheta}-\frac{eM}{c}\frac{\sin\vartheta}{r^2}\right)^2=\frac{m^2v^2}{1-\frac{v^2}{c^2}}. \qquad (1)$$

Here, S is the contracted action function; e, m, and v are respectively the charge, rest mass, and velocity of the particle; c is the velocity of light in vacuum; M is the absolute value of the dipole magnetic moment **M**. The coordinate system is oriented so that the vector **M** is antiparallel to the z axis of the Cartesian coordinate system x, y, z, which corresponds to the selected spherical coordinate system r, θ, ψ. For definiteness, the motion of a positively charged particle is considered. After introduction of the Störmer unit of length

$$a=\sqrt{\frac{eM}{mcv}\sqrt{1-\frac{v^2}{c^2}}}$$

and the function

$$F=\frac{S\sqrt{1-\frac{v^2}{c^2}}}{mva}$$

the Hamilton–Jacobi equation (1) takes the form

$$\rho^2P_\rho^2+P_\vartheta^2+\left(\frac{2\gamma}{\sin\vartheta}-\frac{\sin\vartheta}{\rho}\right)^2-\rho^2=0. \qquad (2)$$

Here

$$\rho=\frac{r}{a},\quad P_\rho=\frac{\partial F}{\partial\rho},\quad P_\vartheta=\frac{\partial F}{\partial\vartheta},$$

$$2\gamma=\frac{\partial F}{\partial\psi}=\rho^2\sin^2\vartheta\frac{d\psi}{dl}+\frac{\sin^2\vartheta}{\rho}=\mathrm{const}, \qquad (3)$$

l is the length of the path traversed by the particle, expressed in Störmer units.

From the system of Hamiltonian equations corresponding to Eq. (2), we obtain

$$\frac{dP_\rho^2}{d\rho}=-\frac{2P_\rho^2}{\rho}+\frac{2}{\rho}-\frac{4\gamma}{\rho^4}+\frac{2\sin^2\vartheta}{\rho^5}. \qquad (4)$$

From Eq. (4), which describes P_ρ^2 as a function of the two variables ρ and ϑ, we transform to differential inequalities characterizing P_ρ^2 as a function of the single variable ρ. We determine allowed values of the quantity $\sin^2\vartheta$, which appears on the right side of Eq. (4), by using the condition

$$\rho^2-\rho^2P_\rho^2-\left(\frac{2\gamma}{\sin\vartheta}-\frac{\sin\vartheta}{\rho}\right)^2\geqslant 0. \qquad (5)$$

which follows from Eq. (2).

This condition is satisfied if

$$f\leqslant\sin^2\vartheta\leqslant g, \qquad (6)$$

where f is the smaller, and g the larger, root of the quadratic equation in $\sin^2\vartheta$:

$$\sin^4\vartheta+\rho u\sin^2\vartheta+4\gamma^2\rho^2=0. \qquad (7)$$

Here,

$$u=\rho^3P_\rho^2-\rho^3-4\gamma. \qquad (8)$$

The solutions of Eq. (7) are of the form

$$f=\frac{\rho}{2}\left(-u-\sqrt{u^2-16\gamma^2}\right), \qquad (9)$$

$$g=\frac{\rho}{2}\left(-u+\sqrt{u^2-16\gamma^2}\right). \qquad (10)$$

The function u is not positive, as follows from Eq. (2):

$$-\rho P_\vartheta^2-\frac{4\gamma^2\rho}{\sin^2\vartheta}-\frac{\sin^2\vartheta}{\rho}\leqslant 0,$$

and therefore both roots of Eq. (7) are nonnegative.

The inequality

$$\frac{dP_\rho^2}{d\rho} \geqslant -\frac{2P_\rho^2}{\rho} + \frac{2}{\rho} - \frac{4\gamma}{\rho^4} + \frac{1}{\rho^4}\left(-u - \sqrt{u^2 - 16\gamma^2}\right), \tag{11}$$

follows from Eqs. (4), (6), and (9), and is transformed by using Eq. (8):

$$\rho \frac{du}{d\rho} \geqslant -\sqrt{u^2 - 16\gamma^2}. \tag{12}$$

From Eq. (12), we obtain

$$\frac{df}{d\rho} \geqslant 0. \tag{13}$$

Actually, because of the nonnegativity of f and the inequality (12),

$$\frac{df}{d\rho} = \frac{f}{\rho\sqrt{u^2 - 16\gamma^2}}\left(\sqrt{u^2 - 16\gamma^2} + \rho\frac{du}{d\rho}\right) \geqslant 0.$$

Considering the equation

$$fg = 4\gamma^2\rho^2 \tag{14}$$

and Eq. (13) we can write

$$\frac{d}{d\rho}\left(\frac{g}{\rho^2}\right) \leqslant 0. \tag{15}$$

We obtain additional inequalities characterizing the properties of the functions f and g by using Eqs. (4), (6), and (10):

$$\frac{dP_\rho^2}{d\rho} \leqslant -\frac{2P_\rho^2}{\rho} + \frac{2}{\rho} - \frac{4\gamma}{\rho^4} + \frac{1}{\rho^4}\left(-u + \sqrt{u^2 - 16\gamma^2}\right).$$

We then have

$$\rho \frac{du}{d\rho} \leqslant \sqrt{u^2 - 16\gamma^2}. \tag{16}$$

From Eqs. (10), (14), and (16), there follows

$$\frac{dg}{d\rho} \geqslant 0, \tag{17}$$

$$\frac{d}{d\rho}\left(\frac{f}{\rho^2}\right) \leqslant 0. \tag{18}$$

Relations which characterize the features of particle motion more precisely than (17) and (18) can be obtained for the case $g_0 > 1$ (the subscript zero indicates initial values of the variables). In this case, using Eq. (4) we write

$$\frac{dP_\rho^2}{d\rho} \leqslant -\frac{2P_\rho^2}{\rho} + \frac{2}{\rho} - \frac{4\gamma}{\rho^4} + \frac{2}{\rho^5}.$$

After simple transformations, we obtain

$$\frac{d}{d\rho}\left(\frac{u\rho + 1}{\rho^2}\right) \leqslant 0. \tag{19}$$

This inequality can also be written

$$\frac{d}{d\rho}\left(\frac{1 - f - g}{\rho^2}\right) \leqslant 0. \tag{20}$$

Using these inequalities we estimate the boundary of the allowed region for particle motion in that portion of the trajectory in which ρ varies monotonically (sign of P_ρ does not change). We consider separately the cases in which ρ is nonincreasing and where ρ is nondecreasing.

1. If ρ decreases monotonically it follows from (13), (15), (17), and (18) that for arbitrary initial conditions

$$f_0\frac{\rho^2}{\rho_0^2} \leqslant f \leqslant f_0, \tag{21}$$

$$g_0\frac{\rho^2}{\rho_0^2} \leqslant g \leqslant g_0. \tag{22}$$

If $g_0 > 1$, features of particle motion are characterized more precisely than the lower bound in (21) and the upper bound in (22) by the inequality following from Eq. (19):

$$\frac{u\rho + 1}{\rho^2} \geqslant \frac{u_0\rho_0 + 1}{\rho_0^2}. \tag{23}$$

From (23) we find a lower bound for f:

$$f \geqslant -\frac{\rho}{2}\left[u_0\frac{\rho}{\rho_0} + \frac{\rho}{\rho_0^2} - \frac{1}{\rho} + \sqrt{\left(u_0\frac{\rho}{\rho_0} + \frac{\rho}{\rho_0^2} - \frac{1}{\rho}\right)^2 - 16\gamma^2}\right], \tag{24}$$

The size of the region of allowed particle motion for $g_0 < 1$ is estimated in the following manner:

$$f_0\frac{\rho^2}{\rho_0^2} \leqslant \sin^2\vartheta(\rho) \leqslant g_0. \tag{25}$$

In this case, a charged-particle approaching the magnetic dipole does not pass through the equatorial plane. When $g_0 > 1$,

$$-\frac{\rho}{2}\left[u_0\frac{\rho}{\rho_0} + \frac{\rho}{\rho_0^2} - \frac{1}{\rho} + \sqrt{\left(u_0\frac{\rho}{\rho_0} + \frac{\rho}{\rho_0^2} - \frac{1}{\rho}\right)^2 - 16\gamma^2}\right] \leqslant \sin^2\vartheta(\rho) \leqslant 1. \tag{26}$$

We have estimated the magnitude of the region of allowed motion under the assumption that ρ decreases monotonically. Under the same assumption, we now find an estimate for the quantity P_ρ^2. From the definition of this quantity, it follows that

$$P_\rho^2 = \cos^2\alpha,$$

where α is the angle between the radius vector **r**, characterizing the particle position in space, and the particle vector velocity **v**. We use the bounds on P_ρ^2 later to investigate charged-particle motion in nonmonotonic variation of ρ along the trajectory.

When

$$\frac{\rho^2}{\rho_0^2} \geqslant \frac{f_0}{g_0} \tag{27}$$

it follows from (13) that

$$\rho^4 P_\rho^2 \leqslant \rho^4 + 4\gamma\rho - \frac{\rho^2}{\rho_0^2} g_0 - f_0. \tag{28}$$

If $\gamma = 0$, $f_0 = 0$ and (28) is valid for all values of ρ. When $\gamma > 0$ and

$$\frac{\rho^2}{\rho_0^2} \leqslant \frac{f_0}{g_0}, \tag{29}$$

the bound for P_ρ^2 reduces to the trivial quantity

$$P_\rho^2 \leqslant 1. \tag{30}$$

If γ is negative and ρ satisfies (29), we can use the bound

$$\rho^4 P_\rho^2 \leqslant 8\gamma\rho + \rho^4, \tag{31}$$

which holds for arbitrary values of ρ, but is less accurate than (28) under condition (27). The inequality (31) follows from the nonnegativity of the expressions under the square root sign in Eqs. (9) and (10).

The lower bound for P_ρ^2 will be different for $g_0 < 1$ and $g_0 > 1$. If $g_0 < 1$, we obtain from (17)

$$\rho^4 P_\rho^2 \geqslant \rho^4 + 4\gamma\rho - \frac{\rho^2}{\rho_0^2} f_0 - g_0. \tag{32}$$

When $g_0 > 1$, we obtain from (23)

$$\rho^4 P_\rho^2 \geqslant \rho^4 + 4\gamma\rho + \frac{\rho^2}{\rho_0^2}(1 - f_0 - g_0) - 1. \tag{33}$$

2. ρ increases monotonically. For arbitrary initial conditions, the limits for the functions f and g now have the form

$$f_0 \leqslant f \leqslant \frac{\rho^2}{\rho_0^2} f_0, \tag{34}$$

$$g_0 \leqslant g \leqslant \frac{\rho^2}{\rho_0^2} g_0. \tag{35}$$

When

$$\frac{\rho^2}{\rho_0^2} \geqslant \frac{1}{f_0} \tag{36}$$

the upper bound for the function f becomes the trivial one

$$f \leqslant 1. \tag{37}$$

If $g_0 > 1$ the features of the particle motion are described by the relation

$$\frac{u\rho + 1}{\rho^2} \leqslant \frac{u_0\rho_0 + 1}{\rho_0^2}. \tag{38}$$

more precisely than by the inequalities (34) and (35) giving an upper bound for f and a lower bound for g.

Using (38) we write the upper bound for f in this case as follows:

$$f \leqslant -\frac{\rho}{2}\left[u_0 \frac{\rho}{\rho_0} + \frac{\rho}{\rho_0^2} - \frac{1}{\rho} + \sqrt{\left(u_0 \frac{\rho}{\rho_0} + \frac{\rho}{\rho_0^2} - \frac{1}{\rho}\right)^2 - 16\gamma^2}\right]. \tag{39}$$

Using these relations we determine the inequalities which bound the dimensions of the allowed region for charged-particle motion. If $g_0 < 1$,

$$f_0 \leqslant \sin^2\vartheta(\rho) \leqslant \frac{\rho^2}{\rho_0^2} g_0. \tag{40}$$

The upper bound in (40) transforms to the trivial quantity

$$\sin^2\vartheta \leqslant 1 \tag{41}$$

for

$$\frac{\rho^2}{\rho_0^2} \geqslant \frac{1}{g_0}, \tag{42}$$

i.e., the trajectory of a particle can intersect the equatorial plane of the magnetic dipole only for $\rho \geq \rho_0/(g_0)^{1/2}$.

When $g_0 > 1$, we have

$$f_0 \leqslant \sin^2\vartheta(\rho) \leqslant 1. \tag{43}$$

The lower bound for the quantity P_ρ^2

$$\rho^4 P_\rho^2 \geqslant \rho^4 + 4\gamma\rho - \frac{\rho^2}{\rho_0^2} g_0 - f_0. \tag{44}$$

follows from (13).

If $g_0 < 1$, we find that for

$$\frac{\rho^2}{\rho_0^2} \leqslant \frac{g_0}{f_0} \tag{45}$$

$$\rho^4 P_\rho^2 \leqslant \rho^4 + 4\gamma\rho - \frac{\rho^2}{\rho_0^2} f_0 - g_0. \tag{46}$$

by using (17).

When $\gamma = 0$, (46) is valid for any value of ρ. When $\gamma > 0$ and

$$\frac{\rho^2}{\rho_0^2} \geqslant \frac{g_0}{f_0}, \tag{47}$$

we have the trivial bound (30). If $\gamma < 0$ and ρ satisfies (47), the relation (31) should be used for the upper bound of the quantity P_ρ^2. When $g_0 > 1$, we obtain from (19)

$$\rho^4 P_\rho^2 \leqslant \rho^4 + 4\gamma\rho + \frac{\rho^2}{\rho_0^2}(1 - f_0 - g_0) - 1. \tag{48}$$

The relations obtained above under the assumption that ρ varies monotonically in the portion of the trajectory under consideration can be used for the investigation of charged-particle trajectories in more complex cases. For example, we consider the motion of a charged particle in one of the most interesting cases from the standpoint of geophysical application, where

$$0 \leqslant \gamma < 1 \tag{49}$$

and the particle approaches the magnetic dipole. It is well known that satisfaction of the condition (49) is necessary in order that a charged particle coming fron infinity approach the center of the dipole. We shall determine below additional conditions which are necessary for particle penetration to the center of the dipole and we shall also determine conditions sufficient for the magnetic dipole to act as a mirror which reflects an incident particle when (49) is satisfied.

For further investigation we shall have to know the roots of

$$\rho^4 + 4\gamma\rho - \frac{\rho^2}{\rho_0^2} g_0 - f_0 = 0, \tag{50}$$

$$\rho^4 + 4\gamma\rho - \frac{\rho^2}{\rho_0^2} f_0 - g_0 = 0. \tag{51}$$

We factor the left sides of these equations. Then Eq. (50) takes the form

$$\left(\rho^2 + \frac{2|\gamma|}{\sqrt{f_0}}\rho - \sigma_\gamma \sqrt{f_0}\right)\left(\rho^2 - \frac{2|\gamma|}{\sqrt{f_0}}\rho + \sigma_\gamma \sqrt{f_0}\right) = 0, \tag{52}$$

where

$$\sigma_\gamma = \begin{cases} \frac{|\gamma|}{\gamma}, & \gamma \neq 0, \\ 1 & \gamma = 0, \end{cases}$$

and Eq. (51) is written in the following manner:

$$\left(\rho^2 + \frac{2|\gamma|}{\sqrt{g_0}}\rho - \sigma_\gamma \sqrt{g_0}\right)\left(\rho^2 - \frac{2|\gamma|}{\sqrt{g_0}}\rho + \sigma_\gamma \sqrt{g_0}\right) = 0. \tag{53}$$

The point on the trajectory at which P_ρ changes sign, i.e., where $\rho(l)$ reaches an extremum, will be called a deflection point. Values of the variables at the deflection point are indicated by the subscript "def". The inequality (28) indicates that for a particle approaching the dipole

$$\rho_{\text{def}} \geqslant \rho_k, \tag{54}$$

at the first deflection point, where ρ_k is the positive root of Eq. (50) closest to ρ_0 having a value less than ρ_0. Since (28) holds where ρ satisfies the inequality (27), the relation (54) is satisfied when

$$\rho_k \geqslant \rho_0 \sqrt{\frac{f_0}{g_0}}. \tag{55}$$

In determining the roots of Eq. (50), we use the fact that it can be written in the form (52). We write expressions for the roots for positive values of γ. If

$$\gamma^2 < f_0 \sqrt{f_0}, \tag{56}$$

Eq. (50) has a single positive root:

$$\rho_{11} = -\frac{\gamma}{\sqrt{f_0}} + \sqrt{\frac{\gamma^2}{f_0} + \sqrt{f_0}}. \tag{57}$$

When the condition

$$\gamma^2 > f_0 \sqrt{f_0} \tag{58}$$

is satisfied, Eq. (50) has the two positive roots in addition to ρ_{11}:

$$\rho_{12} = \frac{\gamma}{\sqrt{f_0}} - \sqrt{\frac{\gamma^2}{f_0} - \sqrt{f_0}}, \tag{59}$$

$$\rho_{13} = \frac{\gamma}{\sqrt{f_0}} + \sqrt{\frac{\gamma^2}{f_0} - \sqrt{f_0}}. \tag{60}$$

When the three roots of Eq. (50) exist, the values of ρ lie either in the interval $[\rho_{11}, \rho_{12}]$ or in the range $[\rho_{13}, \infty]$. In the first case, when

$$\rho_0 \in [\rho_{11}, \rho_{12}], \tag{61}$$

and (56) is satisfied so that Eq. (50) has a single positive root, the bound (54) takes the form

$$\rho_{\text{def}} \geqslant \rho_{11}. \tag{62}$$

However, it is easy to verify that the inequality (55) is not satisfied for $\rho_k = \rho_{11}$. Therefore, under the specified conditions the bound for ρ_{def} reduces to the trivial quantity

$$\rho_{\text{def}} \geqslant 0. \tag{63}$$

If (58) is satisfied and

$$\rho_0 \geqslant \rho_{13}, \tag{64}$$

the bound (54) takes the form

$$\rho_{\text{def}} \geqslant \rho_{13}. \tag{65}$$

Now the inequality (55) holds for $\rho_k = \rho_{13}$.

Thus the conditions (58) and (64) are sufficient for at least one point of deflection to exist on the trajectory of a particle approaching the magnetic dipole. We shall show that when (58) and (64) are satisfied, there will be only one deflection point on the particle trajectory. Using the bound (44) obtained above we write the inequality

$$\rho^4 P_\rho^2 \geqslant \rho^4 + 4\gamma\rho - \frac{\rho^2}{\rho_{\text{def}}^2} g_{\text{def}} - f_{\text{def}}, \tag{66}$$

which characterizes the trajectory of a particle after the point of deflection in a segment where $\rho(l)$ increases monotonically. The equal sign in (66) corresponds to the point of deflection. When $\rho = \rho_{\text{def}}$, therefore, the right side of this expression will be zero, i.e., $\rho = \rho_{\text{def}}$ is a root of

$$\rho^4 + 4\gamma\rho - \frac{\rho^2}{\rho_{\text{def}}^2} g_{\text{def}} - f_{\text{def}} = 0. \tag{67}$$

It is easy to verify that Eq. (67) has three positive roots and $\rho = \rho_{\text{def}}$ is the largest of these. The existence of three positive roots for Eq. (67) follows from the inequality

$$\gamma^2 > f_{\text{def}} \sqrt{f_{\text{def}}}. \tag{68}$$

The last expression can be proven by using relations (21) and (58). We write the positive roots of Eq. (67),

$$\rho_{21} = -\frac{\gamma}{\sqrt{f_{\text{def}}}} + \sqrt{\frac{\gamma^2}{f_{\text{def}}} + \sqrt{f_{\text{def}}}}, \tag{69}$$

$$\rho_{22} = \frac{\gamma}{\sqrt{f_{\text{def}}}} - \sqrt{\frac{\gamma^2}{f_{\text{def}}} - \sqrt{f_{\text{def}}}}, \tag{70}$$

$$\rho_{23} = \frac{\gamma}{\sqrt{f_{\text{def}}}} + \sqrt{\frac{\gamma^2}{f_{\text{def}}} - \sqrt{f_{\text{def}}}}, \tag{71}$$

where

$$\rho_{21} < \rho_{22} < \rho_{23}.$$

The fact that $\rho_{\text{def}} = \rho_{23}$ follows from the inequality

$$\rho_{\text{def}} \geqslant \rho_{13} > \rho_{22}. \tag{72}$$

The inequality $\rho_{\text{def}} \geq \rho_{13}$ is the relation (65) proven above. The inequality $\rho_{13} > \rho_{22}$ is easily proven if the relations (21) and (58) are used. What has been said above shows that the right side of (66) is positive for all $\rho > \rho_{\text{def}}$. Therefore $P_\rho^2 > 0$ for these values of ρ. Thus the conditions (58) and (64) are sufficient for the existence of one, and only one, deflection point on the trajectory of a particle in this case. When these conditions are satisfied, the magnetic dipole acts as a mirror reflecting particles incident on it. For penetration of a particle to the center of a magnetic dipole, it is necessary that condition (56), for which Eq. (50) has a single positive root, be satisfied in addition to (49), or that the conditions (58) and (61) hold.

It is easy to verify that the conditions found, which are sufficient for particle reflection by a magnetic dipole field, are equivalent to a limitation imposed on the value of the angle α_0 between the radius vector $\mathbf{r}_0$ corresponding to the particle position in space at the initial time and the initial vector velocity of the particle, $\mathbf{v}_0$. This limitation is given by

$$b^3 (b-2)^2 < \sin^2 \alpha_0 \leqslant (b^3 - 2)^2, \tag{73}$$

where

$$b = \frac{\gamma^{1/3}}{\rho_0}. \tag{74}$$

For particle penetration to the center of the magnetic dipole, it is necessary that we have either

$$\sin^2 \alpha_0 < b^3 (b-2)^2, \tag{75}$$

or the simultaneous satisfaction of the two inequalities

$$\sin^2 \alpha_0 > b^3 (b-2)^2, \tag{76}$$

$$\sin^2 \alpha_0 > (b^3 - 2)^2. \tag{77}$$

If

$$b < 1, \tag{78}$$

the upper bound in (73) is always satisfied and the inequality (77) cannot hold. Under the condition (78), therefore, a sufficient condition for particle reflection by a magnetic dipole field can be represented as

$$\sin^2 \alpha_0 > b^3 (b-2)^2, \tag{79}$$

and a necessary condition for particle penetration to the center of a magnetic dipole leads to (75).

We now determine an upper bound for ρ_{def}, assuming as before that condition (49) is satisfied and the charged particle approaches the magnetic dipole. This bound will differ depending on whether g_0 is greater or less than unity. We confine ourselves to obtaining a bound for ρ_{def} when $g_0 < 1$. Similar bounds, but in considerably more cumbersome form, can easily be determined for $g_0 > 1$.

Using (32), we find that

$$\rho_{\text{def}} \leqslant \rho_n, \tag{80}$$

where ρ_n is the positive root of Eq. (51) having a value closest to but less than ρ_0. In finding the roots of Eq. (51), we use its representation in the form (53). As in the solution of Eq. (50), we shall assume γ is positive. If

$$\gamma^2 < g_0 \sqrt{g_0}, \tag{81}$$

Eq. (51) has the single positive root

$$\rho_{31} = -\frac{\gamma}{\sqrt{g_0}} + \sqrt{\frac{\gamma^2}{g_0} + \sqrt{g_0}}. \tag{82}$$

Consequently $\rho_n = \rho_{31}$ when (81) is satisfied. When

$$\gamma^2 > g_0 \sqrt{g_0} \tag{83}$$

Eq. (51) has in addition to ρ_{31} the positive roots

$$\rho_{32} = \frac{\gamma}{\sqrt{g_0}} - \sqrt{\frac{\gamma^2}{g_0} - \sqrt{g_0}}, \tag{84}$$

$$\rho_{33} = \frac{\gamma}{\sqrt{g_0}} + \sqrt{\frac{\gamma^2}{g_0} - \sqrt{g_0}}. \tag{85}$$

When (83) is satisfied, $\rho_n = \rho_{31}$ if $\rho_0 \leq \rho_{32}$, and $\rho_n = \rho_{33}$ if $\rho_0 \geq \rho_{33}$.

Thus under condition (49) the minimum distance to which a charged-particle approaches the center of a magnetic dipole when there is monotonic variation of ρ will always be less than ρ_n. When the conditions found for particle reflection by a magnetic dipole field are satisfied, the double bound

$$\rho_k \leqslant \rho_{\text{def}} \leqslant \rho_n.$$

exists for ρ_{def}.

After reflection by the magnetic dipole field, the charged-particle in this case ($g_0 < 1$) will move in a region characterized by the inequality

$$f_0 \frac{\rho_k^2}{\rho_0^2} \leqslant \sin^2 \vartheta(\rho) \leqslant g_0 \frac{\rho^2}{\rho_k^2}. \tag{86}$$

Excitation of acoustic waves by ion-acoustic turbulence

Kh. O. Abdulloev, F. Kh. Khakimov, and V. G. Makhan'kov

(Submitted June 19, 1973)
Zh. Tekh. Fiz., 44, 698-705 (April 1974)

We consider unstable acoustic (a) waves with frequency $\omega \ll \nu_e, \nu_i$ in a dense, fully ionized plasma characterized by a high level of ion-acoustic (s) turbulence. The interaction is a decay interaction. When the level of the (s) turbulence u = W/n T exceeds a threshold value u_{thr}, unstable acoustic waves are excited in the region $\omega < \nu_e, \nu_i$. As a result s-wave energy is transferred to smaller k values. Under certain conditions this process can compete with energy transfer due to induce s-wave scattering on plasma ions. The instability growth rates and the threshold value are given.

1. INTRODUCTION

In connection with the large number of experiments which have been carried out on the turbulent heating of plasmas,[1,3] considerable interest is being given to the study of ion-acoustic (s) turbulence.[4,7]

It is well known that ion-acoustic waves have a nondecay spectrum,[4] i.e., it is impossible to satisfy both of the conditions

$$\left.\begin{array}{l}\omega_1+\omega_2=\omega_3,\\ \mathbf{k}_1+\mathbf{k}_2=\mathbf{k}_3\end{array}\right\} \tag{1.1}$$

simultaneously. Here, ω_1, ω_2, ω_3 and $\mathbf{k}_1$, $\mathbf{k}_2$, $\mathbf{k}_3$, are the frequencies and wave vectors of the interacting waves. As a result, the principal nonlinear effect leading to the establishment of the (s) turbulence spectrum is assumed to be the induced scattering of ion-acoustic waves on plasma particles.[4-6] On the other hand, the "forbiddenness" for decay in the acoustic part of the spectrum is comparatively small: $\Delta\omega_f \sim \omega_s k_i^2 d_e^2$ (d_e is the electron Debye radius).

By applying very trivial dimensional considerations we can draw the following conclusions: The nonlinear frequency shift due to turbulence at a frequency near ω_s can be roughly estimated as[7]

$$\Delta\omega_s \sim \omega_s \frac{W}{nT} \tag{1.2}$$

(here, W is the energy density of the turbulence in the region $\sim \omega_s$ and nT is the thermal energy density in the plasma) and the degree of "forbiddenness" for decay for the ion-acoustic (s) turbulence, as noted above, is

$$\Delta\omega_f \sim \omega_1 k_1^2 d_e^2, \tag{1.3}$$

where

$$k_1^2 d_e^2 \ll 1.$$

Comparing (1.2) and (1.3), we conclude qualitatively that the condition that must be satisfied for a decay interaction is

$$\Delta\omega_s > \Delta\omega_f$$

or in our case (see also ref. 7).

$$\frac{W}{nT} > k_1^2 d_e^2. \tag{1.4}$$

This kind of interaction must lead to an energy transfer from s waves down the spectrum to lower frequencies ω and wave numbers[7] k [in the acoustic part of the spectrum $\omega_s = kv_s$, $v_s = v_{Te}(m_e/m_i)^{1/2}$].

If we are interested in the excitation of acoustic waves by s turbulence we need consider only one low-frequency wave$^{1)}$ $\omega \ll \omega_1, \omega_2$, since $\omega_{1,2} \gg \nu_i$, and $\omega \ll \nu_i$, so that $k \ll k_1, k_2$. The energy change in each interaction event is negligible and the resultant energy transfer of the ion-acoustic waves is of a "relay" (differential) nature.

2. DISPERSION EQUATION FOR A HIGHLY COLLISIONAL PLASMA WITH FULLY DEVELOPED ION-ACOUSTIC TURBULENCE

The ion-acoustic branch in a nonisothermal plasma ($T_e \gg T_i$) goes over to the acoustic branch when $k_\nu \sim \nu_e/v_e$ (ν_e is the frequency of binary electron−electron and electron−ion collisions; ν_i is the ion−ion collision frequency; v_e and v_i are the thermal velocities of the electrons and ions respectively, $v_{e,i}^2 = T_{e,i}/m_{e,i}$). As a result, decay interactions of linear ion-acoustic (s) and acoustic (a) waves are forbidden by the conservation laws. If the ion-acoustic turbulence reaches a certain level [condition (1.4)], however, the broadening of the field correlation functions can lead to decay.[7] In order to study this effect, by analogy with ref. 8 we now obtain the dispersion equation for acoustic (a) waves in the presence of developed ion-acoustic turbulence.

Neglecting dissipative effects connected with Landau damping, we use the equations of collisionless hydrodynamics to describe the (s) waves

$$\frac{\partial n_e}{\partial t}+\operatorname{div} n_e\mathbf{v}_e=0,\quad \frac{\partial n_i}{\partial t}+\operatorname{div} n_i\mathbf{v}_i=0, \tag{2.1}$$

$$\frac{\partial \mathbf{v}_e}{\partial t}+(\mathbf{v}_e\nabla)\,\mathbf{v}_e=-\frac{T_e}{m_e n_e}\nabla n_e+\frac{e}{m_e}\mathbf{E}, \tag{2.2}$$

$$\frac{\partial \mathbf{v}_i}{\partial t}+(\mathbf{v}_i\nabla)\,\mathbf{v}_i=-\frac{e}{m_i}\mathbf{E}. \tag{2.3}$$

For low frequencies the equations have the form

$$\frac{\partial n_e}{\partial t}+\operatorname{div} n_e\mathbf{v}_e=0,\quad \frac{\partial n_i}{\partial t}+\operatorname{div} n_i\mathbf{v}_i=0, \tag{2.4}$$

$$n_e\left[\frac{\partial}{\partial t}+(\mathbf{v}_e\nabla)\right]v_{e,\alpha}=-\frac{1}{m_e}\frac{\partial n_eT_e}{\partial x_\alpha}+\frac{e}{m_e}n_eE_\alpha-\frac{1}{m_e}\frac{\partial \pi_{e\alpha\beta}}{\partial x_\beta}+\frac{R_{T\alpha}}{m_e}, \tag{2.5}$$

$$n_i\left[\frac{\partial}{\partial t}+(\mathbf{v}_i\nabla)\right]v_{i,\alpha}=-\frac{1}{m_i}\frac{\partial n_iT_i}{\partial x_\alpha}-\frac{1}{m_i}\frac{\partial \pi_{i\alpha\beta}}{\partial x_\beta}-\frac{e}{m_i}n_iE_\alpha-\frac{R_{T\alpha}}{m_i}, \tag{2.6}$$

$$n_e\frac{3}{2}\left[\frac{\partial}{\partial t}+(\mathbf{v}_e\nabla)\right]T_e+n_eT_e\frac{\partial \mathbf{v}_e}{\partial \mathbf{r}}=-\pi_{e\alpha\beta}\frac{\partial v_{e\alpha}}{\partial x_\beta}-\frac{\partial}{\partial \mathbf{r}}\mathbf{q}_e, \tag{2.7}$$

Expression (2.22) has been obtained under the assumption that the ion-acoustic wave packet has a spread $\Delta\omega$ in frequency and a spread $\Delta\mathbf{k}_1$ in angle. We denote the aperture angle (i.e. the divergence) of the s-wave packet by $\Delta\vartheta_0$. Using the conservation of energy in the decay and allowing for the nonlinear frequency shifts of the interacting waves we get

$$\delta\left(\omega-\frac{\mathbf{k}\mathbf{k}_1}{kk_1}\omega_a-\delta\omega_{\mathbf{k}_1}^{H}\right)=0 \quad \text{or} \quad 1-\cos\left(\widehat{kk_1}\right)\sim\frac{\vartheta_0^2}{2}\sim\left(\frac{k_1}{k}\right)\frac{W}{nT},$$

assuming that $\delta\omega_{\mathbf{k}_1}^{H}\sim\omega_{\mathbf{k}_1}W/nT$.

The change $\delta\Delta\omega_{\mathbf{k}\mathbf{k}_1}$ for a change of angles $\mathbf{k}_1$ is of order

$$\delta\Delta\omega_{\mathbf{k}\mathbf{k}_1}\approx\left(\frac{kv_s}{2}\right)\frac{k}{k_1}\frac{\Delta k_1}{k_1}+kv_s\Delta\vartheta_0. \tag{2.23}$$

Using (2.23), we can write (2.22) in the form[2)]

$$\begin{aligned}\omega'-i\gamma_{\mathbf{k}}^{s}={}&-i\frac{\pi}{2}\omega_a\cos^2\vartheta_0\frac{u}{\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au}\\&-i\pi\omega_a\cos\vartheta_0\sin^2\vartheta_0\frac{u}{\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au}\\&+i\frac{\pi}{2}\omega_a\cos^2\vartheta_0\sin^2\vartheta_0\frac{u}{\left(\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au\right)^2},\end{aligned} \tag{2.24}$$

where u = W/nT and W is the total energy density in the s-wave packet.

We noted above (see also ref. 10) that if $\delta(\Delta\omega_{\mathbf{k}\mathbf{k}_1})>\omega'$, there is kinetic instability with a growth rate which can be estimated as

$$\gamma_k'=\frac{\pi}{8}\omega_a\frac{W}{nT}\frac{\cos^2\vartheta_0\sin^2\vartheta_0}{\left(\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au\right)^2}. \tag{2.25}$$

From (2.24) we get the condition for the excitation of acoustic waves by ion-acoustic turbulence

$$\cos^2\vartheta_0\sin^2\vartheta_0>\left(\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au\right)(\cos^2\vartheta_0+2\cos\vartheta_0\sin^2\vartheta_0). \tag{2.26}$$

In order-of-magnitude terms

$$\sin^2\vartheta_0>\left(\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au\right)\left(1+2\frac{\sin^2\vartheta_0}{\cos\vartheta_0}\right). \tag{2.27}$$

There is no excitation if $\sin\vartheta_0=0$ or $\cos\vartheta_0=0$. The conditions for decay are $u>k_1^2d_e^2$ and $\vartheta_0^2\sim(k_1/k)u$. Therefore (2.27) can be rewritten as

$$u>u_\vartheta=\frac{k}{k_1}\left(\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au\right). \tag{2.28}$$

Remembering that $\gamma>(m_e/m_i)\nu_e$, we obtain the condition for which *a* waves can be excited:

$$\gamma_{\mathbf{k}}^{s}\sim\frac{\pi}{8}\omega_a\frac{u}{\left(\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au\right)^2}>\frac{m_e}{m_i}\nu_e$$

or

$$u>u_\nu=\frac{m_e}{m_i}\frac{\nu_e}{\omega_a}\frac{8}{\pi}\left(\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au\right)^2. \tag{2.29}$$

The instability threshold is determined by the greater of (2.28) and (2.29):

$$u_{\text{thr}}=\max\{u_\nu,\ u_\vartheta,\ k_1^2d_e^2\}. \tag{2.30}$$

The ratio of (2.28) to (2.29) when

$$\Delta\vartheta\gg\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au$$

is

$$\frac{u_\vartheta}{u_\nu}=\frac{k}{k_1}\frac{m_i}{m_e}\frac{\omega_a}{\nu_e}\frac{1}{\Delta\vartheta}. \tag{2.31}$$

If we neglect imaginary terms in (2.29), which is possible when $\omega'>\delta(\Delta\omega_{\mathbf{k}\mathbf{k}_1})$, (2.24) is replaced by

$$\begin{aligned}\omega'-i\gamma_{\mathbf{k}}^{s}={}&-\frac{\omega_a^2}{2}\cos^2\vartheta_0\frac{u}{\omega'-\Delta\omega_{\mathbf{k}\mathbf{k}_1}}-\frac{\omega_a^2u\cos\vartheta_0\sin^2\vartheta_0}{\omega'-\Delta\omega_{\mathbf{k}\mathbf{k}_1}}\\&-\frac{\omega_a^3}{2}\cos^2\vartheta_0\sin^2\vartheta_0\frac{u}{(\omega'-\Delta\omega_{\mathbf{k}\mathbf{k}_1})^2}.\end{aligned}$$

Thus, when $\omega'\gg\Delta\omega_{\mathbf{k}\mathbf{k}_1}$ we have

$$\begin{aligned}\omega'^2(\omega'-i\gamma_{\mathbf{k}}^{s})={}&-\omega'\frac{\omega_a^2}{2}\cos^2\vartheta_0u-\omega'u\omega_a^2\cos\vartheta_0\sin^2\vartheta_0\\&-u\frac{\omega_a^3}{2}\cos^2\vartheta_0\sin^2\vartheta_0,\end{aligned} \tag{2.32}$$

which for $\omega'>\gamma_{\mathbf{k}}^{s}$ describes the instability of the hydrodynamic type with a growth rate

$$\omega'=(-1)^{1/3}\omega_a^2\left[\frac{u}{2}\sin^2\vartheta_0\cos^2\vartheta_0\right]^{1/3}; \tag{2.33}$$

when $\omega'\ll\gamma_{\mathbf{k}}^{s}$ this gives rise to a dissipative instability

$$\omega'=\omega_a\left(\frac{\omega_a}{i\gamma_{\mathbf{k}}^{s}}\right)^{1/2}\left[\frac{u}{2}\cos^2\vartheta_0\sin^2\vartheta_0\right]^{1/2}. \tag{2.34}$$

The criteria for these instabilities are respectively[3)]

$$1>\sin^2\vartheta_0\cos^2\vartheta_0u_0>\max\left\{2(\Delta\vartheta)^3,\ \left(\frac{m_e}{m_i}\frac{\nu_e}{\omega_a}\right)^3\right\} \tag{2.35}$$

and

$$\left(\frac{m_e}{m_i}\right)^3\left(\frac{\nu_e}{\omega_a}\right)^3>\sin^2\vartheta_0\cos^2\vartheta_0u_0>(\Delta\vartheta)^3. \tag{2.36}$$

It is evident from (2.35) and (2.36) that these instabilities appear when $\Delta\vartheta\ll1$.

DISCUSSION

The above analysis shows that under certain conditions anisotropic ion-acoustic turbulence can be unstable against the excitation of acoustic waves. The growth rate of the instability can be estimated from (2.25) or

$$\gamma\leqslant\frac{\pi}{4}\omega_a\frac{u^2\frac{k_1}{k}}{\left(\Delta\vartheta_0+\frac{k}{2k_1}\frac{\Delta k_1}{k_1}+au\right)^2}\quad\text{for}\quad u<\frac{k}{k_1} \tag{3.1}$$

$$n_i \frac{3}{2}\left[\frac{\partial}{\partial t}+(\mathbf{v}_i\nabla)\right]T_i + n_i T_i \frac{\partial \mathbf{v}_i}{\partial \mathbf{r}} = -\pi_{i\alpha\beta}\frac{\partial v_{i\alpha}}{\partial x_\beta} - \frac{\partial}{\partial \mathbf{r}}\mathbf{q}_i, \qquad (2.8)$$

where

$$\mathbf{R}_T = -0.71 n_e \frac{\partial T_e}{\partial \mathbf{r}}, \quad \mathbf{q}_e = -3.16\frac{n_e T_e}{m_e \nu_e}\frac{\partial T_e}{\partial \mathbf{r}},$$

$$\mathbf{q}_i = -3.9\frac{n_i T_i}{m_i \nu_i}\frac{\partial T_i}{\partial \mathbf{r}}, \quad \pi_{e\alpha\beta} = -0.73\frac{n_e T_e}{\nu_e}W^e_{\alpha\beta},$$

$$\pi_{i\alpha\beta} = -0.96\frac{n_i T_i}{\nu_i}W^i_{\alpha\beta}, \quad W_{\alpha\beta} = \frac{\partial V_\alpha}{\partial x_\beta} + \frac{\partial V_\beta}{\partial x_\alpha} - \frac{2}{3}\delta_{\alpha\beta}\frac{\partial \mathbf{V}}{\partial \mathbf{r}}.$$

It should be noted that the following simplifications have been made in writing (2.4)-(2.8): 1) We are interested in the case $(m_e/m_i)\nu_e \ll \omega \ll kv_e, k^2v_e^2/\nu_e$ [this implies $\omega_a \gg (m_e/m_i)\,\nu_e$, i.e., the frequency of the "acoustic branch" is greater than the temperature equalization rate] so that quantities proportional to $\delta\nu = 3\,(m_e/m_i)\,\nu_e$ can be neglected; 2) we neglect the displacement current $(kv_e \ll \omega_{pe})$, putting $V_i^R = V_e^R$ or $U = V_e - V_i = 0$. We solve the system (2.1)-(2.8) by successive approximations, i.e., we expand all functions in series and retain only terms of second order or lower in the electric field. The system of equations taken to this degree of accuracy with $\omega \gg k^2v_e^2/\nu_e$ is greatly simplified. Equation (2.5) assumes the following form in the frequency range of interest:

$$n_0\frac{dV^{(2)}}{dt} + \frac{1.71}{m_e}n_0\frac{\partial T^{(2)}}{\partial x} + \frac{T_0}{m_e}\frac{\partial n^{(2)}}{\partial x} = \frac{T_0}{m_e n_0}n^{(1)}\frac{\partial n^{(1)}}{\partial x}, \qquad (2.9)$$

while the energy balance for the Fourier components is

$$T^{(2)} = -i\frac{m_e\nu_e}{3.16}\frac{1}{k}V_k^{(2)} - i\frac{m_e\nu_e}{3.16 n_0^2}\frac{1}{k^2}\int \omega_2 n_{k_1}^{(1)} n_{k_2}^{(1)} d\lambda, \qquad (2.10)$$

and for the case in which we are interested

$$V_{ke}^{(2)} = -\frac{1}{2}\frac{e^2}{T_e^2}\frac{\omega}{k}\int\left[1 - \frac{\omega_1}{\omega}\frac{(\mathbf{k}\mathbf{k}_1)}{k_1^2} - \frac{\omega_2}{\omega}\frac{(\mathbf{k}\mathbf{k}_2)}{k_2^2}\right]\frac{E_{k_1}^{(1)}E_{k_2}^{(1)}}{k_1k_2}d\lambda. \qquad (2.11)$$

In order to get (2.11), we make use of the fact that the contribution $(V_e\nabla)\,V_e$ is smaller than $(v_e/n_0)^2\,\tilde{n}_e\,(\nabla\tilde{n}_e)$ by an order of magnitude in $(v_e/v_s)^2 \sim (m_e/m_i)^{-1}$ if $\omega \ll kv_e$; thus the above term can be neglected.

Similar reasoning for the ion component of the plasma gives

$$V_{ik}^{(2)} = \frac{1}{3}\frac{kv_i^2}{\omega}\frac{1}{n_0^2}\int n_{ik_1}^{(1)}n_{ik_2}^{(1)}d\lambda + i\frac{0.71}{m_i}\frac{\nu_e}{k}\frac{1}{n_0^2}\int n_{ek_1}^{(1)}n_{ek_2}^{(1)}d\lambda$$
$$+ \frac{1}{2}\frac{kv_i^2}{\omega}\frac{1}{n_0^2}\int n_{ik_1}^{(1)}n_{ik_2}^{(1)}\left(\frac{\omega_2}{\omega}\frac{(\mathbf{k}\mathbf{k}_2)}{k_2^2} + \frac{\omega_1}{\omega}\frac{(\mathbf{k}\mathbf{k}_1)}{k_1^2}\right)d\lambda. \qquad (2.12)$$

Hence,

$$j_k^{(2)} = en_0\left(V_k^{(e)(2)} - V_k^{(i)(2)}\right) = \int S_1(k, k_1, k_2)E_{k_1}^{(1)}E_{k_2}^{(1)}d\lambda, \qquad (2.13)$$

$$d\lambda = \delta(k - k_1 - k_2)\,dk_1dk_2;$$

$$S_1(k, k_1, k_2) = S_{1e}(k, k_1, k_2) + S_{1i}(k, k_1, k_2).$$

After substitution of the values of S_{1e} and S_{1i} we see that $S_{1e} \gg S_{1i}$; therefore

$$S_1(k, k_1, k_2) = \frac{1}{2}\frac{n_0e^3}{T_{0e}^2}\frac{\omega}{kk_1k_2}\left[\frac{\omega_1}{\omega}\frac{(\mathbf{k}\mathbf{k}_1)}{kk_1} + \frac{\omega_2}{\omega}\frac{(\mathbf{k}\mathbf{k}_2)}{kk_2} - 1\right], \qquad (2.14)$$

where k corresponds to the low frequencies and k_1 and k_2 to the high frequencies which are of the order of the turbulence fluctuation frequencies.

From the system (2.1)-(2.3) we can easily find the components of the nonlinear current $S_2(k_1, k', k_2')$ defined by the functions $\tilde{V}_{k_{1e}}^{(1)}$ and $\tilde{V}_{k_{1i}}^{(1)}$ [see (2.13)]:

$$\tilde{V}_{k_1e}^{(1)} = \frac{e^2}{T_{0e}^2}\int E_{k_2'}^{(0)}E_{k'}^{R}\left[\frac{\omega'}{k_2'k'^2}\frac{(\mathbf{k}_1\mathbf{k}')}{k_1k'} + \frac{\omega_2'}{k_2'^2k'}\frac{(\mathbf{k}_1\mathbf{k}_2')}{k_1k_2'}\right]d\lambda_1'$$
$$- \frac{e^2}{T_{0e}^2}\int E_{k_2'}^{(0)}E_{k'}^{R}\frac{\omega_1}{k_2'k'k_1}d\lambda_1'. \qquad (2.15)$$

It is evident that the dissipation effects are negligible in the case we are considering, $\omega < k^2v_e^2/\nu_e$.

Correspondingly, for the ions

$$\tilde{V}_{k_1i}^{(1)} = \int\frac{(\mathbf{k}_2'\mathbf{k}')}{k_2'k'}\frac{k_1}{\omega_1}\tilde{V}_{k_2'e}^{(0)}V_{k',e}^{R}d\lambda_1'$$
$$= -\frac{e^2}{T_{0e}^2}\int\frac{(\mathbf{k}_2'\mathbf{k}')}{k_2'k'}\frac{\omega_2'}{k_2'^2}\frac{\omega'}{k'^2}\frac{k_1}{\omega_1}E_{k'}^{R}E_{k_2'}^{(0)}d\lambda_1'. \qquad (2.16)$$

The nonlinear current

$$j_{k_1}^{(1)} = -en_0\left(\tilde{V}_{k_1e}^{(1)} - \tilde{V}_{k_1i}^{(1)}\right) = \int S_2(k_1, k', k_2')E_{k_2'}^{(0)}E_{k'}^{R}d\lambda_1', \qquad (2.17)$$

where

$$S_2(k_1, k', k_2') = \frac{e^3n_0}{T_{0e}^2}\frac{1}{k_2'k'}\left[\frac{(\mathbf{k}_1\mathbf{k}')}{k_1k'}\frac{\omega'}{k'} + \frac{(\mathbf{k}_2'\mathbf{k}_1)}{k_2'k_1}\frac{\omega_2'}{k_2'} + \frac{(\mathbf{k}_2'\mathbf{k}')}{k_2'k'}\frac{\omega_2'\omega'}{k_2'k'}\frac{k_1}{\omega_1} - \frac{\omega_1}{k_1}\right]. \qquad (2.18)$$

The dispersion equation describing the excitation of acoustic waves by s waves has the form[8,10]

$$\omega' - i\gamma_{\mathbf{k}}^{s} = -\int\frac{w(\mathbf{k}, \mathbf{k}_1)\left(N_{\mathbf{k}_1}^{s} - N_{\mathbf{k}_1-\mathbf{k}}^{s}\right)}{\omega' - \Delta\omega_{\mathbf{k},\mathbf{k}_1} + i\delta}d\mathbf{k}_1. \qquad (2.19)$$

Here, ω' is the nonlinear correction term to the frequency of the acoustic waves

$$\omega' = \omega - \operatorname{Re}\omega_{\mathbf{k}}^{s}, \quad \Delta\omega_{\mathbf{k},\mathbf{k}_1} = \operatorname{Re}\left(\omega_{\mathbf{k}_1}^{s} - \omega_{\mathbf{k}} + \omega_{\mathbf{k}_1-\mathbf{k}}\right),$$

$\gamma_{\mathbf{k}}^{s}$ is the linear growth rate, $N_{\mathbf{k}_1}^{s}$ is the number of s-wave photons, $w(\mathbf{k}, \mathbf{k}_1)$ is usually the probability of the decay process; in this case it is proportional to the product of the nonlinear polarizabilities S_1 and S_2:

$$w(\mathbf{k}, \mathbf{k}_1) = \frac{2\left(\frac{n_0e^3}{T_{0e}^2}\right)^2\frac{\omega\omega_1}{k^2k_1^2}\left(\frac{\mathbf{k}\mathbf{k}_1}{kk_1}\right)^2}{\frac{\omega_{k_1}^{s}\partial\varepsilon}{\partial\omega}\Big|_{\omega-\Omega_{k_1}^{s}}\frac{\partial\varepsilon}{\partial\omega}\Big|_{\omega_{\mathbf{k}}}\frac{\partial\varepsilon}{\partial\omega}\Big|_{\Omega_{k_1}^{s}}}. \qquad (2.20)$$

After substituting (2.20) into (2.19), we get

$$\omega' - i\gamma_{\mathbf{k}}^{s} = -\frac{\omega_a^2}{2n_0T_e}\int\frac{k_1}{k}\left(\frac{\mathbf{k}_1\mathbf{k}}{k_1k}\right)^2\frac{\mathbf{k}\left(\frac{\partial W_{\mathbf{k}_1}}{\partial\mathbf{k}_1}\right)}{\omega' - \Delta\omega_{\mathbf{k}\mathbf{k}_1} + i\delta}d\mathbf{k}_1. \qquad (2.21)$$

The kinetic instability usually arises when $\Delta\omega_{\mathbf{k}\mathbf{k}_1} > \omega'$ and the integrand is proportional to $-i\pi\delta\,(\Delta\omega_{\mathbf{k}\mathbf{k}_1})$. Then, after integration by parts, Eq. (2.21) becomes

$$\omega' - i\gamma_{\mathbf{k}}^{s} = -i\frac{\pi}{2}\omega_a^2\int\frac{W_{\mathbf{k}_1}}{n_0T_e}d^3\mathbf{k}_1\left(\mathbf{k}\frac{\partial}{\partial\mathbf{k}_1}\right)\left(\frac{k_1}{k}\left(\frac{\mathbf{k}\mathbf{k}_1}{kk_1}\right)^2\delta\left(\omega - \left(\frac{\mathbf{k}\mathbf{k}_1}{kk_1}\right)\omega_a\right)\right)$$
$$= -i\frac{\pi}{2}\omega_a^2\int u_{\mathbf{k}_1}d^3\mathbf{k}_1\left[\left(\frac{\mathbf{k}\mathbf{k}_1}{kk_1}\right)^2\delta\left(\omega - \frac{\mathbf{k}\mathbf{k}_1}{kk_1}\omega_a\right) + 2\left(\frac{\mathbf{k}\mathbf{k}_1}{kk_1}\right)\left(1 - \left(\frac{\mathbf{k}\mathbf{k}_1}{kk_1}\right)^2\right)\right.$$
$$\left.\times\,\delta\left(\omega - \frac{\mathbf{k}\mathbf{k}_1}{kk_1}\omega_a\right) - \left(\frac{\mathbf{k}\mathbf{k}_1}{kk_1}\right)^2\omega_a\left(1 - \left(\frac{\mathbf{k}_1\mathbf{k}}{k_1k}\right)^2\right)\delta'\left(\omega - \frac{\mathbf{k}\mathbf{k}_1}{kk_1}\omega_a\right)\right]. \qquad (2.22)$$

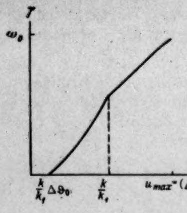

Fig. 1. Variation of the instability growth rate γ with u_0 for fixed values of the cone angle $\Delta\vartheta_0$ and the average wave number k_1 of the s waves.

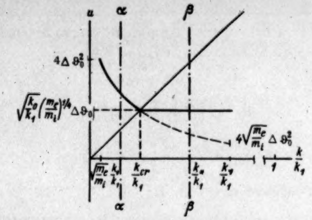

Fig. 2. Variation of the instability threshold for acoustic waves u_0 with the wave number k, where $k_{cr}=\Delta\vartheta_0(k_1k_\nu)^{1/2}(m_e/m)^{1/4}$.

and $\gamma \sim (\pi/4)\,\omega_a\,(u/\Delta\theta_0^2)$ with $u > k/k_1$. We use the fact that $\sin^2\vartheta_0 \sim \vartheta_0^2 \lessgtr (k_1/k)u$.

Remembering that γ must be less than ω_a, we obtain the upper limit on u as

$$u < u_{\max} = \Delta\vartheta_0^2, \tag{3.2}$$

Thus the quantity u can be neglected everwhere in the denominator in comparison with $\Delta\vartheta_0$. It follows from (3.2) that the smaller the cone angle of the s waves, the lower the energy at which there is a large change in dispersion in the acoustic region.

Figure 1 shows the relation between the instability growth rate γ and u_0 for fixed values of the cone angle $\Delta\vartheta_0$ and the average wave number k_1 of the s waves; Fig. 2 gives the variation in the instability threshold for acoustic waves u_0 with wave number k. In Fig. 3 we show the variation of u_0 with the cone angle $\Delta\vartheta_0$ of the s waves for fixed k.

If, on the other hand, the anisotropy of the s turbulence is small, $\Delta\vartheta_0 \to 1$, only the kinetic instability with $\gamma \ll \omega_a$ is possible.

It should be noted in conclusion that the instability we have considered leads to a transfer of the energy of the s waves from the collisionless wave-number region ($k > k_\nu$) to the region in which Coulomb collisions are important. This process can be considered as an additional mechanism for dissipation of the s-wave energy.

In the region of small wave numbers, but larger than k_ν, where, according to ref. 7, the main energy of the turbulence is concentrated, the dissipation of the s waves through ion–ion collisions[11] is characterized by

$$\gamma \sim 0.6\nu_i\frac{T_i}{T_e}, \tag{3.3}$$

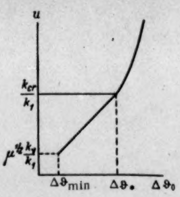

Fig. 3. Variation of the instability threshold for acoustic waves u_0 with the cone angle $\Delta\vartheta_0$ of the s waves for fixed k.

and the Landau damping of the electrons by

$$\gamma \sim \sqrt{\frac{\pi}{8}}\left(\frac{m_e}{m_i}\right)^{1/2}\omega_s. \tag{3.4}$$

Comparing (3.3) and (3.4), we find that when

$$k < k_\nu\left(\frac{T_e}{T_i}\right)^{1/2} \tag{3.5}$$

the damping of the s waves is determined entirely by collisions.

The dissipation of the s-wave energy by the instability we have considered can have a value as high as $\gamma \lessgtr \nu_i$, which not only exceeds (3.3) but also (3.4) if

$$k < k_\nu\left(\frac{T_e}{T_i}\right)^{3/2}. \tag{3.6}$$

Thus [for a sufficiently high level of s turbulence in the region (3.6)] the present process can determine the form of the ion-acoustic turbulence spectrum.

We take this opportunity to thank V. N. Tsytovich for discussion.

---

1) We study the stability of the s turbulence against the excitation of acoustic waves.

2) The resonance denominators in (2.24) contain the frequency spreading connected with the shift and broadening of the s-wave correlation functions.[7]

3) Here $\Delta\vartheta = \Delta\vartheta_0 + (k/k_1)(\Delta k_1/k_1)$.

Plasma acceleration in crossed electric and magnetic fields

V. I. Aref'ev

(Submitted January 10, 1973; resubmitted August 7, 1973)
Zh. Tekh. Fiz., 44, 706-722 (April 1974)

From an analysis of experiments on electromagnetic plasma acceleration in crossed E and H fields we conclude that the acceleration is unstable and turbulent in principle. A model of a plane accelerating current sheath is used to investigate the turbulence ion-acceleration mechanism. Quasilinear theory, which describes weakly turbulent processes in the plasma, is used to study the development of the most dangerous transverse (Hall) current-driven instabilities, which produce a large contribution to the anomalous resistance of the plasma and lead to turbulence acceleration. The anode and pulsed current sheaths are investigated with allowance for the self-consistent anomalous resistance. It is noted that there can be local amplification of the Hall current in the microscopic turbulence; at a high noise level this leads to local demagnetization of the electrons and breakaway of the drift current.

In a number of experimental papers[1-10] on electromagnetic plasma acceleration it has been noted that an important role is played by unstable, turbulence processes; these can determine the flow and runaway patterns of a plasma in crossed E and H fields. Theoretical examinations of these problems (see refs. 11-13, for example) have drawn attention to the fact that the process of plasma acceleration in crossed electric and magnetic fields is, in principle, unstable and turbulent at least because it is impossible in practice to avoid the excitation of the most dangerous low-frequency instabilities of the transverse (Hall) current, which have the maximum effect on the anomalous resistance of the plasma. Thus the problem necessarily arises of dealing with so-called "turbulence plasma acceleration,"[13] based on a systematic analysis of the anomalous processes such as have been fully described in the review of ref. 1.

The most important experimental results are as follows:

1) The existence of limiting acceleration regions (the "current crisis") above which the plasma flow in an accelerator becomes unstable and turbulent.

2) The development of intense low-frequency (coherent) and high-frequency (random) oscillations, which lead to the appearance of many anomalous effects.[1]

3) The partial or total breakdown of "accelerating current layers" (Fig. 1) as a result of the growth of unstable turbulence processes and a basic change in the acceleration conditions.

4) The generation of "fast particles" as a result of the turbulence processes.

Emphasizing the general nature of the anomalous effects 1-4, we can draw the important conclusion that the acceleration of a plasma in E and H fields is an unstable and turbulence process in principle. Thus the frequent and important problem of acceleration in (E, H) fields of an unstable turbulence plasma, which is one aspect of turbulence heating, must be considered entirely on the basis of collective processes. We now consider some of the problems connected with turbulence plasma acceleration.

1. THE MECHANISM OF TURBULENCE PARTICLE ACCELERATION IN (E, H) FIELDS

Although there is a wide variety of existing plasma accelerators, [stationary (Hall), pulsed, etc.][1] a common feature in their operation is the formation of an accelerating current sheath, shown schematically in Fig. 1, in which energy is transferred to the plasma from the electromagnetic field and transformed into kinetic energy of the charged particles. In Hall accelerators, for example, a highly nonuniform current sheath is produced next to the anode (Fig. 1a); this is often called the anode sheath. In pulsed systems (Fig. 1b), a pulsed current sheath is produced. Using the model of a plane accelerating current sheath enables us to classify accelerators according to the interaction time of the external electromagnetic fields: We have stationary pulsed and periodic types. With this model we can take account of the special features of the plasma acceleration process in E, H fields and clarify the details of the turbulence acceleration mechanism.

We make use of the equations for a weakly turbulent plasma and consider the balance of forces acting on the electrons and ions:

$$M\frac{d\mathbf{v}_i}{dt}=e\left(\mathbf{E}+\frac{1}{c}[\mathbf{v}_i\mathbf{H}]\right)+\mathbf{F}_{i,i}+\mathbf{F}^f_{i,i}+\mathbf{F}_{i,e}+\mathbf{F}^f_{i,e}; \qquad (1)$$

$$m\frac{d\mathbf{v}_e}{dt}=-e\left(\mathbf{E}+\frac{1}{c}[\mathbf{v}_e\mathbf{H}]\right)+\mathbf{F}_{e,e}+\mathbf{F}^f_{e,e}+\mathbf{F}_{e,i}+\mathbf{F}^f_{e,i}. \qquad (2)$$

Here, $\mathbf{F}_{i,j}$, $\mathbf{F}_{i,e}$, $\mathbf{F}_{e,e}$, $\mathbf{F}_{e,i}$ are the forces produced by binary collisions and $\mathbf{F}^f_{i,i}$, $\mathbf{F}^f_{i,e}$, $\mathbf{F}^f_{e,e}$, $\mathbf{F}^f_{e,i}$ are the collective friction forces, which appear either between different groups of ions (electrons) or between electrons and ions. In contrast to the forces based on binary collisions, the collective friction forces are generally unbalanced, i.e., the force can be greater on one of the interacting components than on the other. This is because part of the momentum and energy is carried away by unstable plasma oscillations. We can use (1) and (2) to derive the main features of the acceleration mechanism for ions in an unstable, turbulent plasma.

a. The ion–ion friction forces $\mathbf{F}_{i,i}$ and $\mathbf{F}^f_{i,i}$ can pro-

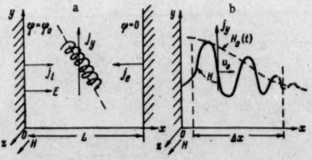

Fig. 1. Movement of a plasma particle in an "accelerating anode layer" (a) and in an pulsed current sheath (b).

duce acceleration only at the expense of ion energy. Examples are plasma currents with ion beams, thermodynamically nonequilibrium energy distributions of groups of similar ions produced by ionization, charge transfer and other processes, and the acceleration of an ensemble of ions of different masses. It should be noted that an energy transfer mechanism based on turbulence ion–ion friction is very effective, especially when it is remembered that the characteristic time for turbulence heating (acceleration) of ions $\tau^f_{i,i} < \tau_{i,i}$, which is of the order of magnitude of the growth time of ion–ion instabilities,[14] can be much less than the transit time of the plasma τ_0. Reference 13 considers several examples which show the effectiveness of this acceleration mechanism. The first of these is connected with the interaction in the accelerating current sheath of two types of ion: light ions and heavy ions with masses and densities equal to n_1, n_2, and M_1, M_2. If both pass across a sheath of identical potential difference (Fig. 1a), the light ions acquire a velocity which is $(M_2/M_1)^{1/2}$ times higher than that of the heavy ions. Under these conditions an ion beam instability is produced and this leads to equalization of the momentum in a time much smaller than the transit time. From the condition for energy and momentum balance between the two types of ion, we find that the limiting estimate of the energy of the heavy ions is $(M_2/M_1)^{1/2}$ times the applied potential difference. A similar situation is considered in ref. 15, where the development of a drift instability in a plasma containing impurity ions is accompanied by anomalous acceleration of the impurities in collective oscillations to very high energies, much greater than the energy of the main mass of ions; the theoretical calculation gives a satisfactory explanation of experiments carried out on Zeta.[16] Another mechanism considered in ref. 13 can appear when a "slow beam" of ions (electrons) is generated as a result of ionization or charge exchange in the accelerating current sheath; under certain conditions an ion–ion or electron–electron beam instability develops and this can lead to the rapid acceleration of a small group of ions to high energies. Estimates of the limiting energies of the fast ions in refs. 13 and 17 show the effectiveness of this mechanism.

b. Of particular interest are the acceleration mechanisms based on the electron–ion friction forces $\mathbf{F}_{i,e}$ and $\mathbf{F}^f_{i,e}$ which exist in a plasma through which a current is flowing. The collective electron–ion friction effect is then necessarily accompanied by the development of low-frequency current-driven instabilities and the appearance of anomalous resistance.[18,19] This acceleration process can also prove effective because the characteristic time for the transfer of momentum from electrons to ions in a turbulent plasma $\tau^f_{e,i}$, which is of the order of the growth time of the current-driven instabilities,[17] is comparatively small. Estimates of the limiting ion energies[13,17] confirm this conclusion. It should be noted, however, that if the turbulent forces acting on the electrons and ions are balanced, i.e., are equal in magnitude and opposite in sign, there can be no acceleration in the direction of the force $\mathbf{F}^f_{i,e}$, i.e., it is necessary that there be a lack of balance in order for this mechanism to be effective. Let us consider in more detail the acceleration effect connected with collective friction forces $\mathbf{F}^f_{e,e}$ and $\mathbf{F}^f_{e,i}$ acting only on the electron component. We thus assume complete imbalance when the momentum lost by the electrons in Cerenkov radiation is not transferred to the ions, but is carried away by turbulent fluctuations; from (2) we obtain the condition for the existence of an electric field in the plasma and can thus determine the electric force on **E**, which is the only one which produces acceleration of the ions:

$$\mathbf{E} = -\frac{1}{c}[\mathbf{v}_e\mathbf{H}] + \frac{1}{e}(\mathbf{F}^f_{e,e} + \mathbf{F}^f_{e,i}) - \frac{m}{e}\frac{d\mathbf{v}_e}{dt}. \tag{3}$$

It can thus be seen that the electric field accelerating the ions can be maintained, firstly by the external forces, i.e., the Lorentz force $-(e/c)\,[\mathbf{v}_e\mathbf{H}]$ (this effect is realized in all Hall accelerators; cf. the classification of acceleration mechanisms in a laminar plasma given in ref. 1); secondly, by the unbalanced forces of internal friction $\mathbf{F}^f_{e,e}$ and $\mathbf{F}^f_{e,i}$; thirdly, by the inertia force of the electrons (this effect is small in practice).

We consider first on the basis of (3) only one of the collective friction forces $\mathbf{F}^f_{e,e}$, $\mathbf{F}^f_{e,i}$, assuming that it is much greater than the others. It is easy to obtain a simple criterion for this condition: It is necessary that the effective frequency of electron scattering by the oscillations exceed the electron cyclotron frequency, $\nu_f > \omega_{He}$, the condition that the electrons should not be magnetized. It thus becomes obvious that the best approach to the turbulence plasma acceleration process is directly related to the most effective realization of the deacceleration process of electrons which actually acquire energy in a noninertial way from the external fields. A large number of experiments on the generation of fast particles are best explained by just this acceleration mechanism; this includes those in fast pinches[20,21] in paramagnetic pinches like Zeta,[16] in stationary[22] and pulsed[23,24] gas discharges, in high-current arcs,[25] and in the plasma focus.[26] For example, the experiments of Plyutto[27] on the generation of fast particles can be satisfactorily interpreted by internal friction forces $\mathbf{F}^f_{e,e}$ and $\mathbf{F}^f_{e,i}$. We may note in this connection that the collective force of electron–electron friction $\mathbf{F}^f_{e,e}$ is directly connected with the thermodynamically nonequilibrium energy distribution of the electrons (which is formed, for example, in a current-beam plasma, during ionization processes in a gas-discharge plasma, and so on). The physical importance of this force is directly related to the development of various beam-type instabilities, which lead to severe slowing down of electrons and transfer of energy to the self-consistent electric field [see (3)]. We may also note that the appearance of a large collective friction force $\mathbf{F}^f_{e,e}$ can lead not only to the formation of strong electric fields which accelerate the ions, but also to demagnetization of the electrons on waves with $\nu_f > \omega_{He}$. A nonsteady-state type of motion is then set up in the accelerating current sheath with changes in the acceleration conditions.

c. In the simplest case, if we exclude all collisions and neglect electron inertia, we can get an electric field, which, owing to the Hall effect in the plasma, is self-consistent with the movement of the charges:

$$\mathbf{E} = -\frac{1}{c}[\mathbf{v}_e\mathbf{H}]. \tag{4}$$

The conditions for this to exist are that there should be a transverse magnetic field and an electron drift motion. A basic requirement is that the ions which are accelerated by the electric field in the plasma should not be "magnetized". This reduces to the requirement that the ion Larmor radius should be much greater than either the size of the system of the characteristic scale size of the inhomogeneities in the electric field ($\rho_{Hi} \gg \Delta$)]. This is in essence, as has been noted in ref. 1, the direct method of accelerating ions in E, H fields, but the very realization of this process necessarily leads to various instabilities and the appearance of the turbulence acceleration mechanisms discussed above. If we use the well-known criterion for ion-acoustic or electron-acoustic instability $u > v_s$, where the velocity of the electrons

$$u=\left(\frac{c}{H}\right)\frac{\partial\varphi}{\partial x},$$

and $v_s = (T_e/M)^{1/2}$ is the velocity of ion sound, we can establish that the microscopic instabilities of the transverse current, which make the biggest contribution to the anomalous resistance of the plasma, exist in any current sheath smaller than the ion Larmor radius $\Delta < \rho_{Hi}$. Thus the question of laminar dissipationless acceleration is contradictory right from the start.

Considering the acceleration process of a plasma in E, H fields as unstable and turbulent from the very beginning, we now analyze this effect in two cases which are of practical interest: stationary (Fig. 1a) and pulsed (Fig. 1b) acceleration.

3. TURBULENCE ACCELERATION IN A STATIONARY HALL SHEATH

There are a number of publications (refs. 1-6, for example) devoted to the experimental study of unstable, turbulence processes in Hall type E, H accelerators. A particular property of these devices is the formation near the anode of a space-charge sheath (called the anode sheath), in which the ionization and electric field are concentrated. Ions are accelerated in this sheath and electrons drift across the magnetic field (Fig. 1a).

The development of high-frequency instabilities in the accelerating anode sheath, as has been noted in refs. 5 and 6, leads to turbulent heating of the plasma and an increase in the transverse mobility of the electrons. As a result, the electron current to the anode is increased. Other instabilities, observed in refs. 1-4, are low-frequency coherent oscillations in the form of a rotating azimuthal inhomogeneity in the electric field. The development of these oscillations brings about a basic change in the acceleration conditions. The accelerating current sheath transfers from the less stable dispersion branch to the more stable; the dissipationless acceleration condition becomes collisional and the stable laminar configuration becomes unstable and turbulent. The study of these processes is left to a special investigation and we limit ourselves here to an analysis of the high-frequency instabilities and microscopic turbulence. Using quasilinear theory[28] to describe a weakly turbulent plasma, we can establish the main microscopic effects resulting from transverse current-driven instabilities.

1. A common idea in the study of accelerating current sheaths is that introduced in ref. 1 of an accelerator from a given dispersion branch. Thus, for example, we can consider acceleration in the following branches: electron-acoustic, ion-acoustic, cyclotron, and so on with stationary acceleration, and magnetoacoustic, Alfvén, etc., for pulsed acceleration.

We will simplify the problem here and consider a plane model of the accelerating anode sheath. In the space between the anode, of potential φ_0, and the cathode, situated at a distance L away with zero potential, a space-charge sheath is formed close to the anode. We assume a constant ion current from the anode j_i directed along the x axis and a constant electron current from the cathode j_e. The ions are accelerated in the x direction by an electric field which is sufficiently strong so that the average ion Larmor radius is considerably greater than the distance between the anode and cathode. A constant magnetic field H is directed along the z axis and the electrons drift in the crossed fields in the y direction, forming a Hall current j_y. In order for there to be an x component of electron current, we must have collisions which produce a change in the electron momentum along the y direction (these collisions might in practice be ionizing or Coulomb collisions). In a collisionless plasma, the role of elastic collisions is played by collective scattering of electrons by the random oscillations excited by the Hall current-driven instabilities.

We consider the high-frequency Hall current-driven instabilities which can lead to turbulent heating of the plasma in the current layer and to the appearance of anomalous resistance. Following ref. 18, we note the following important physical fact. In our model, the ion generation process is reduced to a purely surface (electrode) effect, whereas in practice the generation and acceleration of ions in all experiments[1-6] take place simultaneously. As a result, the ions acquire an effective spread in velocities which may be related to the appearance of an effective ion temperature T_i, i.e., the ions must be considered as "hot", $T_i \simeq e\varphi_0$ from the start.

Making use of refs. 18 and 19, we quote without derivation the dispersion equation which describes the electrostatic instability of the transverse current in a collisionless plasma,

$$\begin{aligned}\varepsilon = 1 + \frac{1}{k^2 d_i^2}\left[1 + i\sqrt{\pi} z_i W(z_i)\right] \\ + \frac{1}{k^2 d_e^2}\sum_{n=-\infty}^{\infty} I_n e^{-\mu}\left[1 + i\sqrt{\pi}\frac{\tilde{\omega}}{k_z v_{T_e}} W\left(\frac{\tilde{\omega} - n\omega_{He}}{k_z v_{T_e}}\right)\right] = 0.\end{aligned} \tag{5}$$

Here

$$d_\alpha = \frac{v_{T_\alpha}}{\omega_{p_\alpha}},\quad v_{T_\alpha} = \left(\frac{2T_\alpha}{m_\alpha}\right)^{1/2},\quad \omega_{p_\alpha} = \left(\frac{4\pi n_\alpha e_\alpha^2}{m_\alpha}\right)^{1/2},\quad z_i = \frac{(\omega - \mathbf{k}\mathbf{v}_i)}{k v_{Ti}},$$

$$\tilde{\omega} = \omega - \mathbf{ku} - \mathbf{kv}_e,\quad \alpha = e,\ i;\quad \omega_{He} = \frac{eH}{mc};$$

m and M are the electron and ion masses respectively, $\mu = k_\perp^2 \rho_{He}^2/2$, $\rho_{He} = v_{Te}/\omega_{He}$, k_x, k_y, and k_z are the components of the wave vector **k**, ω is the oscillation frequency, $I_n(\mu)$ is the Bessel function, W is a Cramp function, u is the current velocity of the electrons along the y axis:

$$u = \frac{c}{H}\frac{\partial\varphi}{\partial x}, \tag{6}$$

v_i and v_e are the average ion and electron velocities along the x axis ($v_i = j_i/n_ie$, $v_e = j_e/n_ee$).

a. A study of (5) in the region $\omega_{Hi} \ll \omega \lessdot \omega_{He}$ for the case of high electron energy $T_e > T_i$ shows[18,19] that the most unstable perturbations are the "oblique" ones $(m/M)^{1/2} < k_z/k \ll 1$ with wavelengths of the order of the Larmor radius $k^{-1} \simeq \rho_{He}$ (ion-acoustic oscillations). For a Maxwellian electron velocity distribution, the frequency ω_k and growth rate γ_k of the most unstable oscillations are ($\gamma_k < \omega_k$).

$$\left.\begin{aligned} &\omega_k = \mathbf{kv}_i + kv_s\bar{a},\ \bar{a} = (1 + k_\perp^2\rho_{He}^2)^{-1/2},\ v_s = \left(\frac{T_e}{M}\right)^{1/2};\\ &\gamma_k = \frac{\sqrt{\pi}}{2}kv_s\bar{a}^3 z_e \exp\left(-\frac{z_e^2}{2}\right),\ z_e = \frac{(\mathbf{ku} + \mathbf{kv}_e - \omega_k)}{k_z v_{Te}}. \end{aligned}\right\} \quad (7)$$

The most unstable perturbations are those for which $k_z/k \lessdot u/v_{Te}$. The oscillations are unstable when $u > v_s$ and have a maximum growth rate of order $\omega_{e,i} = (\omega_{Hi}\omega_{He})^{1/2}$ (which is reached when $k_\perp^{-1} \simeq \rho_{He}$).

b. In the high-frequency region $\omega \simeq \omega_{He}$ for a plasma with hot ions $T_i > T_e$, an instability (Bernstein modes) is excited at harmonics of the electron cyclotron frequency[29] for high values of the current velocity $u \gtrdot v_{Te}$. In the particular case of purely transverse oscillations ($k_z \equiv 0$) near the n-th cyclotron harmonic, from (5) we have

$$\begin{gathered} \omega_k = +k(u^* - u),\ u^* = \frac{n\omega_{He}}{k}\left[1 + \frac{T_i}{T_e}I_n e^{-\mu}\right];\\ \gamma_k = \gamma_{\max}\left(\frac{u - u^*}{v_{Ti}}\right)\exp\left[-\frac{(u - u^*)^2}{2v_{Ti}^2}\right],\\ \gamma_{\max} = n\omega_{He}\frac{v_{Ti}}{u}\left[2\ln\left(\frac{u}{v_{Ti}}\frac{T_i}{T_e}\sqrt{\pi}\, I_n e^{-\mu}\right)\right]^{1/2}. \end{gathered} \quad (8)$$

The most unstable waves are those with $u - u^* \lessdot v_{Ti}$. The development of this instability, as is shown in ref. 29, produces a significant increase in the anomalous resistance of the plasma. This subject is currently being discussed in connection with collisionless shocks.

c. In the low-frequency region $\omega_{Hi} \ll \omega < \omega_{He}$ with $T_i > T_e$, a low-threshold instability of the electron-acoustic type[18] is excited; this can be considered as an instability at the zeroth cyclotron harmonic. The frequency ω_k and growth rate γ_k of the most unstable of the oblique perturbations $m/M \ll k_z/k \ll (m/M)^{1/2}$ of this type are

$$\left.\begin{aligned} &\omega_k = \mathbf{ku} + \mathbf{kv}_e + k_z\left(\frac{T_i}{m}\right)^{1/2}\bar{a},\ \bar{a} = (1 + k_\perp^2\rho_e^2)^{-1/2};\\ &\gamma_k = \frac{\sqrt{\pi}}{2}k_z\left(\frac{T_i}{m}\right)^{1/2}\bar{a}^3 z_i \exp\left[-\frac{z_i^2}{2}\right],\ z_i = \frac{\left[u - \frac{k_z}{k}\left(\frac{T_i}{m}\right)^{1/2}\right]}{v_{Ti}}. \end{aligned}\right\} \quad (9)$$

The unstable oscillations with $u > (k_z/k)(T_i/m)^{1/2}$, $\mathbf{ku} < 0$ have the maximum growth rate, of order $\sim \omega_{e,i}$. The development of microscopic turbulence in these forms can lead to turbulent plasma heating and the appearance of anomalous resistance. We will analyze the situation on the basis of quasilinear theory.

2. As an example showing the main features of the quasilinear relaxation of current-driven instabilities, we consider the development in the anode sheath of instabilities of the ion-acoustic type. In the drift approximation, the quasilinear equation which describes the turbulent heating and diffusion of electrons in (x, v_z) space as a result of Cerenkov radiation–absorption has the form[30]

$$\begin{aligned} &\frac{\partial f_e}{\partial t} + \frac{\partial}{\partial x}\left(\frac{j_e}{n_ee}f_e\right)\\ &= \sum_k\left(\frac{1}{v_z}\frac{\partial}{\partial v_z} - \frac{k_y}{\bar{\omega}_k\omega_{He}}\frac{\partial}{\partial x}\right)D_k\left(\frac{1}{v_z}\frac{\partial f_e}{\partial v_z} - \frac{k_y}{\bar{\omega}_k\omega_{He}}\frac{\partial f_e}{\partial x}\right), \end{aligned} \quad (10)$$

where

$$D_k(x, t) = \pi\frac{e^2}{m^2}|\varphi_k|^2\bar{\omega}_k^2\delta(\bar{\omega}_k - k_zv_z),$$

and the oscillation energy density W_k is given by $[W_k = (k^2|\varphi_k|^2/8\pi)\omega_k(\partial\varepsilon/\partial\omega_k)]$

$$\left(\frac{\partial}{\partial t} + \frac{\partial\omega_k}{\partial k_x}\frac{\partial}{\partial x}\right)\ln W_k = \pi\frac{\omega_k^2M}{k^2mn_e}\int\left(k_z\frac{\partial f_e}{\partial v_z} - \frac{k_y}{\omega_{He}}\frac{\partial f_e}{\partial x}\right)\delta(\bar{\omega} - k_zv_z)\,dv_z. \quad (11)$$

The study of the self-consistent system of equations (10) and (11) follows the pattern in ref. 30 for the case of turbulence effects at the front of a magnetoacoustic shock wave. We supplement (10) and (11) by the equations describing the motion of the ions in the anode sheath and the equation for the potential

$$\left.\begin{aligned} &j_i = en_iv_i,\ \frac{\partial}{\partial x}\left(\frac{Mv_i^2}{2} + e\varphi\right) = 0;\\ &\frac{\partial^2\varphi}{\partial x^2} = 4\pi e(n_e - n_i),\ n_e = \int f_e dv_z. \end{aligned}\right\} \quad (12)$$

We also use the approach of ref. 30 and replace the summation over k in (10) and (11) by a single term, which gives a small contribution to the diffusion coefficient D(k). Finally, we introduce the new variables

$$\xi = \frac{v_z^2}{2},\quad \eta = \frac{v_z^2}{2}\Big| + \frac{\omega_{He}}{\bar{k}_y}\int_0^x\left(\omega_k - \bar{k}_y\frac{c}{H}\frac{\partial\varphi}{\partial x'}\right)dx' = \frac{v_z^2}{2} - \frac{e}{m}(\varphi_i - \varphi_0),$$

and we obtain the following heat-wave type solution for the stationary case:

$$\left.\begin{gathered} f_e = f_{0e} + \left(\frac{\bar{k}_zj_i}{\omega_{\bar{k}}j_e}\right)\frac{\partial}{\partial\xi}(W_{\bar{k}} - W_0),\\ \mathrm{li}\left(\frac{W_{\bar{k}}}{W_0}\right) = \frac{1}{2}z_0(z_0 - z). \end{gathered}\right\} \quad (13)$$

Here li is the logarithmic integral, f_{0e} is the electron distribution function at $\varphi = 0$, $W_k = W_0$, W_0 is the energy of the thermal fluctuations,

$$z = \frac{\xi}{\sqrt{\eta}}\left(\frac{\pi\omega_k^2W_0e}{m\omega_{Hi}\bar{k}j_e}\right)^{-1/2},$$

z_0 is the initial self-similar coordinate, defined by the conditions $\varphi = 0$, $u = v_s$:

$$z_0 = \left(\frac{T_e\omega_{Hi}\bar{k}j_e}{\pi W_0e\omega_k^2}\right)^{1/2}.$$

It follows from this solution that the electron distribution function in velocity space has the form of a steep step with a width which increases monotonically with potential.

Thus the thermal energy of the electrons, defined as $nT_e = (1/2)\int mv_z^2 f_e dv_z$, increases monotonically from the cathode to the anode. The limiting electron energy is determined by the competition between turbulent heating and cooling by diffusion along the x axis; from (10) we find

$$T_e \lesssim \frac{m\omega_{He}\bar{\omega}_k \Delta x}{\bar{k}_y} \simeq e\varphi_0. \tag{14}$$

A similar analysis can be made of the nonlinear effects which appear on the development of instabilities at the electron cyclotron harmonics (8) and electron-acoustic modes (9). The principal macroscopic effect which arises in the development of these instabilities can be reduced to the appearance of a collective friction force

$$\mathbf{R}_f = \sum_k \gamma_k \frac{\mathbf{k}}{\omega_k} W_k. \tag{15}$$

Here, γ_k is the growth rate of the instabilities and W_k is the energy density of the oscillations.

It is well known[19,29] that an important question which arises in the study of instabilities of the types (8) and (9) is the identification of the nonlinear mechanism producing saturation of the oscillation energy. The relevant mechanism here is the electron nonlinearity. This means that the transfer of oscillation momentum to the electrons takes place by nonlinear processes. It is likely that in the saturation region of instabilities of types (8) and (9), the momentum lost by the ions in Cerenkov radiation of the oscillations is transmitted entirely to the electrons. Thus there will be a collective friction force $\mathbf{R}_{fe}$ (15) acting on the electrons and this will be equal in magnitude but opposite in sign to the force $\mathbf{R}_{fi}$ acting on the ions. We now consider cases where the energy level of the oscillations is close to the saturation value.

3. Let us determine the structure of the anode sheath (Fig. 1a) in two cases which are important in practice: a) when an ion-acoustic instability develops, i.e., in a plasma with $T_e > T_i$; b) when an instability develops at the electron cyclotron harmonics, i.e., in a plasma with $T_i > T_e$. In this way we are able to allow quantitatively for the main macroscopic effect of the turbulence – the self-consistent anomalous resistance – and to establish the principal qualitative effects of particle dynamics in a weakly turbulent plasma.

We approximate the electron and ion distribution functions, which have the form of steep steps in velocity space, by Maxwellian distributions with effective temperatures T_e and T_i. The problem then reduces to a system of hydrodynamic equations. We consider the first case.

a. Substituting the Maxwellian function for the electrons into the original system (10)-(12), integrating over velocities and summing over wave numbers, we obtain the following equations by analogy with ref. 30 after allowing for the resonance variation of the diffusion coefficient D_k with k discussed above:

$$j_i = en_i v_i, \quad \frac{d}{dx}\left(\frac{Mv_i^2}{2} + e\varphi\right) = 0, \quad \frac{d^2\varphi}{dx^2} = 4\pi e(n_e - n_i),$$

$$j_e = \frac{c}{H}\left[\frac{mn_e\nu c}{H}\frac{d\varphi}{dx}\right.$$
$$\left. + \sum_k k_y \frac{W_k}{\omega_k}\frac{\sqrt{\pi}}{2}\left(\frac{kv_e}{k_z v_{Te}}\right)\left(\frac{k_y c}{H}\frac{d\varphi}{dx} - \mathbf{kv}_i - \mathbf{kv}_e\right)\right],$$

$$v_i \frac{d\ln W_k}{dx} = \sqrt{\pi}\left(\frac{kv_e}{k_z v_{Te}}\right)\left(\frac{k_y c}{H}\frac{d\varphi}{dx} - \mathbf{kv}_i - \mathbf{kv}_e\right). \tag{16}$$

Here, ν is the frequency of elastic electron collisions unconnected with the turbulence effect. We note that we have to maximize with respect to wavelengths in (16), $\bar{k}_z/\bar{k} \leqslant u/v_{Te}$, $\bar{k}^{-1} \simeq \rho_{He}$, to get the values for which the growth rate (7) is a maximum. In addition to (16), which gives a correct qualitative account of the principal macroscopic effects of ion-acoustic turbulence, we introduce the boundary conditions

$$\varphi(0) = \varphi_0, \quad \varphi(L) = 0, \quad v_i(0) = v_0, \quad W_k(L) = W_0. \tag{17}$$

The integral of (16), which shows how the noise energy varies with potential, has the form

$$\ln\left(\frac{W_k}{W_0}\right) = 2\sqrt{\pi}\frac{\bar{k}_y}{\omega_{Hi}}\left(\frac{\bar{k}v_e}{k_z v_{Te}}\right)\left[\left(v_0^2 + \frac{2e\varphi_0}{M}\right)^{1/2} - \left(v_0^2 + \frac{2e}{M}(\varphi_0 - \varphi)\right)^{1/2}\right]$$
$$- \sqrt{\pi}\frac{\bar{k}v_e}{k_z v_{Te}}\bar{k}(L - x). \tag{18}$$

We make use of the neutrality condition in the sheath $n_e \simeq n_i$ (the criterion for this is that $\Delta x > (T_i/m)^{1/2}(1/\omega_{He})$ and get a single equation for the potential from (16):

$$j_e = \frac{mc^2\nu j_i}{eH^2\left[v_0^2 + \frac{2e}{M}(\varphi_0 - \varphi)\right]^{1/2}}\frac{d\varphi}{dx} + \frac{c}{2H}W_0\frac{d}{dx}\exp\left(\frac{\sqrt{\pi}\bar{k}v_e}{\left|\frac{c}{H}\frac{d\varphi}{dx}\right|}\right)$$
$$\times \left\{\frac{2\left[\left(v_0^2 + \frac{2e\varphi_0}{M}\right)^{1/2} - \left(v_0^2 + \frac{2e}{M}(\varphi_0 - \varphi)\right)^{1/2}\right]}{\omega_{Hi}} - (L - x)\right\}. \tag{19}$$

We have here maximized with respect to the most unstable oscillations. It can be seen from this equation that the role of binary collisions is important over the scale lengths of the inhomogeneities in the potential:

$$\Delta x \sim \frac{v_0}{\omega_{Hi}}\left(\frac{\nu}{\omega_{He}}\frac{j_i}{j_e}\right).$$

The role of turbulence dissipation appears in a nonlinear form through the exponential variation of the friction force with the current velocity and potential

$$R_f = \frac{d}{dx}W_{\bar{k}} = W_0\frac{d}{dx}\exp\left(\frac{\sqrt{\pi}\bar{k}v_e}{\left|\frac{c}{H}\frac{d\varphi}{dx}\right|}\right)$$
$$\times \left\{\frac{\left[\left(v_0^2 + \frac{2e\varphi_0}{M}\right)^{1/2} - \left(v_0^2 + \frac{2e}{M}(\varphi_0 - \varphi)\right)\right]^{1/2}}{\omega_{Hi}} - (L - x)\right\}. \tag{20}$$

It can be seen from this expression that the friction force decreases with increasing current velocity. As a result, the structure of the anode sheath is again of the steep step type (Fig. 2a) with a sharp change in potential near the cathode, i.e., in the region where there is an exponential growth in the noise energy from the thermal fluctuation level W_0 to some maximum value W_{max} determined by the nonlinear processes. From (19) we can estimate the integrated effect of the turbulent dissipation in the anode sheath. This dissipation occurs over a region of typical size:

$$\Delta x \simeq \frac{1}{4\sqrt{\pi}} \frac{v_0}{\omega_{Hi}} \ln\left(\frac{W_{\max}}{W_0}\right). \tag{21}$$

It has been noted in ref. 30, however, that local effects of the microscopic turbulence occurring over much smaller scales are also important. Physically, this is because the diffusion character of the quasilinear relaxation process implies that the Hall current, which is the cause of the instability, is pulled by the noise into the region in which the energy of the oscillations is small, i.e., towards the cathode. The general solution, which describes the potential over both the sloping and steep parts of the distribution, can be found from (19) by a method similar to that used for a shock wave in ref. 30:

$$\begin{aligned}\frac{1}{\omega_{Hi}}\left[\left(v_0^2+\frac{2e\varphi_0}{M}\right)^{1/2}-\left(v_0^2+\frac{2e}{M}(\varphi_0-\varphi)\right)^{1/2}-\omega_{Hi}(L-x)\right] \\ =\frac{2\sqrt{\pi}\,\bar{k}v_s}{\omega_{Hi}}\int_L^x dx'\left\{\ln\left[\frac{2Hj_e(L-x')}{cW_0}-\frac{2Hj_i\nu}{cW_0\omega_{He}\omega_{Hi}}\right.\right. \\ \left.\left.\times\left\{\left(v_0^2+\frac{2e\varphi_0}{M}\right)^{1/2}-\left(v_0^2+\frac{2e}{M}(\varphi_0-\varphi)\right)^{1/2}\right\}\right]\right\}^{-1}.\end{aligned} \tag{22}$$

The corresponding Hall current distribution is

$$\begin{aligned}j_y=en\frac{c}{H}\frac{d\varphi}{dx}=\frac{j_i}{\left(v_0^2+\frac{2e(\varphi_0-\varphi)}{M}\right)^{1/2}\ln\left(\frac{W_{\tilde{k}}}{W_0}\right)}\left[\left(v_0^2+\frac{2e\varphi_0}{M}\right)^{1/2}\right. \\ \left.-\left(v_0^2+\frac{2e}{M}(\varphi_0-\varphi)\right)^{1/2}-\omega_{He}(L-x)\right].\end{aligned} \tag{23}$$

Figure 2a shows the distribution of the principal quantities φ, W_k, and j_y in the anode sheath. A characteristic feature of the solution is the steep front in the potential, current, and noise level near the cathode. The typical scale of the inhomogeneity here is

$$\Delta x \simeq \frac{eW_{\tilde{k}}}{2j_e m\omega_{He}}, \tag{24}$$

i.e., it can be smaller than the Larmor radius when $\Delta x < \rho_{He}$. If this happens, then the local method of investigating the instabilities is no longer valid and it becomes impossible to consider the electrons as magnetized, $\nu_f > \omega_{He}$; we therefore assume that above some sufficiently high noise level $W_{\tilde{k}} > 2mj_i v_0 \nu/(e\omega_{Hi})$, the potential drop near the cathode becomes so sharp that there is local demagnetization of the electrons and a complex nonstationary system of motion is set up. We can use the solution we have obtained to find the value of the electron current (which is a free parameter in this problem) at which ion-acoustic turbulence is necessarily established:

$$j_e \simeq \frac{c}{2H}\frac{dW_{\tilde{k}}}{dx} \simeq \frac{cW_{\max}}{2H\Delta x} \simeq en\frac{2\sqrt{\pi}}{3}\left[\frac{T_e}{M\left(\frac{2e\varphi_0}{M}\right)^{1/2}}\right]\frac{1}{\ln\left(\frac{nT_e}{3W_0}\right)}. \tag{25}$$

Here we have estimated $W_{\max} \simeq nT_e/3$. The power scattered in turbulent heating of the plasma is equal to the work done by the electron current j_e in the electric field E and the power fed into acceleration of the ions is equal to the work done by the ion current in this electric field. We can compare these two powers: the useful power which goes to accelerating the ions, and the power which is used for turbulent heating of the electrons,

$$\frac{j_i E}{j_e E} \simeq \frac{3}{2\sqrt{\pi}}\left(\frac{2e\varphi_0}{T_e}\right)\ln\left(\frac{nT_e}{3W_0}\right). \tag{26}$$

It can be seen from these estimates that if the ion-acoustic instability is set up, a considerable fraction of the power fed to the accelerator is scattered in turbulent heating of the electrons.

b. We now consider the second case, in which macroscopic turbulence at the electron cyclotron harmonics occurs in the anode sheath [see (8)]. By analogy with the previous case, we write down the initial system of hydrodynamic equations describing the distribution of the principal parameters φ, W_k, and j_y in the anode sheath,

$$\left.\begin{aligned}j_i=en_iv_i,\quad \frac{d}{dx}\left(\frac{Mv_i^2}{2}+e\varphi\right)=0,\quad \frac{d^2\varphi}{dx^2}=4\pi e(n_e-n_i), \\ j_e=\frac{c}{H}\left[\frac{\nu n_e mc}{H}\frac{d\varphi}{dx}+\sum_k\gamma_k\frac{k}{\omega_k}W_k\right], \\ v_e\frac{d\ln W_k}{dx}=2\gamma_k, \\ \omega_k=k(u^*-u),\quad \gamma_k=\gamma_{\max}\left(\frac{u-u^*}{v_{Ti}}\right)\exp\left[-\frac{(u-u^*)^2}{2v_{Ti}^2}\right].\end{aligned}\right\} \tag{27}$$

The boundary conditions are the same as those in (17). The structure of the turbulent Hall sheath is studied as before. For example, the integral relating the noise energy to the potential is

$$\begin{aligned}\ln\left(\frac{W_{\tilde{k}}}{W_0}\right)=\frac{2\gamma_{\max}j_i}{v_{Ti}j_e}\left[\frac{\left(v_0^2+\frac{2e\varphi_0}{M}\right)^{1/2}-\left(v_0^2+\frac{2e}{M}(\varphi_0-\varphi)\right)^{1/2}}{\omega_{Hi}}\right. \\ \left.-\int_L^x\frac{u^*dx'}{\left[v_0^2+\frac{2e}{M}(\varphi_0-\varphi)\right]^{1/2}}\right].\end{aligned} \tag{28}$$

We now find the principal equation for the potential φ and the expression for the collective friction force R_f:

$$\begin{aligned}j_e=\nu n_e m\left(\frac{c}{H}\right)^2\frac{d\varphi}{dx} \\ +\frac{c}{H}\frac{\gamma_{\max}}{v_{Ti}}W_0\exp\left\{\frac{2\gamma_{\max}j_i}{v_{Ti}j_e\omega_{Hi}}\left[\left(v_0^2+\frac{2e\varphi_0}{M}\right)^{1/2}-\left(v_0^2+\frac{2e}{M}(\varphi_0-\varphi)\right)^{1/2}\right.\right. \\ \left.\left.-\omega_{Hi}\int_L^x\frac{u^*dx'}{\left[v_0^2+\frac{2e}{M}(\varphi_0-\varphi)\right]^{1/2}}\right]\right\},\end{aligned} \tag{29}$$

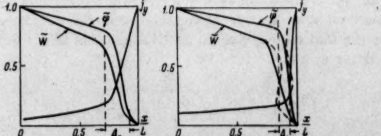

Fig. 2. Variation of the main parameters in the accelerating anode sheath; $\tilde{\varphi} = \varphi/\varphi_{\max}$, $\tilde{W} = W_{\tilde{k}}/W_{k,\max}$, $\tilde{j}_y = j_y/j_{y,\max}$ for the development of an ion-acoustic instability (a) and an electron cyclotron instability (b).

$$R_f = \frac{\gamma_{\max}}{v_{Ti}} W_k. \tag{30}$$

The first term in (29) gives the contribution to the current from the classical transverse mobility $b_{e\perp} = \nu/\omega_{He}^2(e/m)$, while the second term allows for the effect of turbulence on this mobility. Using the boundary conditions, we find the following solution from (27), (28), and (29):

$$\left.\begin{aligned} \ln\left|\frac{W_k f_e^*}{W_0\left(f_e^* + \frac{c}{H}\frac{\gamma_{\max}}{v_{Ti}}W_k\right)}\right| &= \frac{2\gamma_{\max}\omega_{He}}{v_{Ti}\nu}\left(\frac{f_e^*}{j_e}\right)(L-x), \\ j_y = en\frac{c}{H}\frac{d\varphi}{dx} &= enu^* + \frac{j_e v_{Ti}}{2\gamma_{\max}}\frac{d\ln W_k}{dx}, \end{aligned}\right\} \tag{31}$$

where

$$f_e^* = \frac{\nu}{\omega_{He}} en_0 u^* - j_e.$$

Figure 2b shows the x distribution of the main parameters φ, W_k, and j_y. The characteristic inhomogeneity scale over which the integrated effect of the turbulence is felt is equal to

$$\Delta x \simeq \frac{c}{\omega_{pe}}\left(\frac{m}{M}\right)^{1/2}\frac{1}{n'}\frac{\ln\left(\frac{W_{\max}}{W_0}\right)}{\left[2\ln\left(\frac{u}{v_{Ti}}\sqrt{\pi}\frac{T_i}{T_e}I_n e^{-\mu}\right)\right]^{1/2}} \quad (n' = 1,\ 2,\ 3,\ \ldots).$$

The power going into turbulent heating can be estimated as

$$(j_e E) \simeq \frac{c}{H}\frac{\gamma_{\max}}{v_{Ti}}W_{\max}E \simeq (j_i E)\frac{W_{\max}\ln\left(\frac{W_{\max}}{W_0}\right)}{mnv_0^2}\left(\frac{m}{M}\right)^{1/2}\left(\frac{H_0^2}{8\pi ne\varphi_0}\right)^{1/2}, \tag{32}$$

and forms a significant fraction of the useful power $(j_i E)$ going into the acceleration of the ions. We can also estimate the integrated value of the transverse electron mobility:

$$b'_{e\perp} = \frac{e}{m\omega_{He}}\left(\frac{mv_{Ai}j_e}{Mv_0 j_i}\right)\frac{1}{n'}\frac{\ln\left(\frac{W_{\max}}{W_0}\right)}{\left[2\ln\frac{u}{v_{Ti}}\frac{T_i}{T_e}\right]^{1/2}}.$$

It should be noted that the stationary solutions found above for the two types of instability in the anode sheath might not be realized in practice. This is because, as we saw earlier, the potential front near the cathode may become so steep that $\Delta x < \rho_{He}$. The electron drift may then be demagnetized and there can be a breakaway in the current j_y. This effect is analogous to the inversion of the ion flow at a shock front considered in ref. 30. It can be shown that with cyclotron oscillations this effect occurs earlier at a noise level of

$$\ln\left(\frac{W_{\max}}{W_0}\right) \simeq \left(\frac{\omega_{He}}{\nu}\frac{T_e}{2e\varphi_0}\right)\left(\frac{f_e^* 2n'}{j_e}\right)\left[2\ln\frac{u}{v_{Ti}}\frac{T_i}{T_e}\sqrt{\pi}I_n e^{-\mu}\right]^{1/2}. \tag{33}$$

In Fig. 2b, the flow inversion effect in the anode sheath is depicted by the dashed line. Thus, during turbulent acceleration in a stationary sheath there are two effects to be considered. Firstly, there can be severe energy dissipation in turbulent heating of the plasma at small-scale instabilities. Secondly, new effects can occur: local amplification of the Hall current, leading to demagnetization of the electron drift and inversion of the ion flow.

3. TURBULENCE ACCELERATION IN A PULSED CURRENT SHEATH

A pulsed current sheath (a model of which is shown in Fig. 1b) is characterized by strong perturbation of the magnetic field because the transfer of energy takes place at a rate close to the Alfvén velocity $v_{Ai} = H/(4\pi nM)^{1/2}$. For this reason a pulsed current sheath is often considered as a magnetoacoustic wave[17] propagating in the positive x direction with a velocity v_0 across the magnetic field (Oz). Thus the problem of acceleration in pulsed current sheaths is similar in many ways to that of collisionless dissipation in the front of a magnetoacoustic shock wave.[30] This approach is used in ref. 13 for an analysis of the turbulence processes involved in the generation of fast particles in many pulsed plasma devices.[20,21,16,22-27] We may also note that this problem is strongly connected with the turbulent heating of a plasma by nonlinear MHD waves.[7-10] One of the characteristic features of the dynamics of a pulsed current sheath is the excitation of intense MHD oscillations. This excitation can occur, for example, under the well-known "fast" acceleration conditions spontaneously as a result of growth of transverse current-driven instabilities. The excitation of MHD oscillations is accompanied by a change in the conditions of acceleration and leads to a rearrangement of the pulsed sheath owing to the fact that the acceleration transfers from a less stable to a more stable branch. In addition, this excitation also necessarily leads to the appearance of an electrostatic instability in the transverse current and turbulent heating of the ions.[7-10] Since these effects have had direct experimental confirmation (for example in the turbulent heating of ions by MHD waves[9,10] and in experiments on the generation of fast particles in pulsed plasma accelerators[23,24]), it is desirable to be able to describe them quantitatively.

We introduce a system of hydrodynamic equations which include the macroscopic effects of electron-acoustic (9) or cyclotron (8) instabilities and the principal Maxwell equations; these describe the dynamics of a plane pulsed current sheath when nonlinear MHD oscillations are excited:

$$\left.\begin{aligned} &\frac{\partial\rho}{\partial t} + \frac{\partial}{\partial x}(\rho v) = 0 \quad (\rho = nM), \\ &\frac{\partial}{\partial t}(\rho v) = -\frac{\partial}{\partial x}\left(\rho v^2 + \frac{H^2}{8\pi}\right), \\ &\frac{1}{c}\frac{\partial H}{\partial t} + \frac{\partial E_y}{\partial x} = 0, \\ &E_y = -\left(\frac{\partial}{\partial t} + v\frac{\partial}{\partial x}\right)\frac{mc}{4\pi ne^2}\frac{\partial H}{\partial x} + \frac{vH}{c} - \frac{1}{ne}R_{fy}, \\ &\left(\frac{\partial W_k}{\partial t} + \frac{\partial\omega_k}{\partial k_x}\frac{\partial W_k}{\partial x}\right) = 2\gamma_k W_k. \end{aligned}\right\} \tag{34}$$

We consider two cases for the frequency ω_k and growth rate γ_k; a) electron-acoustic instability (9); b) cyclotron instability (8). These give effects which are qualitatively similar but which are different in magnitude. The first equation in (34) is the law of conservation of mass, the second shows the conservation of momentum, the third is one of the Maxwell equations, the fourth is a statement of Ohm's law allowing for the electron inertia along y and the collective friction force, and the fifth is the noise equation.

We first neglect any energy dissipation and obtain equations which describe the nonlinear magnetoacoustic oscillations:

$$\left.\begin{aligned}\frac{\partial\rho}{\partial t}&=-\frac{\partial}{\partial x}(\rho v),\\ \frac{\partial(\rho v)}{\partial t}&=-\frac{\partial}{\partial x}\left(\rho v^2+\frac{H^2}{8\pi}\right),\\ \frac{\partial H}{\partial t}+\frac{\partial}{\partial x}(vH)-\frac{\partial}{\partial x}\left(\frac{\partial}{\partial t}+v\frac{\partial}{\partial x}\right)&\frac{mc^2}{4\pi ne^2}\frac{\partial H}{\partial x}=0.\end{aligned}\right\}\tag{35}$$

In the linear approximation we obtain a periodic solution for the magnetic field from (35):

$$H(x,t)=H_{0\sim}\cos(\Omega t-qt+\Psi).\tag{36}$$

The amplitude of the oscillations in the magnetic field $H_{0\sim}$ is independent of time. The frequency Ω of the magnetoacoustic oscillations is given by the dispersion relation

$$\frac{\Omega^2}{q^2}=\frac{H_0^2}{4\pi\rho_0}\frac{\frac{\omega_{pe}^2}{c^2}}{\left(q^2+\frac{\omega_{pe}^2}{c^2}\right)},\tag{37}$$

where q is the wave number. If friction is taken into account, the energy of the magnetoacoustic wave is dissipated and $H_{0\sim}(t)$ is reduced. If we know the attenuation, we can determine the rate of the turbulent heating of the ions.[10] Following the well-known Van der Pol method from the theory of nonlinear oscillations, we average the system (34) over the phase of the "fast" oscillations Ψ and get a system of truncated equations, which describe the change in amplitude of the magnetoacoustic wave.

a. We now assume that the amplitude of the wave is a slow function of time and we expand (34) in a series in the small parameters $v_\sim q/\Omega \ll 1$, $\gamma_{\max}/\Omega < 1$; allowing for dissipation due to electron-acoustic turbulence we find

$$\left.\begin{aligned}&\rho_\sim=\rho_0\frac{H_0H_\sim}{4\pi\rho_0}\left(\frac{q}{\Omega}\right)^2,\quad v_\sim=\frac{H_0H_\sim}{4\pi\rho_0}\left(\frac{q}{\Omega}\right)+\frac{H_\sim^2}{8\pi\rho_0}\left(\frac{q}{\Omega}\right),\\ &H_\sim=\left(\frac{aq}{\Omega}\right)^2\frac{\partial^2H_\sim}{\partial t^2}+\frac{q}{\Omega}v_\sim H_0+\frac{q}{\Omega}v_\sim H_\sim\\ &\qquad+\frac{\partial}{\partial t}\sum_{k_z}\left(\frac{qc}{2\Omega n_0e}\right)\frac{W_{\bar k}}{\left[|\mathbf{u}|-\frac{k_z}{\bar k}\left(\frac{T_i}{m}\right)^{1/2}\right]},\\ &\frac{\partial\ln W_k}{\partial t}=\sqrt{\pi}\,k_z\left(\frac{M}{m}\right)^{1/2}\left[|\mathbf{u}|-\frac{k_z}{\bar k}\left(\frac{T_i}{m}\right)^{1/2}\right],\end{aligned}\right\}\tag{38}$$

where

$$a=\frac{c}{\omega_{pe}},\quad |\mathbf{u}|=\frac{cq}{4\pi en_0\Omega}\frac{\partial}{\partial t}|H_\sim|,$$

We now maximize in terms of the wavelength of the most unstable oscillations, $\bar k_z(T_i/m)^{1/2}=\bar k|\mathbf{u}|$, $\bar k^{-1}=\rho_e$. As a result, we can replace the summation over k_z by a single term. Then averaging over the fast phase Ψ from (38) we have

$$\begin{aligned}\frac{\partial H_{0\sim}}{\partial t}&=\frac{16\Omega W_0}{H_{0\sim}(aq)^2}\int\limits_{\Psi_0}^{\pi/4}\frac{\sin\Psi\,d\psi\,\frac{d}{d\psi}\exp|\beta H_{0\sim}^2 2\sin\Psi\cos\Psi|}{\left\{\sin\Psi-\sin\Psi_0\left[1+\left(\frac{M}{m}\right)^{1/4}\right]\right\}}\\ &\simeq\frac{16\Omega W_0}{H_{0\sim}(aq)^2}\left\{\exp(\beta H_{0\sim}^2)-\left(\frac{m}{M}\right)^{1/4}\exp[\beta H_{0\sim}^2\sin 2\Psi_0]\right\}.\end{aligned}\tag{39}$$

We have used the notation

$$\beta=\sqrt{\pi}\,\frac{\omega_{ei}}{\Omega}(aq)^2\frac{M}{m8\pi n_0T_i},\quad \sin\Psi_0=\frac{4\pi en_0}{cqH_{0\sim}}v_{Ti}\left(\frac{m}{M}\right)^{1/4}.$$

The solution of (39) has the form

$$\exp(-\beta H_{0\sim}^2)+\frac{32W_0\beta}{(aq)^2}(\Omega t)+C=0.\tag{40}$$

Here C is a constant of integration which depends on the initial conditions, for example on the way the energy is introduced into the pulsed sheath by the magnetic piston. Using (40), we can estimate the characteristic size of the attenuation front Δx and the amount of attenuation $(\Omega\Delta t)$ of the nonlinear wave:

$$\left.\begin{aligned}\Delta x&\simeq\frac{4}{\pi q}\beta H_{\sim,\max}^2,\\ (\Delta t\Omega)&\simeq\frac{4}{\pi}\beta H_{\sim,\max}^2.\end{aligned}\right\}\tag{41}$$

Knowing the attenuation $(\Delta t\Omega)$, we can estimate the rate for the turbulent heating of the ions in the front $d(nT_i)/dt$ and the limiting energy of the ions $T_{i,\mathrm{lim}}$:

$$\left.\begin{aligned}\frac{d(nT_i)}{dt}&=\frac{H_{\sim,\max}^2}{8\pi}\Omega,\\ T_{i,\mathrm{lim}}&=2\left(\frac{M\omega_{e,i}}{m\Omega}\right)^{1/2}\frac{H_{\sim,\max}^2}{8\pi n_0}(aq).\end{aligned}\right\}\tag{42}$$

Thus the ions can be effectively heated as a result of the dissipation of the energy of the nonlinear magnetoacoustic wave. This effect is a well-known one in experiments[9,10] on plasma heating by magnetoacoustic waves. The electrons are heated either by nonlinear processes or by Coulomb collisions. The turbulent heating of the ions by magnetoacoustic waves (which are known to be excited in many pulsed accelerators[7,8]) can explain the observed generation of fast particles.

b. The development of cyclotron instabilities which produce a large increase in anomalous resistance is possible at comparatively large magnetic field amplitudes, i.e., $H_\sim > H_0(m/M)^{1/2}(u^*/v_{Ai})$. We can estimate the importance of this effect in the turbulent heating (acceleration) of ions. The initial equations in this case are written in the form

$$\left.\begin{aligned}H_\sim&=\left(\frac{aq}{\Omega}\right)^2\frac{\partial^2H_\sim}{\partial t^2}+\left(\frac{qv_{Ai}}{\Omega}\right)^2H_\sim+\frac{\partial}{\partial t}\frac{qc}{2\Omega n_0e}\frac{W_{\bar k\sim}}{|\mathbf{u}_\sim|-u^*},\\ \frac{\partial\ln W_{\bar k\sim}}{\partial t}&=2\gamma_{\max}\frac{|\mathbf{u}_\sim|-u^*}{v_{Ti}}.\end{aligned}\right\}\tag{43}$$

We use the notation

$$|\mathbf{u}_{\sim}|=\frac{cq}{4\pi e n_0\Omega}\left|\frac{\partial H_{\sim}}{\partial t}\right|.$$

Averaging over the fast phase Ψ, we obtain an equation for the amplitude of the magnetic field oscillations:

$$H(x,\ t)=H_{0\sim}(t)\cos(\Omega t-qx+\Psi), \tag{44}$$

$$\frac{\partial H_{0\sim}}{\partial t}=\frac{8\Omega W_0}{H_{0\sim}(aq)^2}\exp(\tilde{\beta}H_{0\sim}), \tag{45}$$

where

$$\tilde{\beta}=\frac{2\gamma_{\max}cq}{v_{T_i}4\pi e n_0\Omega}.$$

We can get the solution of the equation by the same method as for (40) and can then determine the characteristic size of the front Δx and the magnitude of the attenuation $(\Omega\Delta t)$:

$$\left.\begin{aligned}\Delta x&=\frac{4a}{\pi}\left(\frac{H_{\sim,\max}\gamma_{\max}}{H_0\Omega}\right)\left(\frac{MH_0^2}{m4\pi n_0T_i}\right)^{1/2},\\ \Delta t\Omega&\simeq\Delta xq.\end{aligned}\right\} \tag{46}$$

Using these expressions, we can find the rate of turbulent heating of ions and the limiting energy of the ions as

$$\left.\begin{aligned}\frac{d}{dt}(nT_i)&=\frac{H_{0\sim}^2}{8\pi}\Omega,\\ T_{i,\,\lim}&=\left(\frac{H_{\sim,\max}^2}{8\pi n_0}\right)\left(\frac{M}{m}\right)^{1/3}\left(\frac{4\sqrt{2}aq}{\pi}\frac{H_{\sim,\max}\gamma_{\max}}{H_0\Omega}\right)^{2/3}.\end{aligned}\right\} \tag{47}$$

It follows from a comparison of (42) and (47) that instabilities at the electron cyclotron harmonics lead to a more effective dissipation of the energy of a nonlinear magnetoacoustic wave and a stronger heating of the ions than do the electron-acoustic instabilities. The conductivity, estimated from (46) by the equation $\sigma_f\simeq(ne^2/m)\cdot(a^2q/\Omega\Delta x)$, is

$$\sigma_f\simeq\left(\frac{ne^2}{m\gamma_{\max}}\right)\frac{\pi qa}{4}\left(\frac{H_0}{H_{\sim,\max}}\right)\left(\frac{m4\pi n_0T_i}{MH_0^2}\right)^{1/2}.$$

Thus the propagation of a pulsed current sheath and the excitation of nonlinear MHD waves produce, as a result of microscopic turbulence, effective mechanisms for collective friction and lead to a severe dissipation of the MHD-wave energy and the turbulent heating (acceleration) of the ions.

Conversion of regular charge-density waves in an inhomogeneous plasma

S. S. Kalmykova and A. P. Tolstoluzhskii

A. M. Gor'kii State University, Khar'kov

(Submitted February 12, 1973; resubmitted October 5, 1973
Zh. Tekh. Fiz., 44, 723-728 (April 1974)

The efficiency of conversion into an electromagnetic wave of a regular charge-density wave amplified by a monoenergetic beam is studied theoretically for an anisotropic plasma waveguide with inhomogeneous axial density. The dependence of the conversion coefficient on the degree of plasma inhomogeneity obtained through numerical calculations in a self-consistent approximation is compared with the corresponding results of an analytic study of a piecewise uniform density profile.

Collective interactions between a charged-particle beam and a plasma lead to an experimental increase in the amplitude of the field because of induced coherent Cerenkov radiation of the beam particles, which is amplified by the bunching caused by this radiation.[1,2] It is important to emphasize that the gain (growth rate) which characterizes the efficiency of this interaction is only positive for slow beam charge-density waves ($V_f < V_0$); fast charge-density waves ($V_f > V_0$) are damped with the same factor; however, the damping of transverse waves is not sensitive to beam density, but is determined by binary or collective collisions between plasma particles.

In many applications (astrophysics, plasma-beam heating, microwave generation, etc.), there is an interest in investigation of the efficiency for conversion of a charge-density wave amplified collective interaction into electromagnetic waves.[1)] Such conversion may occur in an inhomogeneous plasma in the neighborhood of a point at which the wave vectors of both waves coincide; the basis is the coherent transition radiation from the sequence of bunches formed by the field of a slow quasilongitudinal wave.[8-10]

Analytic study of this problem is made difficult by the lack of effective methods for solving differential equations with variable coefficients. In fact, the semiclassical approximation is not applicable in the region of greatest interest: the neighborhood of the conversion point, at which the wave number spectrum in the problem is degenerate. On the other hand, when this degeneracy is removed, because of dissipation for example, these waves prove to be weakly coupled so that the magnitude of the conversion effect becomes small.[2)] Those analytic solutions that can be obtained for certain special density profiles are not always realized experimentally (in an experiment, for example, it is impossible to achieve a linear density profile without encountering a contradiction with the requirement for a positive plasma density n_p). Under these conditions, there is interest in the use of a numerical experiment for studying the interconversion of waves in a nonequilibrium plasma. The present paper is devoted to this problem.

We consider the simplest model in which collective interaction of a monoenergetic electron beam with an inhomogeneous magnetized plasma is described by a self-consistent system of hydrodynamic equations of motion and continuity for the beam particles and by the Maxwell equations for the field. When the beam and plasma densities are uniform over a section of a circular cylindrical waveguide with conducting walls at the radius a located in a strong external magnetic field (ω_b^2, ω_p^2, $\omega \ll \omega_H^2$), the problem of finding the dependence on the longitudinal coordinate of the dimensionless amplitudes of the electric field and also on the variable components of density and velocity ($\tilde{N}$ and $\tilde{V}$) of a beam of regular (ω = const) axially symmetric oscillations reduces to a solution of the following system of differential equations:

$$\left.\begin{array}{c}
\varkappa\frac{d\mathcal{E}_\perp}{d\zeta}=(\beta_0^2\varepsilon-\varkappa^2)\mathcal{E}_z-i\mu\beta_z(\tilde{N}+\tilde{V});\quad \frac{d\tilde{V}}{d\zeta}=i\tilde{V}-\mathcal{E}_z;\\
\frac{d}{d\zeta}(\varepsilon\mathcal{E}_z)=-\varkappa\mathcal{E}_\perp-\mu\tilde{N};\quad \frac{d\tilde{N}}{d\zeta}=i(\tilde{N}-\tilde{V})+\mathcal{E}_z;\\
\varepsilon(\zeta)\equiv 1-\frac{\omega_p^2(\zeta)}{\omega^2(1+i\eta)};\quad \eta\equiv\frac{\nu}{\omega};\quad \beta_0\equiv\frac{V_0}{c};\\
\mu\equiv\frac{4\pi e^2 n_0}{m_0\gamma^3\omega^2};\quad \varkappa\equiv\frac{\lambda_n V_0}{\omega a};\quad \gamma\equiv(1-\beta_0^2)^{-1/2};\quad \zeta\equiv\frac{\omega z}{V_0},
\end{array}\right\} \tag{1}$$

where V_0 is the equilibrium beam velocity; ν is the collision frequency for plasma particles; $J_0(\lambda_n) = 0$; $\omega_p^2 = (4\pi e^2 n_p)/(m_0)$.

In the absence of plasma inhomogeneity [$d/d\zeta n_p(\zeta) = 0$), the system (1) has four independent plane-wave solutions for which the wave numbers are determined by the dispersion equation

$$\varkappa^2=\left[\varepsilon(\zeta)-\frac{\mu}{(1-k)^2}\right](\beta_0^2-k^2). \tag{2}$$

Two of these solutions, which vanish when the beam current goes to zero, we shall call the fast (1) and slow (2) quasilongitudinal waves (l). The other two solutions, which are characterized by finite values of the wave numbers when $V_0 \to 0$ and which remain finite in the absence of a beam,[8,9] are called the forward (3) and backward (4) transverse waves (t). Analytic expressions for the corresponding wave numbers are easily obtained in the limiting case of small beam currents ($\mu \ll 1$):

$$\left.\begin{array}{c}
k_{1,2}=1\mp\frac{\mu^{1/2}}{[\varepsilon(\zeta)+\varkappa^2\gamma^2]^{1/2}};\\
k_{3,4}=\pm\left[\beta_0^2-\frac{\varkappa^2/\varepsilon}{1-\frac{\mu}{\varepsilon\left(1\mp\sqrt{\beta_0^2-\frac{\varkappa^2}{\varepsilon}}\right)^2}}\right]^{1/2}.
\end{array}\right\} \tag{2a}$$

We estimate the conversion efficiency for an amplified slow charge-density wave (2) at a plasma density inhomogeneity. It is necessary to assign a plasma density profile. Most suitable for a numerical experiment is a profile such that the plasma density is constant at large distances from the inhomogeneity. For example, this condition is satisfied by the following dependence of plasma density on the coordinate ζ:

$$n_p(\zeta)=\frac{1}{2}[n_+ + n_- + (n_+ - n_-)\,\mathrm{th}\,\zeta|z], \tag{3}$$

where the density values $n_\pm$ for $\zeta \to \pm\infty$ are determined respectively by the requirement that the conversion point $\zeta = \zeta_*$ be located within the range of density values under consideration. The coordinate ζ_* of the conversion point is determined by the agreement of the quasiclassical wave numbers for the amplified slow wave (2) and the forward transverse wave (3); at this point the gain for a slow longitudinal wave goes to zero in the absence of dissipation ($\eta = 0$). Differentiating Eq. (2) with respect to ε and equating the coefficient of $dk/d\varepsilon$ to zero, we obtain

$$-k_*\left[\varepsilon_* - \frac{\mu}{(1-k_*)^2}\right] + \frac{\mu(\beta_0^2 - k_*^2)}{(k_*-1)^3} = 0, \tag{4}$$

which, together with Eq. (2), determines the value of ε at the conversion point (ε_*) and the corresponding wave number k_*. In the limiting case $\mu \ll 1$, $\beta_0^2 \ll 1$, and $\eta \to 0$, we obtain

$$\left.\begin{aligned} \varepsilon_* &= -\varkappa^2 + \left(\frac{\mu}{\varkappa^2}\right)^{1/3}; \\ k_* &= 1 + \left(\frac{\mu}{\varkappa^2}\right)^{1/3}. \end{aligned}\right. \tag{4a}$$

It is then clear that the conversion point is shifted from the point of beam synchronism with the transverse wave 3 ($\varepsilon + \varkappa^2 = 0$) into the region of lower plasma densities. In the self-consistent problem the region of maximum Cerenkov amplification ($\varepsilon + \varkappa^2 = 0$) and the region of maximum conversion (emission of a transverse wave) $\varepsilon + \varkappa^2 = (\mu/\varkappa^2)^{1/3}$ are separated in space. This makes it possible to distinguish the effects of Cerenkov and transition radiation by the beam particles, at least qualitatively. In the constrained problem, which corresponds to the case of low beam current, the region of maximum radiation intensity corresponds to the point of synchronism ($\varepsilon + \varkappa^2 = 0$, compare ref. 10) and the separation of Cerenkov and transition radiation is obviously difficult[3)] in the case ($\mu \to 0$).

The variation in plasma density chosen above makes it possible to provide with sufficient accuracy the conditions corresponding to the scattering of any of the characteristic waves of both uniform waveguides. In fact, at large distances from the inhomogeneity ($|\zeta| \gg z$), where the plasma density is constant, these waves are independent so that their field patterns can be identified in accordance with the solutions of Eq. (2) for the corresponding homogeneous plasma waveguide; by substituting the various roots of Eq. (2) into the relations between the field amplitudes

$$\left.\begin{aligned} &\tilde{V}_s = A_s\tilde{N}_s;\ (\mathcal{E}_\parallel)_s \equiv B_s\tilde{N}_s;\ (\mathcal{E}_\perp)_s \equiv C_s\tilde{N}_s;\ H_s = D_s\tilde{N}_s; \\ &A_s \equiv \frac{1-k_s}{k_s};\ B_s \equiv i\frac{(k_s-1)^2}{k_s};\ C_s \equiv -\frac{\varkappa(k_s-1)^2}{k_s^2-\beta_0^2};\ D_s \equiv \frac{\varkappa}{k_s}C_s, \end{aligned}\right\} \tag{5}$$

we obtain boundary conditions at infinity for a type s wave.

Solutions of physical interest must not yield a backward transverse wave (4) arriving at the inhomogeneity from $+\infty$. When $z \to \infty$, this solution must give a reflected wave of desired amplitude and also a forward transverse wave (3) and charge-density waves (1 and 2) with given amplitudes.[11] We assume below that $\tilde{N}_1^- = \tilde{N}_3^- = 0$, $\tilde{N}_2^- = 1$.

The numerical solution of the corresponding boundary value problem is difficult and we therefore use a reduction to the Cauchy problem[12] for the determination of the scattered fields; a solution of the original boundary value problem is sought in the form of a superposition of two solutions of the system (1) with initial conditions at $-\infty$, each of which corresponds to the existence at $-\infty$ of only one of the characteristic waves of the system. The ratio of the amplitudes of these waves is determined by the requirement that there be no wave coming from $+\infty$ in the general solution.

For example, let $N^{(l)}(\zeta)$ be the solution which transforms into an amplified wave of a left-handed waveguide and $N^{(t)}(\zeta)$ the solution which describes the scattering of backward transverse wave (4) of a right-handed waveguide, which also transforms into the same wave – the backward wave in the left-handed waveguide – for $\zeta \to -\infty$. The superposition $N = N^{(l)} + N^{(t)}$ yields the desired solution if the corresponding amplitudes of the supplementary waves $N^{(l)}(-\infty)$ and $N^{(t)}(-\infty)$ meet the condition for the incoming wave amplitudes going to zero when $\zeta \to +\infty$,

$$N_4(\zeta \to +\infty) \equiv T_{4\,2}^{(l)}N_2^{(l)}(-\infty) + T_{4\,4}^{(t)}N_4^{(t)}(-\infty) = 0, \tag{6}$$

where $T_{4\,2}^{(l)}$ and $T_{4\,4}^{(t)}$ are the conversion factors for the supplementary solutions "l" and "t".

Considering condition (6), the amplitude of a scattered type s wave and particularly the coefficient $T_{3\,2}$ for the conversion of a quasilongitudinal wave 2 into a quasitransverse wave 3 are determined uniquely by

$$\left.\begin{aligned} N_s(+\infty) &= N_s^{(l)} + N_s^{(t)} = \left[T_{s\,2}^{(l)} + T_{s\,4}^{(t)}\frac{T_{4\,2}^{(l)}}{T_{4\,2}^{(t)}}\right]N_2(-\infty); \\ N_3(+\infty) &= T_{3\,2}N_2(-\infty) = \left[T_{3\,2}^{(l)} - \frac{T_{3\,4}^{(t)}}{T_{4\,4}^{(t)}}T_{4\,2}^{(l)}\right]N_2(-\infty). \end{aligned}\right\} \tag{7}$$

Thus the problem of calculating the conversion of an amplified wave into other types of waves reduces to Fourier analysis of the supplementary solutions (l) and (t) in the region $\zeta \gg L$.

Numerical solutions of the supplementary problems "l" and "t" are obtained by the Runge–Kutta technique using an M-220 computer. For each fixed value of the parameters L, $n_\pm$, μ, η, and β_0^2, we calculate the fields (l, t), velocities $\tilde{V}^{(l,t)}$, and densities $\tilde{N}^{(l,t)}$ as functions

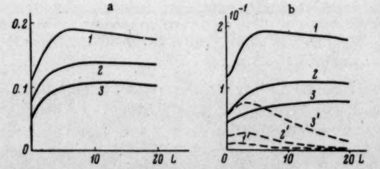

Fig. 1. Dependence on plasma density gradient for modulus of the coefficient T_{32} for conversion of an amplified wave into a transverse wave. a) $\eta = 10^{-7}$; $\mu = 10^{-2}$; $\beta = 0.2$; $\varepsilon_- = -2.25$; $\varkappa$: 1, 2) 0.8; 3) 1.0; ε_+: 1, 3) −0.16; 2) −0.10. b) $\varkappa$: 1, 1') 0.8; 2, 2') 1.0; 3, 3') 1.2; ε_-: 1, 2, 3) −3.0; 1', 2', 3') −0.16; ε_+: 1, 2, 3) −0.16; 1', 2', 3') 3.0.

of the coordinates, after which the conversion coefficients are determined from the solution of the algebraic equation system

$$\left.\begin{aligned}
\tilde{N}^{(l)}(\zeta) &= \sum_{s=1}^{4} T_{s2}^{(l)} \exp(ik_s\zeta)\, N_2^{(l)}(-\infty),\\
\tilde{V}^{(l)}(\zeta) &= \sum_{s=1}^{4} A_s T_{s2}^{(l)} \exp(ik_s\zeta)\, N_2^{(l)}(-\infty),\\
\mathcal{E}_{\parallel}^{(l)}(\zeta) &= \sum_{s=1}^{4} B_s T_{s2}^{(l)} \exp(ik_s\zeta)\, N_2^{(l)}(-\infty),\\
\mathcal{E}_{\perp}^{(l)}(\zeta) &= \sum_{s=1}^{4} C_s T_{s2}^{(l)} \exp(ik_s\zeta)\, N_2^{(l)}(-\infty);
\end{aligned}\right\} \quad (8a)$$

$$\left.\begin{aligned}
\tilde{N}^{(t)}(\zeta) &= \sum_{s=1}^{4} T_{s4}^{(t)} \exp(ik_s\zeta)\, N_4^{(t)}(-\infty),\\
\tilde{V}^{(t)}(\zeta) &= \sum_{s=1}^{4} A_s T_{s4}^{(t)} \exp(ik_s\zeta)\, N_4^{(t)}(-\infty),\\
\mathcal{E}_{\parallel}^{(t)}(\zeta) &= \sum_{s=1}^{4} B_s T_{s4}^{(t)} \exp(ik_s\zeta)\, N_4^{(t)}(-\infty),\\
\mathcal{E}_{\perp}^{(t)}(\zeta) &= \sum_{s=1}^{4} C_s T_{s4}^{(t)} \exp(ik_s\zeta)\, N_4^{(t)}(-\infty).
\end{aligned}\right\} \quad (8b)$$

As expected, the values of the conversion coefficients $T_{s2}^{(l)}$ and $T_{s4}^{(t)}$ are constant for $\zeta/L > 4$ within the error of the numerical calculations (10^{-3}). Substitution of the quantities $T_{s2}^{(l)}$ and $T_{s4}^{(t)}$ into Eq. (7) yields values of the desired conversion coefficient T_{32}.

Values of the modulus of the conversion coefficient computed in this way are shown in Fig. 1 as functions of the degree of plasma inhomogeneity. It is clear from the figure that in the general case the efficiency for conversion of an amplified wave into a transverse wave depends weakly on the magnitude of the plasma density gradient, remaining the same in order of magnitude both for discontinuously changing plasma density[4] and for relatively small gradient (L = 20). Physically, this effect can be explained by the fact that the number of coherently radiating bunches[2] increases as the gradient decreases, which compensates for the reduction of the losses from each bunch. The curves given in Fig. 1a also illustrate the conversion anisotropy (see ref. 9): the dependence of conversion efficiency not only on the value of the plasma density differential, but also on the sign of the corresponding gradient; the modulus of the conversion coefficient is greater for a decreasing density than for an increasing density.

To check the accuracy of the numerical experiment, the results are compared with the results of an analytic study of the problem for a discontinuously varying plasma density.[9] In this case an explicit expression for the desired conversion coefficient (L = 0) is easily obtained from the conditions for equality of the tangential components of the electric and magnetic fields and also of the beam density and velocity at the surface of discontinuity $\zeta = 0$

$$\left.\begin{aligned}
1 + T_{42}^{(-)} &= T_{32}^{(+)} + T_{12}^{(+)} + T_{22}^{(+)},\\
A_2^{(-)} + T_{42}^{(-)} A_4^{(-)} &= T_{32}^{(+)} A_3^{(+)} + T_{12}^{(+)} A_1^{(+)} + T_{22}^{(+)} A_2^{(+)},\\
C_2^{(-)} + T_{42}^{(-)} C_4^{(-)} &= T_{32}^{(+)} C_3^{(+)} + T_{12}^{(+)} C_1^{(+)} + T_{22}^{(+)} C_2^{(+)},\\
D_2^{(-)} + T_{42}^{(-)} D_4^{(-)} &= T_{32}^{(+)} D_3^{(+)} + T_{12}^{(+)} D_1^{(+)} + T_{22}^{(+)} D_2^{(+)},
\end{aligned}\right\} \quad (9)$$

where the coefficients A_s, B_s, C_s, and D_s are defined by Eqs. (5).

In the numerical experiment, as in a real experiment, the parameter μ is small ($\mu \lessdot 10^{-2}$); thus, we obtain the following analytic expression for T_{32} at L = 0:

$$T_{32}(L=0) = \frac{\mu\varkappa^2 R_+ (1+R_-)(S_- - S_+)}{(R_+ + R_-)(1-R_-)^2 (S_- + S_+)\,|\varepsilon_+|}, \qquad (10)$$

$\varkappa \equiv (\lambda_n V_0)/\omega a$, λ_n is the n-th root of the Bessel function $J_0(\lambda) = 0$;

$$R_\pm \equiv \left(\beta_0^2 + \frac{\varkappa^2}{|\varepsilon_\pm|}\right)^{1/2};\ S_\pm \equiv |\varepsilon_\pm| - \varkappa^2\gamma^2;$$

$$\varepsilon_\pm \equiv 1 - \frac{\omega_{p\pm}^2}{\omega(\omega + i\nu)};\ \omega_{p\pm}^2 \equiv \frac{4\pi e^2}{m_0} n_\pm;\ n_\pm \equiv n_p(\pm 0).$$

It is easy to see that the asymptotes to the curves given in Fig. 1 agree as expected with calculated results from Eq. (10) with an accuracy of the order of $\mu^{1/2}$. In the nonrelativistic case ($\beta_0^2 \ll 1$), this expression agrees with that given in ref. 10.

The main results of the numerical analysis can be formulated as follows.

1. The efficiency for conversion from an amplified longitudinal wave into a transverse wave for a varying density gradient depends weakly on the details of the density profile because of the increase in the number of coherently emitting bunches as the degree of plasma inhomogeneity decreases. The conversion rate in this case is considerably greater than for the case of a linear profile (compare ref. 10).

2. In order of magnitude, the modulus of the conversion coefficient is determined by its value for a discontinuous density profile given the same value for the plasma density differential and for its other geometrical parameters.

3. Numerical calculations and analytical studies demonstrate the existence of significant anisotropy in the dependence of conversion rate on the sign of the plasma density gradient, for which the anisotropy of transition radiation from beam particles provides a basis.

---

[1] Results for the conversion of the characteristic waves in an equilibrium plasma are presented in a monograph[3] and review papers;[4,5] this effect was first discussed in ref. 7 for nonequilibrium beam–plasma systems (see also refs. 8-10).

[2] Furthermore, dissipation changes qualitatively the behavior of both waves; the slow beam wave in the neighborhood of the conversion point grows with a gain proportional to the value of the resistive splitting $\Delta k_\parallel \sim (\nu/\omega)^{1/2} \times (n_b/n_p)^{1/2}$ and the quasitransverse wave is damped with the same factor.[10]

[3] The authors thank V. K. Yulpatov for pointing this out.

[4] For several values of $\varkappa$, the numerical calculations are carried out to L ≈ 50; in this case, the drop in the modulus of T_{32} remains linear with a slight slope ($\alpha \approx 0.15$).

An experiment on localization of rf power absorption in the FT-1 Tokamak device for a low-temperature discharge mode at frequencies close to the lower hybrid frequency is described. The role of collisional absorption of retarded electromagnetic waves is analyzed. Calculated results are given for the real and imaginary parts of the transverse index of refraction for $\nu/\omega = 0.01$. It is concluded that the efficiency of collisional absorption in the neighborhood of the lower hybrid frequency is high under the present experimental conditions.

Experiments on the interaction between high-frequency waves and the plasma in the FT-1 device at frequencies close to the lower hybrid frequency have been reported previously.[1] It was assumed that the absorption of rf power by the plasma was associated with the conversion of electromagnetic waves into slow, highly damped plasma waves.[2] Such a conversion should occur locally in plasma regions where the "hybrid resonance" condition is satisfied – the lower hybrid frequency is equal to the field frequency:

$$\omega = \omega_L = \left(\omega_{He}\omega_{Hi}\frac{\omega_p^2}{\omega^2_{He} + \omega_p^2}\right)^{1/2}. \tag{1}$$

Here, ω_L is the lower hybrid frequency, ω_p is the plasma frequency ω_{He} and ω_{Hi} are the electron and ion cyclotron frequencies.

However, collisional absorption of electromagnetic waves should also play an important role in a cool plasma. Experiments are described here for a low-temperature discharge mode, and the role of collisional absoption of slowed waves near the lower hybrid frequency is analyzed.

The FT-1 device is a Tokamak. The discharge chamber has a major radius of 62 cm, a minor radius of 20 cm, and a limiter radius of 17 cm. The toroidal magnetic field along the axis can reach 9 kOe. The discharge is excited in hydrogen at $2 \cdot 10^{-4}$ mm Hg. At comparatively low discharge currents, 0.5-5 kA, where complete ionization of the plasma is not achieved, the density depends on the current and varies from $0.5 \cdot 10^{12}$ to $7 \cdot 10^{12}$ cm^{-3}. In this mode the main mechanism for plasma energy loss is optical emission from neutrals and impurity ions. For this reason the electron temperature is "frozen" at a level of 3-4 eV. The intensity of light emission from the plasma is proportional to the absorbed power. By observing the variation in the luminous intensity from various plasma regions affected by an rf pulse one can determine the amount of absorbed rf power and the localization of the regions in which absorption occurs.[3]

Plasma luminosity is recorded with two photomultipliers fitted with periscopes which can be shifted vertically in diagnostic ports in the neighborhood of the plasma column. The light detectors record luminosity from narrow regions of the discharge along a chord parallel to the equatorial plane of the torus. The relative locations of the antennas and the optical detectors are shown in Fig. 2a. As is clear from the figure, it is possible to observe plasma luminosity distribution over a section of the discharge both at an antenna location and in sections separated from an antenna by 90 and 180° around the torus.

The rf oscillator is operated at 280 MHz and the power fed into a pulse is 8 kW for a period of 0.5 msec. Two stub antennas 18 cm long enclosed in a quartz shell are used to excite the waves and to pick up a signal transmitted through the plasma. The antennas are inserted from the upper side of the chamber and are located in the shadow of the limiter in sections separated by 90° along the torus; they are oriented along the stationary magnetic field. Because the antenna length is less than a quarter vacuum wavelength, the antennas excite a radio-frequency electric field with an effective longitudinal deceleration factor $N_z \approx 1.5$-2.0.

The experiments are carried out with a magnetic field of 5 kOe on the chamber axis. The mean plasma density over a cross section is determined by microwave interferometry in the 4-millimeter range. The density distribution over a cross section is determined by means of a double probe. A typical density distribution measured for a discharge current of 4 kA is shown in curve 1 of Fig. 1. The density varies slightly within the limits of the limiter and decreases by a factor of 2-3 at the wall of the discharge chamber in the shadow of the limiter. Because of toroidal nonuniformity of the longitudinal magnetic field, condition (1) for the conversion of waves with a frequency of 280 MHz can be satisfied at various points over the chamber cross section for plasma densities of $3 \cdot 10^{12}$ cm^{-3} and higher. Curve 2 in Fig. 1 shows the distribution of magnetic field over the chamber cross section and curve 3, the value of the "resonance" plasma densities corresponding to condition (1) for this magnetic field distribution. The points at which curves 1 and 3 intersect determine the regions of wave conversion in the equatorial section of the

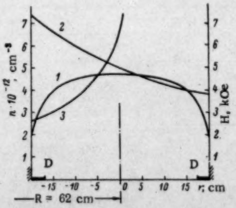

Fig. 1. 1) Plasma density distribution over discharge section; 2) magnetic field distribution; 3) values of "resonance" plasma densities for experimental conditions; D) diaphragm position.

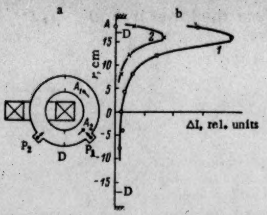

Fig. 2. a) Diagram of device: A_1, A_2) rf antennas; P_1, P_2) light detectors; b) distribution of additional luminosity over chamber cross section; radiator, A_1; $n = 2 \cdot 10^{12}$ cm^{-3}; 1) curve obtained from detector P_1, 2) curve obtained with detector P_2.

chamber. Within the plasma volume these regions form a closed surface which is asymmetric with respect to the discharge axis. As is well known, there is usually an opaque barrier between the plasma boundary and the conversion region, in which the electromagnetic waves are damped exponentially. However, the opaque barrier vanishes when the waves are decelerated along the magnetic field, and the hybrid resonance region becomes accessible to waves incident from outside.[4]

The measurements show that rf power is absorbed in the plasma under the present experimental conditions. During discharge the level of reflected power in the channel feeding the antenna does not exceed 20% of the operating power over a broad range of magnetic fields and plasma densities, while the reflection from the empty chamber is close to 100%. Transmission of a rf signal between the two antennas separated by 90° along the torus is observed only at very low densities ($n < 10^{11}$ cm^{-3}). At the same time, it turns out that the distribution of additional luminosity over the chamber volume due to the rf pulse depends significantly on plasma density. When $n \gtrsim 4 \cdot 10^{12}$ cm^{-3}, additional luminosity arises only in the immediate neighborhood of an antenna. When $n \approx 2 \cdot 10^{12}$ cm^{-3}, the increase in luminosity becomes noticeable at distances up to 1 m from the antenna along the length of the torus (Fig. 2b). A sharp drop in luminosity is observed moving away from an antenna across the magnetic field. When $n \lesssim 1 \cdot 10^{12}$ cm^{-3}, an increase in luminosity occurs over the entire volume of the chamber (Fig. 3). When $n \approx 5 \cdot 10^{11}$ cm^{-3}, the luminosity distribution both over a cross section and around the chamber is uniform. It should be remembered that linear conversion cannot occur when $n < 3 \cdot 10^{12}$ cm^{-3}. Obviously, the absorption of waves under these conditions is to be attributed to a collisional mechanism.

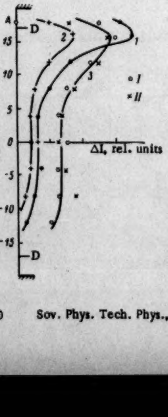

Fig. 3. 1) Light distribution curve obtained for detector P_1 with $n = 1 \cdot 10^{12}$ cm^{-3}; 2) the same for detector P_2; 3) $n = 5 \cdot 10^{11}$ cm^{-3} [(I)P_1; II) P_2].

In order to clarify the role of collisional damping of retarded electromagnetic waves we calculate the dependence of the real ($N_\perp$) and imaginary ($\varkappa$) parts of the index of refraction on plasma density for conditions resembling the experimental conditions. Terms associated with collisions of ions and electrons are taken into account in the dielectric tensor. In a coordinate system with its z axis along the magnetic field ($\omega_{Hi} \ll \omega \ll \omega_{He}$) we have

$$\hat{\varepsilon} = \begin{pmatrix} \varepsilon_1 & \varepsilon_2 & 0 \\ -\varepsilon_2 & \varepsilon_1 & 0 \\ 0 & 0 & \varepsilon_3 \end{pmatrix}, \tag{2}$$

where

$$\left.\begin{aligned} \varepsilon_1 &= 1 + \frac{\omega_p^2}{\omega_{He}^2} - \frac{\omega_{pi}^2}{\omega^2} - i\left(\frac{\omega_p^2}{\omega_{He}^2}\frac{\nu_e}{\omega} + \frac{\omega_{pi}^2}{\omega^2}\frac{\nu_i}{\omega}\right); \\ \varepsilon_2 &= 2\left(\frac{\omega_p^2}{\omega_{He}^2}\frac{\omega}{\omega_{He}}\frac{\nu_e}{\omega} - \frac{\omega_{pi}^2}{\omega^2}\frac{\omega_{Hi}}{\omega}\frac{\nu_i}{\omega}\right) + i\left(\frac{\omega_p^2}{\omega_{He}^2}\frac{\omega_{He}}{\omega} + \frac{\omega_{pi}^2}{\omega^2}\frac{\omega_{Hi}}{\omega}\right); \\ \varepsilon_3 &= 1 - \frac{\omega_p^2}{\omega^2}\left(1 + i\frac{\nu_e}{\omega}\right). \end{aligned}\right\} \tag{3}$$

The quantity $N_z = (k_z c)/\omega$, which characterizes the deceleration of a wave along the magnetic field, is taken as a parameter. It is assumed that the plasma parameters depend on a single coordinate perpendicular to the magnetic field. In this case, only the component of the wave vector parallel to this coordinate varies in wave propagation. The two solutions of the dispersion equation

$$(N_\perp - i\varkappa)^2 = \frac{B \pm \sqrt{B^2 - 4AC}}{2A} \tag{4}$$

determine the variation in the real and imaginary parts of the transverse index of refraction for propagation of E and H waves.[5] Here,

$$\left.\begin{aligned} A = \varepsilon_1;\ B &= \varepsilon_1^2 + \varepsilon_2^2 + \varepsilon_1\varepsilon_3 - (\varepsilon_1 + \varepsilon_3)N_z^2; \\ C &= \varepsilon_3(\varepsilon_1^2 + \varepsilon_2^2 - 2\varepsilon_1 N_z^2 + N_z^4). \end{aligned}\right\} \tag{5}$$

A calculation is performed for E waves in a hydrogen plasma in which the E_z component of the field is different

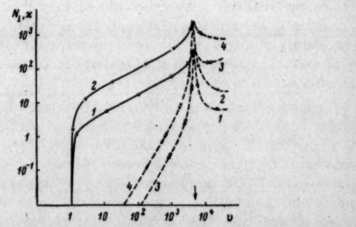

Fig. 4. Dispersion curves for $u = 2800$. 1) $N_\perp$ ($N_z = 2$); 2) $N_\perp$ ($N_z = 10$); 3) $\varkappa$($N_z = 2$); 4) $\varkappa$($N_z = 10$). Solid curves for $\nu_e = \nu_i = 0$, dashed curves for $\nu_e/\omega = \nu_i/\omega = 0.01$.

from zero. As has been shown,[5] the index of refraction for this mode has a singularity, where the condition (1) for lower hybrid resonance is satisfied.

The dependence of the real and imaginary parts of the transverse index of refraction on the parameter $v = \omega_p^2/\omega^2$, which is proportional to the plasma density, is shown in Fig. 4. Curves are given for two values of the longitudinal deceleration, $N_z = 2$ and $N_z = 10$. The value of the magnetic field determines the dimensionless parameter $u = \omega_{He}^2/\omega^2 = 2800$. For at 280 MHz the corresponding magnetic field is 5.3 kOe. The resonance density for these conditions is $5 \cdot 10^{12}$ cm^{-3}, and the critical density is 10^9 cm^{-3}. The dashed curves refer to $\nu_e/\omega = \nu_i/\omega = 0.01$. Values calculated for a collisionless plasma are represented by the solid lines. It is clear that even when $n = 10^{10}$-10^{11} cm^{-3} ($v = 10$-100), $N_\perp$ is of the order of 10. Note that at the antenna positions in this mode of operation the probe measurements yield density values of at least 4-$6 \cdot 10^{11}$ cm^{-3} ($v = 400$-600). Collisions begin to show an effect on the index of refraction only in the neighborhood of the conversion region (indicated in the figure by an arrow). It is also clear that when $n \gtrsim 10^{12}$ cm^{-3} and for the assumed collision frequencies, the absorption coeffficient $\varkappa$ can reach values of the order of unity. This means that the characteristic damping length $\delta = \lambda_0/(4\pi\varkappa)$, in which the power in an electromagnetic wave is reduced by a factor of e, is reduced to a few centimeters.

The relative roles of ion and electron collisions in wave damping is also determined by calculation. In this case the collision frequency of either electrons or ions with other particle species is alternately set to zero in the calculation. It turns out that when $\nu_e = \nu_i$ the contribution of ion collisions to the absorption coefficient is 60% in the given range of plasma parameters.

We now estimate the collision frequency typical of the plasma under these experimental conditions. The electron collision frequency is determined directly from measurements of the conductivity. Under these conditions, $\nu_e \approx 2 \cdot 10^{-6} n_e$. For $n_e = 5 \cdot 10^{12}$ cm^{-3}, we obtain $\nu_e = 10^7$ sec^{-1}. This value includes electron collisions with ions and with neutrals. Thus for the maximum values of plasma density realized in the experiment, $\nu_i/\omega \approx 0.01$. As far as the ions are concerned we find that the frequency of elastic and charge-exchange collisions of ions with neutral hydrogen falls within the range 10^5-10^6 sec^{-1} so that $10^{-4} < \nu_i/\omega < 10^{-3}$. It is clear from these estimates that in the low-temperature discharge mode studied here collision damping lengths from 10 cm to 1 m can be expected, depending on n_e. Electron collisions should play the main role in wave absorption. Furthermore, in the high-density case ($n > 3 \cdot 10^{12}$ cm^{-3}), where the hybrid resonance region appears in the plasma, collision damping is so large that the excited waves are absorbed near an antenna and do not reach regions where their conversion into plasma waves is possible.

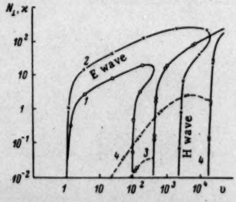

Fig. 5. Dispersion curves for u = 700. 1) $N_\perp$ ($N_z = 2$); 2) $N_\perp$ ($N_z = 10$); 3) $\varkappa$ ($N_z = 2$); 4) $\varkappa$ ($N_z = 10$). Solid curves are for $\nu_e = \nu_i = 0$, dashed curves for $\nu_e/\omega = \nu_i/\omega = 0.01$.

The dependence of $N_\perp$ and $\varkappa$ on plasma density is shown in Fig. 5 for low magnetic fields (u = 700); the lower hybrid resonance condition is not satisfied anywhere. It is clear that conversion of an E wave into an H wave occurs at a certain plasma density. The dispersion curves for both types of waves close on each other, forming a loop. For high densities the index of refraction becomes imaginary, i.e., a cutoff develops, even in the absence of collisions. The existence of collisions is responsible for a marked rise in the absorption coefficient of the waves near the cutoff. The damping lengths near the cutoff are of the same order of magnitude as in the previous case. This explains why good absorption of hf power over a broad range of magnetic fields is observed experimentally. The appearance of a transmitted signal during plasma decay when $n_e < 10^{11}$ cm^{-3} is obvious evidence for a rise in damping length to values of the order of the spacing between the antennas (1 m).

It is of interest to compare the magnitude of collisional absorption in the plasma and the chamber walls. We use the absorption coefficient for normal incidence of a plane wave on a metal surface, which is

$$\alpha = \frac{4}{c}\sqrt{\frac{\omega\mu}{8\pi\sigma}},$$

where σ is the conductivity of the metal and μ is the magnetic permeability. For stainless steel $\alpha \approx 3 \cdot 10^{-4}$ at these frequencies. The coefficient for absorption of a wave by a plane plasma layer of thickness l can be taken to be l/δ for a single passage of the wave. When the plasma is contained within a closed metal shell, high-frequency power will be absorbed in the plasma by collision after multiple reflections if $l/\delta > \alpha$. Under our experimental conditions, this relation is satisfied over the entire range of the parameters. It is clear, however, that the fraction of hf power lost to the chamber walls will increase in proportion to the rise in plasma temperature. Estimates show that in our case ($n = 2 \cdot 10^{12}$ cm^{-3}) the absorption in the walls is comparable to collision absorption in the plasma only when $\nu/\omega \approx 10^{-6}$, which corresponds to an electron temperature of approximately 1 keV for a hydrogen plasma.

The calculations thus show that for frequencies very different from the lower hybrid frequency even comparatively rare collisions lead to a large value for the absorption coefficient in plasma. This mechanism is connected with significant slowing down of the waves and does not have a critical dependence on the magnetic field. When a reflecting metal shell is present around the plasma, it can ensure good absorption of hf power at comparatively low collision frequencies also because of multiple reflection of electromagnetic waves from the chamber walls. The experimental results agree with the calculation.

The authors are grateful to V. E. Golant, A. D. Piliya, and V. I. Fedorov for valuable discussions.

(Submitted June 26, 1973)
Zh. Tekh. Fiz., 44, 735-742 (April 1974)

Closed systems for feedback control of the equilibrium position of the plasma in a tokamak are described. The equilibrium is analyzed for an arbitrary distribution of the longitudinal current over the plasma cross-section for a large aspect ratio $a/R \ll 1$. The feedback control, a control shell, is introduced by means of the winding density function γ and the function W(p), which relates the magnetic flux incident on the shell, Φ_0, to the flux due to the current flowing in the winding Φ_1. The dynamical errors due to the nonideal nature of the frequency characteristic and the effect of the steel chamber are analyzed. This method can be used to analyze plasma equilibrium in a variety of feedback control systems. This method yields the requirements that must be satisfied by the feedback control system.

Experience has now been gained in the use of a special winding system with feedback controlled winding currents intended for use in maintaining the equilibrium of the toroidal plasma in a tokamak.[1] A feedback control system of this type has been used successfully in extending the time for which plasma is confined in equilibrium. However, this capability does not exhaust all the advantages of this new method for actively intervening in plasma processes.

Below we describe closed systems for feedback control of the equilibrium state of a plasma in a tokamak; we analyze the equilibrium of the plasma in the vacuum chamber, taking account of complicating factors (the effect of the steel chamber, the iron core, and the physical devices used for control), and analyze the requirements imposed on the control system.

We analyze the equilibrium under the assumption of "weak toroidicity" for large aspect ratio: $a/R_0 \ll 1$ (a and R_0 are respectively the minor and major radii of the plasma). Following ref. 2, we introduce a special coordinate system (r, θ, ω), which is related to the cylindrical coordinates (R, φ, z) based on the symmetry axis of the torus by

$$R=R_0+r\cos\omega,\ \varphi=\theta,\ z=r\sin\omega. \quad (1)$$

The components of the metric tensor introduced in ref. 3, which correspond to the coordinate system selected here, are used in carrying out differentiation and integration and in vector equations.

The equilibrium can be described for an arbitrary distribution of the longitudinal current over the cross-section of the plasma. In the first approximation in $\varepsilon = a/R_0$, if a plasma of circular cross-section is to be at equilibrium at the $R = R_0$, $z = 0$ axis, the magnetic field at the plasma surface ($r = a$) must be, according to ref. 2,

$$H_r=0,\ H_\theta=H_0\left(1-\frac{a}{R_0}\cos\omega\right),\ H_\omega=H_I\left[1+\frac{a}{R_0}\Lambda(a)\cos\omega\right]. \quad (2)$$

Here, H_0 is the longitudinal magnetic field on the axis, H_I is the longitudinal field in the plasma at the upper and lower parts of the plasma surface, and $\Lambda(a)$ is the asymmetry parameter of the poloidal field, which is a function of the distributions of the plasma pressure and the current density.

Satisfaction of (2) requires the application of an external magnetic field perpendicular to the plane of the torus. If this field, $H_\perp$, is constant the changes in the longitudinal plasma current, the radius a, and the parameter $\Lambda(a)$ will cause the plasma to move in the chamber during the discharge, at any time assuming a position such that condition (2) is satisfied. Accordingly, during the discharge control should be maintained by a perpendicular magnetic field on the basis of a specified program or automatically, by a feedback system; combined control is also possible. In this work we analyze the feedback control case; we analyze the dynamics of plasma formation in the quasistatic (equilibrium) approximation, in which the characteristic time for changes in the position of the plasma in the chamber is much longer than the period of the natural oscillations of the plasma for the spatial modes with m = 1, k = 0.

The task of the feedback-control system is to limit movements of the plasma in the vacuum chamber to a tolerable range during the discharge. One way to do this would be to construct a distributed feedback "enforcer", a control shell in the form of windings on the toroidal surface surrounding the plasma. Two-pole feedback controllers are connected to the windings.[4] If the winding consists of a large number of turns wound with in inhomogeneous density on the toroidal surface ($r = b$, $b > a$), the winding-density function $\gamma(\omega)$ can be used to introduce an equivalent surface current density at the control shell:

$$\mathbf{j}(p,\ \omega)=I(p)\,\gamma(\omega), \quad (3)$$

where I(p) is the Laplace transform of the winding current. Accordingly, the structure of the quasisteady-state magnetic field produced by the current in the winding is specified completely by the function $\gamma(\omega)$, which is a spatial characteristic of the enforcer (such feedback control systems are called distributed feedback controllers). Since the purpose of the feedback control system is to influence the plasma motion by means of a magnetic field perpendicular to the plane of the torus, the function $\gamma(\omega)$ must be

$$\gamma(\omega)=\{0,\ \gamma_\theta(\omega),\ 0\}.$$

Here, $\gamma_\theta(\omega)$ must be as good as possible an approximation of a cosinusoidal function of ω for the first harmonic. The presence of other, higher, harmonics can affect, the equilibrium shape of the plasma cross-section (especially for high gain coefficients).

The current in the winding is controlled by means of a two-pole controller which is a controllable source or controllable resistance with a power supply. We can consider the input to the controller to be the flux of the incident magnetic field, Φ_0. Correspondingly, the flux of the magnetic field of the winding current, Φ_1, can be treated as the output of the controller. Our problem is to synthesize a control function W(p) which establishes the required functional dependence between the input and the output:

$$\Phi_1(p) = -W(p)\,\Phi_0(p) \tag{4}$$

or

$$\Phi_0(t) = -\int_0^t f(t-\tau)\,\Phi_1(\tau)\,d\tau, \tag{5}$$

where

$$f(t) = \frac{1}{2\pi j}\int_{s-j\infty}^{s+j\infty}\frac{e^{pt}}{W(p)}\,dp;$$

here Φ_0(p) and Φ_1(p) are the Laplace transforms of the corresponding fluxes, and *f*(t) is the kernel of the inverse operator of the controller.

The condition for the feasibility of a controller using elements with lumped parameters is that W(p) be a proper, rational-fraction function with real coefficients. The minus sign means that the control magnetic field must be in the direction opposite the incident field. Accordingly, (4) corresponds to the boundary condition for a shell having a negative μ and a definite dispersion characteristic.

In these feedback-control systems the incident flux must be decoupled from that reflected from the shell, since the sensed and controlled fields exist at the same point in space. In this connection it is expedient to use a single winding, which is used simultaneously for the sensing and control functions. In this case the decoupling can be achieved in the electrical circuit of the controller by means of bridges. A controller of this design is convenient and is structurally analogous to the copper housing which performs the same functions in many tokamak devices. The controller can also be designed according to the classical principle. In this case two windings are required; they are decoupled either by means of an electrical circuit (e.g., a transformer circuit) or by virtue of their spatial arrangement. However, this structural solution can be cumbersome and may not provide a sufficient decoupling in the necessary frequency range. The magnetic field in the region between the plasma and the control shell and in the region outside the shell can be expressed in terms of the scalar potential H = grad φ, which satisfies the Laplace equation

$$\frac{\partial}{\partial x^i}\left(\sqrt{g}\,g^{ik}\frac{\partial\varphi}{\partial x^k}\right) = 0\ (x^1 = r,\ x^2 = \theta,\ x^3 = \omega,\ g = det\,\|g_{ik}\|), \tag{6}$$

where g^{ik} are the components of the metric tensor.

The scalar potential φ for the region between the plasma and the control shell can be written

$$\varphi = \varphi_0 + \varphi_1.$$

Here, φ_0 is the magnetic potential due to the longitudinal plasma current, and φ_1 is the potential associated with the external sources, including the controlling effect of the shell.

In a first approximation, with equilibrium condition (2) satisfied, we find

$$\left.\begin{aligned}\varphi_0 &= H_I a\omega + \frac{H_I^{-}a}{2R_0}\left(-r\ln\frac{8R_0}{r} + \frac{a^2}{r}\Lambda_1\right)\sin\omega,\\ \varphi_1 &= R_0H_0\theta + \frac{r}{2R_0}H_I a\left(\ln\frac{8R_0}{a} - 1 + \Lambda_1\right)\sin\omega,\\ \Lambda_1 &= \Lambda(a) + \frac{1}{2}.\end{aligned}\right\} \tag{7}$$

Similarly, we can write the magnetic potential outside the shell as

$$\varphi = \varphi_2 + \varphi_3.$$

Here φ_2 corresponds to the potential passing through the magnetic-field shell, and φ_3 corresponds to the external longitudinal field and the field reflected from the iron core. The effect of the iron core is taken into account in ref. 5. Using the result found there we write

$$\left.\begin{aligned}\varphi_2 &= H_I a\omega + \frac{H_I a}{2R_0}\left(-r\ln\frac{8R_0}{r} + \frac{C}{r}\right)\sin\omega,\\ \varphi_3 &= R_0H_0\theta + \frac{r}{2R_0}H_I a\psi\sin\omega,\\ \psi &= 4R_0^2\int_0^\infty x\left[I_0(xR_1)\,K_1(xR_0)\frac{K_0(xR_0)}{K_0(xR_1)}\right]dx,\end{aligned}\right\} \tag{8}$$

where R_1 is the radius of the cylindrical iron core.

For further manipulations we transform to the coordinate system (r_1, θ, ω_1), which is fixed in the control shell:

$$r \approx r_1 - \Delta\cos\omega_1,\quad \sin\omega \approx \sin\omega_1\left(1 - \frac{\Delta}{r_1}\cos\omega_1\right),$$

$$\omega \approx \omega_1 + \frac{\Delta}{r_1}\sin\omega_1,\quad \cos\omega \approx \cos\omega_1 + \frac{\Delta}{2r_1} - \frac{\Delta}{2r_1}\cos 2\omega_1,$$

where Δ is the displacement of the geometric axis of the control shell with respect to the axis of the plasma formation, and Δ/b is a small parameter. Since the shell is narrow, we can find the arbitrary constant C in (8) from the continuity condition for the normal component of the magnetic field at the surface $r_1 = b$.

$$\left(\frac{\partial\varphi_0}{\partial r_1} + \frac{\partial\varphi_1}{\partial r_1}\right)_{r_1=b} = \left(\frac{\partial\varphi_2}{\partial r_1} + \frac{\partial\varphi_3}{\partial r_1}\right)_{r_1=b}. \tag{9}$$

We find, to first-order

$$C = -b^2\left[\ln\frac{8R_0}{a} - 1 + \left(1 - \frac{a^2}{b^2}\right)\Lambda_1 - \psi\right]. \tag{10}$$

Now we must find the flux incident on the magnetic-field shell, Φ_1, and the flux of the magnetic field produced by the current in the shell, Φ_2. Then, using (5) we find the displacement of the plasma with respect to the control shell Δ.

Following ref. 6, we write the winding-density function $\gamma(\omega)$ in terms of the surface magnetization function $\Gamma(\omega)$ by means of

$$\left.\begin{aligned} &\gamma = \operatorname{rot}\Gamma, \quad \Gamma = \{\Gamma_b(\omega),\ 0,\ 0\}, \\ &\Gamma_b(\omega) = \sum_{m=1}^{\infty} \Gamma_m \sin m\omega. \end{aligned}\right\} \tag{11}$$

Then, to calculate the magnetic flux penetrating the shell, Φ, we use the equation[6]

$$\Phi = \iint_S \mathbf{B}\cdot\Gamma\, dS = \mu_0 \int_0^{2\pi}\int_0^{2\pi} \left(g_{\theta\theta}^{1/2} g_{\omega_1\omega_1}^{1/2} g^{-1} \frac{\partial\varphi}{\partial r_1}\right)_{r_1=b} \Gamma_b(\omega_1)\, d\omega_1 d\theta, \tag{12}$$

finding

$$\begin{aligned} \Phi_0 &= \mu_0 \int_0^{2\pi}\int_0^{2\pi} \left[g_{\theta\theta}^{1/2} g_{\omega_1\omega_1}^{1/2} g^{-1}\left(\frac{\partial\varphi_0}{\partial r_1} + \frac{\partial\varphi_3}{\partial r_1}\right)\right]_{r_1=b} \Gamma_b(\omega_1)\, d\omega_1 d\theta \\ &\approx -\pi^2\mu_0 abH_I\left[\ln\frac{8R_0}{b} - 1 + \frac{a^2}{b^2}\Lambda_1 + \frac{2R_0\Delta}{b^2} - \psi\right]\Gamma_1, \\ \Phi_1 &= \mu_0 \int_0^{2\pi}\int_0^{2\pi} \left[g_{\theta\theta}^{1/2} g_{\omega_1\omega_1}^{1/2} g^{-1}\left(\frac{\partial\varphi_1}{\partial r_1} - \frac{\partial\varphi_3}{\partial r_1}\right)\right]_{r_1=b} \Gamma_b(\omega_1)\, d\omega_1 d\theta \\ &\approx \pi^2\mu_0 abH_I\left[\ln\frac{8R_0}{a} - 1 + \Lambda_1 - \psi\right]\Gamma_1. \end{aligned} \tag{13}$$

Substituting (13) into (5), we find an expression for the displacement:

$$\begin{aligned} \Delta(t) = \frac{b^2}{2R_0}\Bigg[&\frac{1}{a(t)H_I(t)}\int_0^t f(t-\tau)\,a(\tau)\,H_I(\tau)\left(\ln\frac{8R_0}{a} - 1 + \Lambda_1 - \psi\right)d\tau \\ &- \left(\ln\frac{8R_0}{b} - 1 + \frac{a^2\Lambda_1}{b^2} - \psi\right)\Bigg]. \end{aligned} \tag{14}$$

We find the current in the conductor winding, I, from the condition giving the discontinuity in the tangential magnetic field components at the control shell; in our case this condition is[6]

$$I\Gamma_b = \varphi_-(b) - \varphi_+(b), \tag{15}$$

where $\varphi_+ = \varphi_2 + \varphi_3$, $\varphi_- = \varphi_0 + \varphi_1$.

Then, to a first approximation we can write

$$I = \frac{abH_I}{R_0\Gamma_1}\left(\ln\frac{8R_0}{a} - 1 + \Lambda_1 - \psi\right). \tag{16}$$

Accordingly, the current in the control shell is not a function of the control relation (in which the natural oscillations of the plasma are not taken into account), but is a function of the spatial characteristics of the winding alone. The current decreases as the winding is brought closer to the plasma and as the plasma is made more cosinusoidal.

For the case of stiff control W(p) = k, we find

$$\Delta = \frac{b^2}{2R_0}\left[\frac{1}{k}\left(\ln\frac{8R_0}{a} - 1 + \Lambda_1 - \psi\right) - \left(\ln\frac{8R_0}{b} - 1 + \frac{a^2}{b^2}\Lambda_1 - \psi\right)\right]. \tag{17}$$

With k = 1 and $\psi = 0$, this equation is the same as that derived by Shafranov for the case of an ideal liner:

$$\Delta = \frac{b^2}{2R_0}\left[\ln\frac{b}{a} + \left(1 - \frac{a^2}{b^2}\right)\Lambda_1\right].$$

The second expression in parentheses in (17) gives the position of the equivalent magnetic axis of the system, which is displaced in the chamber; the first expression in parentheses gives the displacement of the plasma from this magnetic axis. Using the coefficient k we can effectively control the plasma position from values $\Delta < 0$ all the way to the magnetic axis and for any values $\Delta > 0$ within the limits specified by the chamber. During discharge the plasma parameters can change, leading to changes in the parameter Λ_1 and the radius a. Accordingly, the plasma position is not fixed, even in case of an ideal regulator W(p) = k. If the plasma radius does not change (a = const), in the case k = b^2/a^2 the situation can be invariant with respect to other plasma parameters. Then the plasma position is governed by geometric factors alone, being independent of the plasma parameters:

$$\Delta = \frac{1}{2R_0}\left[a^2\left(\ln\frac{8R_0}{a} - 1 - \psi\right) - b^2\left(\ln\frac{8R_0}{b} - 1 - \psi\right)\right]. \tag{18}$$

In general, a second feedback loop should be formed making use of information on the plasma radius and perhaps other parameters of the plasma which are measured during the discharge.

Let us consider the control function contemporary control systems:

$$W(p) = k\frac{\tau p\,(Tp+1)}{(\tau p+1)(\theta p+1)}. \tag{19}$$

In (19) we neglect the nonideal nature of the differentiating unit of the controller.

Then we have

$$f(t) = \frac{1}{k}\left[\frac{\theta}{T}\,\delta(t) + \left(\frac{T-\theta}{T^2} - \frac{1}{\tau}\right)e^{-t/T} + \frac{1}{\tau}\right]. \tag{20}$$

Here $\delta(t)$ is the Dirac delta function, the time constants τ and θ determine the working frequency (τ = 1-5 sec, θ = 10^{-4}-$5\cdot10^{-4}$ sec), and T is the time constant of the differentiating unit.

Using asymptotic expansions to evaluate the integral in (14), we find the following approximate equation, which holds at times long after the beginning of the discharge:

$$\begin{aligned} \Delta(t) \approx \frac{b^2}{2R_0}\Bigg\{&\frac{1}{k}\Bigg[\Delta_0(t) + \frac{\theta - T}{aH_I}\frac{d}{dt}(aH_I\Delta_0) \\ &+ \frac{1}{\tau aH_I}\int_0^t a(\tau)\,H_I(\tau)\,\Delta_0(\tau)\,d\tau\Bigg] \\ &- \left(\ln\frac{8R_0}{b} - 1 + \frac{a^2}{b^2}\Lambda_1 - \psi\right)\Bigg\}, \end{aligned} \tag{21}$$

where

$$\Delta_0(t) = \ln\frac{8R_0}{a} - 1 + \Lambda_1 - \psi.$$

With this control function the displacements of the plasma caused by changes in its parameters are supplemented by a displacement due to the nonideal nature of the controller at low and high frequencies. From the second expression in brackets in this equation we can find the requirements which are imposed on the upper controller frequency: $T \ll \tau_1$, $\theta \ll \tau_1$, where τ_1 is the minimum characteristic time for changes in the plasma parameters and the current during the discharge. The integral term describes the plasma drift and is due to the steep drop in the controller characteristic at low frequencies. Hence, the condition $\tau_p/\tau \ll 1$, where τ_p is the plasma confinement time, must be satisfied. Accordingly, the requirements on the controller are determined from (20) in terms of the tolerable displacements and the nature of the changes in the plasma parameters.

In most experimental devices there is a steel chamber (a bellows) between the plasma and the control shell; this chamber affects (albeit slightly) the control dynamics of the equilibrium plasma position. To take this effect into account we consider the passage of the magnetic field through a thin cylindrical chamber ($h/c \ll 1$, where h is the thickness and c is the radius of the chamber) with conductivity σ. We find the penetration of the magnetic field through the chamber from the diffusion equation

$$\frac{\partial \mathbf{H}}{\partial t} = \nu_H \nabla^2 \mathbf{H}, \ \left(\nu_H = \frac{1}{\sigma\mu_0}\right). \qquad (22)$$

In the case under consideration here, the approximate solution for the Laplace transforms of the magnetic field components, $\widetilde{H}_r$ and $\widetilde{H}_\omega$, is

$$\left.\begin{aligned} H_r &= (D_1 e^{\gamma_1 x} + D_2 e^{\gamma_2 x}) \sin \omega, \\ H_\omega &= [(c\gamma_1 + 1) D_1 e^{\gamma_1 x} + (c\gamma_2 + 1) D_2 e^{\gamma_2 x}] \cos \omega. \end{aligned}\right\} \qquad (23)$$

Here,

$$\gamma_1 = \frac{1}{2c}(\sqrt{9 + 4c^2\sigma\mu_0 p} - 3); \ \gamma_2 = \frac{1}{2c}(\sqrt{9 + 4c^2\sigma\mu_0 p} + 3);$$

$$x = r - c; \ x/c \ll 1,$$

and D_1 and D_2 are arbitrary constants, to be determined from the boundary conditions.

The changes in the normal and tangential components of the magnetic field in the chamber are given by

$$\left.\begin{aligned} H_r|_0 - H_r|_h &= [(1 - e^{\gamma_1 h}) D_1 + (1 - e^{\gamma_2 h}) D_2] \sin \omega, \\ H_\omega|_0 - H_\omega|_h &= [(c\gamma_1 + 1)(1 - e^{\gamma_1 h}) D_1 \\ &+ (c\gamma_2 + 1)(1 - e^{\gamma_2 h}) D_2] \cos \omega. \end{aligned}\right\} \qquad (24)$$

It follows from (24) that the radial component of the magnetic field changes significantly during passage through the chamber when $\gamma_1 h$ or $\gamma_2 h$ is on the order of unity. This situation corresponds to a characteristic frequency of the order of 500 kHz for the changes in the magnetic field with $h = 10^{-3}$ m and $c = 0.2$ m. On the other hand, there is an appreciable change in the tangential component of the magnetic field when $\gamma_1^2 ch$ or $\gamma_2^2 ch$ is of order unity. In turn, the field changes at a corresponding frequency of the order of 4-5 kHz for the same chamber dimensions. Accordingly, in the frequency range over which we are examing the the equilibrium of the plasma configuration we can assume that the normal component of the magnetic field is continuous at the surface $r_1 = c$, while the tangential component has a discontinuity equal to some equivalent surface current. Accordingly, the effect of the chamber can be taken into account by means of an inertial shell between the plasma and the distributed controller. We therefore consider another shell, at $r_1 = c(a < c < b)$, having a transfer function $W_1(p)$ which relates the flux of the magnetic field incident on it, Φ_2, to the flux of the magnetic field of the intrinsic current in the shell, Φ_3:

$$\Phi_3(p) = -W_1(p)\Phi_2(p). \qquad (25)$$

Then, by analogy with the procedure used to determine the equilibrium position with a single shell, we write the magnetic potential φ as two terms (corresponding to the transmitted field and the field of the external sources) for each of three regions: that between the plasma and the first shell, that between the shells, and that outside the second shell. The arbitrary constants are determined from conditions (2) and (25) and the continuity condition for the normal components at the surfaces $r_1 = c$ and $r_1 = b$. The magnetic flux is calculated from (12) and (13). Then, using (5), we find an equation for the position of the plasma configuration in the chamber:

$$\Delta(t) = \frac{1}{2R_0}\left[b^2\Delta_1 F_1(t) + c^2 F_2(t) - a^2\Delta_1 - c^2\left(\ln\frac{8R_0}{c} - 1 - \psi\right)\right], \qquad (26)$$

where

$$F_1(t) = \frac{1}{a(t)H_I(t)}\int_0^t f_1(t-\tau)\,a(\tau)\,H_I(\tau)\,d\tau;$$

$$F_2(t) = \frac{1}{a(t)H_I(t)}\int_0^t f_2(t-\tau)\,a(\tau)\,H_I(\tau)\,\Delta_0(\tau)\,d\tau;$$

$$f_1(t) = \frac{1}{2\pi j}\int_{s-j\infty}^{s+j\infty} \frac{W_2(p) + W_1(p)W_2(p)}{W_1(p) + W_2(p)} e^{pt}\,dp;$$

$$f_2(t) = \frac{1}{2\pi j}\int_{s-j\infty}^{s+j\infty} \frac{1 + W_1(p)W_2(p)}{W_1(p) + W_2(p)} e^{pt}\,dp;$$

$$W_2(p) = \frac{c^2}{b^2}W(p); \ \Delta_1 = \frac{c^2}{b^2}\left(\ln\frac{8R_0}{c} - 1 - \psi\right) - \ln\frac{8R_0}{b} + 1 + \psi.$$

If we set $W_1(p) = 0$ or $W_2(p) = 0$, we find that Eq. (26) is the same as Eq. (14) above, for the displacement in the case of a single shell.

We can use Eq. (26) to analyze the equilibrium position of the plasma configuration, taking the chamber into account, even when there is feedback control system. Treating the chamber as an aperiodic differentiating unit in the automatic-regulation system, we find

$$W_1(p) = \frac{\tau_k p}{l(\tau_k p + 1)}. \qquad (27)$$

Here l ($l \sim 1$) is a dimensionless quantity, equal to the first coefficient in the Fourier expansion of the equivalent surface current in the chamber in terms of ω, and $\tau_k = L_k/R_k$ is the time constant of the chamber, equal to the self-induction L_k divided by the resistance R_k.

Analysis of (23) shows that τ_k is of the order of $(1.6-2.0)\cdot 10^{-4}$ sec for the chamber dimensions listed above. Taking (19) into account with T = 0, and using the asymptotic expansions to evaluate the integrals, we find

$$\Delta(t)\approx\frac{b^2}{2R_0}\left\{\Delta_1\frac{(k_1-1)\tau_k}{k_1 laH_I}\frac{d}{dt}(aH_I)+\frac{c^2}{b^2k_1}\left[\Delta_0(t)+\frac{1}{\tau aH_I}\int\limits_0^t a(\tau)H_I(\tau)\Delta_0(\tau)\,dt\right]+\frac{c^2}{b^2k_1}\left[\frac{(k_1^2-1)\tau_k}{k_1 l}+\theta\right]\frac{1}{aH_I}\frac{d}{dt}(\Delta_0 aH_I)-\left(\ln\frac{8R_0}{b}-1+\frac{a^2}{b^2}\Lambda_1-\psi\right)\right\}. \qquad (28)$$

Here $k_1=(c^2/b^2)k$; Δ_1 is given by (26); and $\Delta(t)$ is given in (21). We see from Eq. (28) that the effect of the steel chamber is an additional displacement which occurs during changes in the plasma parameters during the discharge. The quantity τ_k must satisfy $\tau_k \ll \tau_1$.

The method of this paper can be used to analyze various means and principles of systems for feedback control of the equilibrium position of the plasma in a tokamak and to take the effects of various factors and the surroundings into account.

We note in conclusion that the results of this theoretical work agree with experimental results obtained on the TO-1 device.

The results of a numerical calculation of classical diffusion of a fully ionized plasma in an axisymmetric model of the Tornado trap are reported and discussed. Comparison of the calculated results with experiment shows that the actual plasma decay is governed by classical or pseudoclassical diffusion. The ratio of the local Bohm and classical diffusion coefficients ($n \approx 10^{12}$ cm^{-3}, $T_e = 0.5$ eV) is in the range 3-30. The assumption of a classical diffusion mechanism leads to a satisfactory description of the plasma lifetime as a function of the particle density, the neutral pressure, the current, and the ratio of the helix currents, m.

The lifetimes of individual particles in the Tornado device are evaluated in refs. 1 and 2 in the drift approximation and for conditions under which drift is suppressed. These terms are at least two orders of magnitude higher than the plasma lifetimes measured in ref. 3. In this situation, a natural next step toward understanding the mechanism governing the plasma loss from the trap is to analyze collective effects, in particular, to analyze classical particle diffusion and determine the diffusive lifetime. The simple estimate of this time $\tau \cong L^2/D$ is unreliable for Tornado since the magnetic field in this trap, as in multipoles,[4] can vary from point to point by an order of magnitude. On the other hand, a rigorous formulation of the plasma-diffusion problem meets with the ncessity of having to solve a three-dimensional diffusion equation in a complicated magnetic field.

As a compromise, the actual Tornado trap is replaced by an axisymmetric model. The magnetic field in this model has closed magnetic surfaces throughout the volume, so that the problem can be reduced to one of solving a one-dimensional diffusion equation.[4] The equation is solved numerically, and the calculated results furnish a basis for a discussion of experimental data on plasma confinement[3] from the standpoint of classical transverse diffusion.

The axis is partitioned into segments, and the trap is partitioned into unconnected regions.

1. CALCULATION MODEL AND PROCEDURE

Figure 1 shows one-quadrant of a cross-section of the axisymmetric model of the Tornado device. Each helix of the trap is replaced by a set of k rings (equal to the number of turns of the helix) lying on the surface of the sphere in parallel planes. On the spheres, the rings are arranged at identical angular intervals and in such a manner that if a radius drawn from the common center of these spheres intersects a ring on the inner sphere, it also intersects a ring on the outer sphere. Furthermore, two semiinfinite, unclosed conductors P, lying on the symmetry axis of the system, 00_1, are used to simulate the linear crosspiece and the current conductors of the Tornado. The current is assumed to be the same in all the rings on the surface of the given sphere, while the ratio of the currents in the rings in different spheres, m, can be adjusted. It is also assumed that all the conductors are of finite thickness; in the calculations of the magnetic field and the lines of force, however, the current is assumed to be concentrated at the axes of the conductors.

The magnetic field of this current system has toroidal magnetic surfaces throughout the volume; the layers of these surfaces are separated by multiply connected separatrices (Fig. 1a). The position of each magnetic surface can be specified by the value of the magnetic flux Φ between this surface and the outer magnetic surface, Φ_9.

If the diffusion perpendicular to magnetic field **B** is governed by a local diffusion coefficient $D_1(r, B, t)$, the particle flux through magnetic surface Φ is

$$\Gamma(\Phi, t) = -2\pi \oint r D_1 \nabla_\perp n\, dl,$$

where n is the density and r is the distance from the symmetry axis of the system to element dl. The integration is carried out over a closed line of force of the field of the annular conductors, B_p, i.e., along the intersection of the magnetic surface with a plane (Fig. 1). Since the derivative of the density with respect to the normal to surface Φ, h is $\partial n/(\partial h) = -2\pi r B_p\, \partial n/(\partial \Phi)$, if the density at the magnetic surface is constant we can write

$$\Gamma(\Phi, t) = D(\Phi, t) \frac{\partial n}{\partial \Phi},$$

where

$$D(\Phi, t) \equiv (2\pi)^2 \oint r^2 B_p D_1 dl$$

is the surface diffusion coefficient.

Applying the continuity equation to a force tube of volume $dV = -U(\Phi)\, d\Phi$, where $U(\Phi) = \oint (dl/B_p)$, we find

$$U(\Phi)\frac{\partial n}{\partial t} = \frac{\partial}{\partial \Phi} D(\Phi,\ t)\frac{\partial n}{\partial \Phi}, \qquad (1)$$

the one-dimensional diffusion equation.[4]

The boundary conditions for Eq. (1) are the conditions $n = 0$ at the outer magnetic surface, Φ_9, and at the bounding magnetic surfaces, Φ_p(p = 5.8; Fig. 1a), which are tangent to the conductor surfaces. Figure 1 shows the magnetic surfaces for the case $k = 8$ (k is the number of rings on a single sphere). We see that, in addition to the outer separatrix the magnetic field has $k/2$ multiply connected separatrices passing through the null points of poloidal field B_p. Corresponding to these separtrices are the magnetic fluxes Φ_s(s = 1, 2, 3 and 4). At these values of Φ the magnetic-flux coordinate axis branches. Figure 1b illustrates the branching for the case $k = 8$. Here, the magnetic-flux axis, which begins at the outer magnetic surface Φ_9, branches at points Φ_s and ends at the magnetic surfaces Φ_p which are tangent to the conductors. At the branch points the continuity conditions for the particle density and flux must hold:

$$n_{ls}(\Phi_s,\ t) = n_{ms}(\Phi_s,\ t) = n_{ns}(\Phi_s,\ t);\ \Gamma_{ls} + \Gamma_{ms} + \Gamma_{ns} = 0,$$

where l, m, n run over the values corresponding to adjacent regions.

Accordingly, the problem of plasma diffusion in the trap is reduced to that of finding a common solution of a system of equations like (1), each of which describes diffusion in the gap of the magnetic-flux axis either between two neighboring branch points or between a branch point and a neighboring end point.

The local classical-diffusion coefficient of a magnetized plasma is known to be

$$D = \frac{\alpha + \beta n}{B^2};\ \alpha = \frac{m_e c^2}{e^2}\nu_{en}(T_i + ZT_e);\ \ \beta = \frac{m_e c^2 \nu_{ei}}{e^2 n}(T_i + ZT_e),$$

where T_e and T_i are the electron and ion temperatures, and ν_{ei} and ν_{en} are the rates at which electrons collide with ions and neutrals, respectively. Otherwise, the notation is standard. Below we assume that α and β are independent of magnetic flux Φ, i.e., we assume that the temperatures, the neutral density, the chemical composition, etc., are independent of the coordinates throughout the plasma.

After the equation for the diffusion coefficient is substituted into Eq. (1), the latter becomes

$$U(\Phi)\frac{\partial n}{\partial t} = \frac{\partial}{\partial \Phi}(1 + \lambda n) F(\Phi)\frac{\partial n}{\partial \Phi}, \qquad (2)$$

where

$$F(\Phi) = (2\pi)^2 \oint \frac{r^2 B_p}{B^2}\, dl.$$

Here, the density is given in arbitrary units n_0, the magnetic flux Φ is given in units of IR/c (I is the current in one of the inner rings and R is the radius of the inner sphere), and the time is given in units of $\vartheta_1 = I^2/\sigma c^2$. The single parameter, λ is the ratio of the rate at which electrons collide with ions at a density n_0 to the rate at which

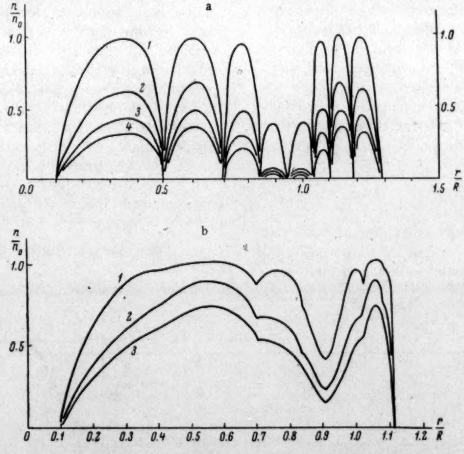

Fig. 2. a: Radial density distributions in the equatorial plane corresponding to various values of t/ϑ_2: 1) 0.05; 2) 0.40; 3) 0.80; 4) 1.25 (m = 0.7; the conductors are intersected by the separatrices $\Delta\Phi/\Phi_0 = -2$). b: Radial density distributions in the equatorial plane corresponding to various values of t/ϑ_2: 1) 0.05; 2) 0.30; 3) 0.60 (m = 0.7; between the sepratrices and the magnetic surfaces tangent to the conductors there is a magnetic-surface layer $\Delta\Phi/\Phi_0 = +3$).

electrons collide with neutrals: $\lambda = \nu^0_{el}/\nu_{en}$.

In two limiting cases – the case of a strongly ionized plasma, $\lambda n \gg 1$, and that of a weakly ionized plasma, $\lambda n \ll 1$, – we can incorporate all physical parameters (the density $\lambda n \gg \lambda$, the temperature, the current, etc.) into the time scale. (In the case $\lambda n \gg 1$ it is convenient to introduce the scale $\vartheta_2 = \vartheta_1/\lambda = I^2/\beta n_0 c^2$). Then the solution of Eq. (2) in these two cases is a function only of the arrangement of bounding surfaces and the nature of the functions, U(Φ), F(Φ), and F'(Φ).

The positions of the magnetic surfaces bounding the plasma are a function of the conductor diameter d. As this diameter is increased, the distance from the bounding surfaces to the inner separatrices, i.e., to the branch points of the magnetic-flux axis is reduced. If the conductor diamter is such that the separatrices are tangent to or intersect the conductors, system (2) can be broken up into individual segments (Fig. 1c).

The dimensionless functions U and F are independent of the current in the conductors and of the trap dimensions; they are governed completely by the field structure, i.e., by the arrangement of lines of force and the relative distribution of the magnetic field along these lines. In the present problem there are three parameters which govern the field structure: the number of rings on a sphere, k; the ratio of the radii of the spheres, μ; and the ratio of the currents in the rings in different spheres, m. Accordingly, the solution of system (2) is a function of the four parameters d, k, μ, and m.

System (2) with the initial condition n(Φ, 0) = 1 is solved on a computer by the method of finite differences; the values of U, F, and F' at the mesh points are determined by numerical integration along the lines of force. Because of the calculation times required we are not able to find solutions expressed as functional dependences of all four parameters, so we hold two of them (the number of rings and the ratio of the sphere radii) constant, at values approximately equal to the experimental values: k = 8 and μ = 1.25. Nevertheless, from the calculations which have been carried out we can draw certain conclusions regarding the behavior of the solution as a function of k and μ.

2. CALCULATED RESULTS

Most of the calculations have been carried out for the case of a fully ionized plasma. Figure 2 shows the radial density distributions in the equatorial plane of the trap,

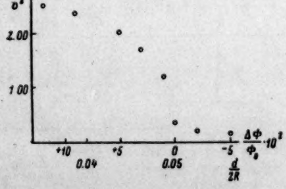

Fig. 3. Plasma lifetime as a function of the magnetic flux between the separatrix and the bounding magnetic surface.

TABLE 1. Relative Particle Loss at the Various Conductors and Through the Outer Magnetic Surface

	Conductor

Flux gi (the separatrices do not intersect the conductor surfaces)	0.02	0.09	0.18	0.23	0.48

Note: see Fig. 1 for an explanation of the conductor designations.

n = n(r, t), obtained for various times from the solution of system (2), n(Φ, t), and from the calculated function Φ = Φ(r). The conductor diameters in Fig. 2a are such that the inner separatrices touch the conductor surfaces, and the trap volume is divided into four independent regions, at whose boundaries n = 0 is satisfied. In Fig. 2a the abscissas of the points with n = 0 are equal to the distances between the separatrices and the symmetry axis of the system in the equatorial plane. Because of the different diffusion lengths the plasma decay occurs at different rates in different gaps; the relative number of particles in the gap having the maximum diffusion length increases continuously in time, and the decay rate of the entire plasma approaches that of the plasma in this gap.

At smaller conductor diameters (Fig. 2b), i.e., when the conductors are "protected" by a layer of magnetic surfaces, the radial density distribution also has minima, but they are not as deep, and the depths fall off monotonically with increasing thickness of this layer.

Figure 3 shows the lifetime as a function of the conductor diameter, or, more precisely, as a function of the flux between the separatrices and the magnetic surfaces tangent to the conductors, ΔΦ. The flux is assumed to be negative if the separatrices intersect the conductor surfaces; it is assumed to vanish if the separatrices are tangent to the conductor surfaces; and it is assumed to be positive if the conductors are separated from the separatrices by a layer of magnetic surfaces. In our system, this is possible only if the conductor diameters are different, but the difference need not be great (no greater than 10%). The numbers below the abscissa show the relative conductor diameter of the ring nearest the equatorial plane of the trap.

We see that the lifetime is strongly influenced by the

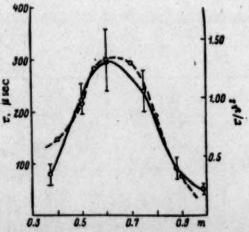

Fig. 4. Plasma lifetime as a function of the ratio of helix currents, m. Solid curve, left-hand scale) experimental;[3] dashed curve) calculated.

conductor diameter: It increases by about an order of magnitude as the diameter is reduced 25% from the value at which the separatrix is tangent to the conductor surface.

As the conductor diameter is reduced the particle loss decreases, as can be seen from Table 1, which shows the relative particle fluxes to the conductors and through the outer magnetic surface, $g_i = \Gamma_i/\Sigma\Gamma_i$.

The flux

$$\Gamma_i = \beta n_i F_i(\Phi) \frac{\Delta n_i}{\Delta\Phi_i}$$

is determined from the difference between the densities at the outer magnetic surface and the one adjacent to it, one step away from it on the flux mesh. When the corresponding separatrices intersect the conductor surfaces, most of the loss (82%) occurs at the conductors, and the loss of particles through the outer bounding magnetic surface is only 18%. Table 1 also shows the loss for the case of a minimum conductor diameter ($\Delta\Phi/\Phi_0 = +12$). In this case an appreciable loss occurs through the outer bounding magnetic surface (48%), while the loss at the conductors is 52%. These values remain essentially constant in time after the establishment of a diffusion density distribution.

Figure 4 shows the calculated plasma lifetime τ/ϑ_2 as a function of the current ratio m for a device with conductors tangent to the separatrices (dashed curve). In these calculations we take account of the functional dependence on m of the outer bounding magnetic surface: As the current ratio is reduced from the value at which a spherical separatrix exists in the two-helix device the separatrix in the model with rings becomes deformed and expands. At a certain value m_1 the separatrix begins to intersect the surface of the conductors on the outer sphere. As m is reduced further, other magnetic surfaces, under the separatrix, also begin to intersect the conductors. The outer bounding surface for the plasma in the case $m < m_1$ is a surface which is tangent to at least one conductor. Its position is determined by successive approximations, based on a check of the magnetic lines of force.

We see from Fig. 4 that as the current ratio is reduced the lifetime increases, reaching a maximum at m = 0.65, after which it decreases. We offer the following qualitative explanation for this behavior: At m = 0.9 the fields within the inner sphere and in the gap between the spheres are markedly different. For example with m = 0.9 for a device with k = 8 the field within the inner sphere is lower than that between the spheres[5] by a factor of 6–7. As the current ratio is reduced, i.e., as the current in the rings on the surface of the outer sphere is reduced, the field within the inner sphere increases, while that in the gap between the spheres decreases. When m = 0.65 the fields become equal, and the device becomes "uniformly stable" with respect to local diffusion loss. At this point the lifetime reaches a maximum. A further decrease leads to an expansion of the separatrix, which begins to intersect conductors on the outer sphere (see ref. 2, especially the figures there). The result is a decrease in the diffusion length. The field in the gap between spheres becomes weaker than that within the inner sphere, and the two factors reduce the lifetime.

On the basis of these functional dependences of the plasma lifetime on the current ratio and conductor diameter we can also draw certain conclusions regarding the lifetime as a function of the number of rings k and the ratio of the sphere radii, μ.

The lifetime $\tau \sim L^2H^2$ should apparently be a weak function of k, at least for devices with relatively thick conductors, since $H \sim k$, while the diffusion length $L \cong R/k$, where R is the radius of the device.

The functional dependence of the lifetime on μ should apparently be similar to that on the current ratio m. At μ = 1.25 and m = 0.9, the field within the inner sphere is weaker than that in the gap between the spheres. As μ, is increased, i.e., as the radius of the outer sphere is increased, these fields become equal, and eventually the field in the gap between the spheres becomes weaker than that within the inner sphere. There is some basis for assuming that the lifetime reaches a maximum when the fields are equal as in the case of the functional dependence on m.

It is interesting to determine the values of m and μ for which the device has both a spherical separatrix and a maximum lifetime with respect to classical diffusion. A spherical separatrix exists if m and μ satisfy[6] $m = \mu^{-1/2}$. Approximate equality of the fields within the inner sphere and in the gap between the spheres leads to[1,2] $8/(\mu - 1) = \pi k(1 - m/\mu)$. From these conditions we can find m and μ for a specified value of k. For example, of the devices with k = 8 the best is that with μ = 1.6 and m = 0.7. Accordingly, if the intention is to achieve longer diffusion times experimentally (usually, μ = 1.25 and m = 0.9), and if the radius of the inner sphere is specified, the outer radius should be increased.

3. COMPARISON OF THE CALCULATED RESULTS WITH EXPERIMENTAL DATA

Confinement experiments[3] have been carried out with two devices whose parameters are shown in Table 2. These devices differ in the dimensions, thickness, and currents of the conductors. In each case the device is filled with plasma through a discharge between an electrode inserted into the trap near one pole and a conductor of the inner helix near the other pole. During the plasma decay the density is determined by means of a microwave interferometer ($\lambda = 10.8$ mm, $n_{cr} = 10^{13}$ cm^{-3}). Functional dependences of the density and the time are found for various conditions and used to calculate the lifetime $\tau = d \ln n/dt$

as a function of: 1) the initial H_2 pressure in the chamber, 2) the magnetic field (i.e., the current in the helices), and 3) the ratio of the currents in the helices (see ref. 3, especially the curves there and Figs. 4 and 5).

Considerably less information has been obtained about the electron and ion temperatures. The electron temperature is determined from the conductivity at the end of the active cycle and is of the order of 3-5 eV. Furthermore, during the plasma decay, more precisely, at the point at which the microwave signal is cutoff, probe measurements are carried out in trap No. 1. The electron temperature turns out to be $T_e = 1.5\text{-}1.2$ eV some 100-150 μsec after the end of the active cycle. In trap No. 2 the electron temperature is determined at the cutoff time from the relative intensity of the hydrogen Balmer lines. The temperature was found to be $T_e = 3$ eV. No reliable information has been obtained about the ion temperature T_i.

Most of the experiments carried out to determine the lifetime for various physical conditions are carried out at $n = 10^{12}$ cm^{-3} during the plasma decay. This density level is reached some 150-200 μsec after the end of the active cycle. Other plasma parameters (T_e, T_i, n_0) are not determined at these times, but we can estimate them on the basis of the available data.

An electron temperature of 1 eV is found by extrapolating the measured values for the time interval 100-150 μsec.

The density of neutrals, n_0, during the plasma decay is assumed to be equal to the density before breakdown (usually, $n_0 = 3 \cdot 10^{13}$ cm^{-3}). Because of the relatively large volume of the chamber and because the mean free path of the neutrals with respect to dissociation and ionization is considerably longer than the characteristic plasma dimensions under the conditions $T_e \leq 3\text{-}5$ eV and $n^+ \leq 10^{14}$ cm^{-3}, estimates show the relative density change is $\Delta n_0/n_0 \ll 1$.

An estimate of the ion temperature T_i can be found from the energy balance and by comparing the characteristic times for energy transfer from electrons to ions, τ_i, and from ions to the neutrals. With $T_e \cong T_i \cong 1$ eV we have[1]) $\tau_i \cong 7 \cdot 10^{-5}$ sec and $\tau_{tra} \cong 3 \cdot 10^{-6}$ sec. Accordingly, the plasma ions must be much cooler than the electrons, at a temperature approximately equal to that of the neutrals. For subsequent estimates we assume $T_i \cong 0.2$ eV.

Several assumptions are used in the derivation of the equations describing classical diffusion and in the calculations. We will now show that these assumptions are justified in the real plasma of ref. 3.

Estimates show that the inequality $\nu_{ei} > \nu_{en}$ is satisfied in the plasma; this inequality also follows from the shape of the decay curves, according to which the decay constant is a function of the density.

In the calculations the plasma is assumed to be magnetized, i.e., the assumption $\nu_{ei}\nu_{en}/\omega_e\omega_i \ll 1$ is used. This condition is satisfied if the current satisfies the inequality $10^2\ \mathrm{A} \ll \mathrm{I}$.

The equations describing classical diffusion are applicable if the conditions $l_\perp \gg \rho_i$ and $l_\perp \gg \rho_i(\nu_{ei}/\omega_e)(\lambda + T_e/T_i)$ are satisfied, where $l_\perp = |n/\nabla n|$ and ρ_i is the ion Larmor radius. The first condition is the more stringent since the factor $(\nu_{ei}/\omega_e)(1 + T_e/T_i)$ is considerably smaller than unity under the experimental conditions ($\nu_{ei} \cong 3 \cdot 10^6$ sec^{-1}, $\omega_e \cong 1 \cdot 10^{10}$ sec^{-1}, $T_e \cong 1$ and $T_i \cong 0.2$ eV). A lower estimate on the characteristic length for changes in the density, $l_\perp$, can be found from the radial density distribution in Fig. 2a. For the case of the least favorable density distribution, in which the modulation depth of the distribution is nearly 100% in the central region of the device, we have $l_\perp = R/k$, where k is the number of rings on a single sphere. In the central region of the device and in the gap between the spheres, the values of $l_\perp$ are 1 and 0.1 cm, respectively, while the ion Larmor radii are 0.1 and 0.01 cm. Accordingly, the inequality $l_\perp \gg \rho_i$ is satisfied in these regions, except near singularities of the poloidal field, where the opposite inequality $l_\perp < \rho_i$, in fact seems to hold. However, the volume over which this latter inequality holds is much smaller than the plasma volume; hence we can neglect the influence of the processes which occur in these less extensive regions on the decay mechanism for the plasma as a whole.

The principal distinction between the Tornado device and the model adopted for the calculations is that there are no magnetic surfaces in the actual device. Therefore, the density should be leveled off not only as a result of diffusion but also as a result of the motion of macroscopic plasma volumes along lines of force, in the direction opposite that of $\nabla_\parallel p$. The characteristic lifetimes in this case are of order $L[m_i/(T_e + T_i)^{1/2}]$, where L/R is the length over which the pressure falls to zero. The average length of the lines of force, L/R, is of order 10^3-10^4 in a device with infinitesimally thin conductors in the case m = 1 (i.e., when there is no separatrix).[2] In this case the characteristic times are of order 10^{-2}-10^{-1} sec (R = 10 cm) under the experimental conditions. In a device with conductors of finite thickness, the lines of force have a smaller average length, since they intersect the conductors. Nevertheless, the average length and the characteristic time are apparently of the same order of magnitude in this case, since the conductors are intersected repeatedly by given lines of force[5] belonging to the surface layer itself. The transit lifetimes found are much longer than the diffusion lifetimes, so the presence or absence of precise magnetic surfaces is not important; from this standpoint the behavior of the plasma in the model should be essentially the same as that in the device.

In the calculations it is also assumed that the density is the same over an entire magnetic surface and that the temperature and density ot the neutral are the same throughout the plasma. The first condition implies that the density does not vary appreciably over a single revolution of a line of force around a system. This is the case if at least one of the inequalities λ_i, $\lambda_e < l_\parallel$ is satisfied, where $l_\parallel = H/|\Delta_\parallel H|$ is the characteristic dimension of the inhomogeneities in the magnetic field and λ_e and λ_i are the electron and ion mean free paths. Under the experimental conditions these values are $\lambda_e \cong 10$ cm, $\lambda_i \cong 0.2$ cm, and $l_\parallel \cong 1$ cm. Furthermore, the adiabatic condition for the particle motion is not satisfied near the singularities of the poloidal field, i.e., $\rho_i|\nabla H|/H > 1$. Again the result is a tendency for the density to become constant along a line of force. The density of neutrals

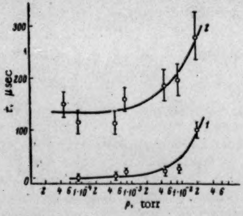

Fig. 5. Plasma lifetime as a function of the neutral pressure in trap No. 1. 1) H = 0; 2) H = H_{max} = 1300 Oe (this curve is from ref. 3).

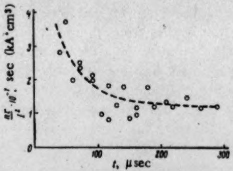

Fig. 6. The quantity $\tau_0 T_e^{1/2} = kn\tau / I^2$ as a function of the time elapsed since the end of the active cycle.

is apparently constant over the plasma volume, since the mean free path of the neutrals with respect to charge exchange and ionization is much longer than the characteristic dimensions of the plasma formation at $n = 10^{12}$ cm^{-3}. It follows that the ion and electron temperatures are also approximately constant over the plasma volume, if we assume that the energy loss of the ions is governed by charge exchange, and that the electrons lose energy as a result of collisions with ions.

Accordingly, the assumptions used in these calculations are justified and it is legitimate to compare the calculated and experimental results, even though the actual Tornado trap and its model differ radically in field structure.

The plasma lifetime is given by

$$\tau\,(\mathrm{sec}) = \vartheta_2\tau_0 = 4.5\cdot 10^7\tau_0 \frac{I^2\,(\mathrm{kA})\,T_e^{1/2}\,(\mathrm{eV})}{n\,(\mathrm{cm}^{-3})}, \tag{3}$$

where τ_0 is a dimensionless time, ϑ_r is the time scale, and I is the current in the inner helix. It follows from Eq. (3) that the lifetime is proportional to the square of the current, i.e., to the square of the field, and inversely proportional to the density. Experimentally the lifetime is found to be a quadratic function of the field and is found to increase with decreasing density (see the curves in ref. 3). The dimensionless time τ_0 is a function of the field structure and, in particular, of the ratio of the currents in the helices. Figure 4 shows the experimental and calculated functional dependences of the lifetime τ on the current ratio m. The calculated curve is normalized to the experimental curve at m = 0.6. These curves coincide within the experimental errors.

The only experimental curve which cannot be explained on the basis of transverse diffusion is that showing the lifetime as a function of the neutral pressure (Fig. 5). At $p \lessapprox 5\cdot 10^{-3}$ torr the lifetime is independent of the pressure, but as the pressure is increased from $5\cdot 10^{-3}$ to $2\cdot 10^{-2}$ torr it increases by a factor of about 2-3. In the case of transverse diffusion the behavior of the function $\tau(p)$ should be just the opposite, since an increase in the pressure would be accompanied by an increase in the rate of collisions, both because of an increase in the number of neutrals and because of a possible decrease in T_e. However, we note that the curves in Fig. 5 for H = 0 and H ≠ 0 begin to arise at approximately the same pressure. In the case H = 0 the lifetime increases because the plasma decay acquires a diffusion nature (at $p \cong 5\cdot 10^{-3}$ torr, we would have $\lambda_{in} \cong R$). It is natural to assume that even in the case H ≠ 0 longitudinal diffusion will begin to play a decisive role at $p > 5\cdot 10^{-3}$ torr. In particular, for devices in which the density distribution is deeply modulated (Fig. 2a), the appearance of an appreciable number of neutrals can alter the loss mechanism at the conductors, from a drift mechanism along the lines of force to a diffusion mechanism in the longitudinal direction. In turn, there is a decrease in the modulation depth of the density distribution, a decrease in the density gradients, and an increase in the lifetime. This effect is noticeable if the characteristic time for particle transport across the magnetic field is comparable to that for particle transport along the lines of force over a length of the order of the device radius. From the curves in Fig. 5 we find $\tau(H \neq 0, p < 5\cdot 10^{-3}$ torr$) \cong \tau(H = 0, p = 2\cdot 10^{-2})$, so it is physically plausible to conclude that an increase in the lifetime by a factor of 2-3 upon a pressure change from $5\cdot 10^{-3}$ to $2\cdot 10^{-2}$ torr is in fact cause by this mechanism. We thus conclude that there is a qualitative agreement between the calculated and experimental results.

A quantitative comparison of the results runs into certain difficulties: There is the familiar uncertainty regarding the magnitude of the electron temperature, and there is an uncertainty regarding the value of τ_0 for real helical devices. However, if we assume τ_0 to be the same as for models having the same relative conductor radius v/R, we find that the calculations yield lifetimes of $\tau = 5\cdot 10^{-3}$ and $7\cdot 10^{-4}$ sec for the larger and the smaller device respectively (I = 7.5, 4 kA; τ_0 = 2.5, 1.0), with m = 0.6, T_e = 1 eV, and $n = 1\cdot 10^{-2}$ cm^{-3}. The experimental lifetimes for the same conditions are $\tau = 8\cdot 10^{-4}$ and $3\cdot 10^{-4}$ sec, respectively, for the larger and smaller devices. Accordingly, we find extremely satisfactory agreement between the calculated and experimental values of τ.

If we assume that the assumption of a diffusion mechanism for the experimental plasma decay is now justified, we can determine the temperature as a function of the time and the parameter τ_0.

Figure 6 shows the quantity $\tau_0 T_e^{1/2} = n\tau/I^2$ as a function of the time for the smaller device, plotted from the experimental values of n, τ and I. The active cycle ends at time t = 0; at this time $T_e \cong$ 3-5 eV. One hundred microseconds after the end of the discharge $\tau_0 T_e^{1/2}$ has fallen by a factor of about 3, corresponding to a decrease in T_e to 0.3-0.5 eV. Over the next 200 μsec the changes in $\tau_0 T_e^{1/2}$ do not exceed 20-30%. If we assume T_e = 0.3-0.5 eV, we find τ_0 = 0.5-0.6.

A density level of 10^{12} cm^{-3} is generally reached experimentally 100-150 μsec after the end of the active cycle. If we assume that at this time T_e is not 1 eV, but, as follows from Fig. 6, smaller by a factor of 2-3, we find an even better agreement between the calculated and experimental results for τ (the calculated values are $\tau = 3 \cdot 10^{-3}$ and $4 \cdot 10^{-4}$ sec, and the experimental values are $\tau = 8 \cdot 10^{-4}$ and $3 \cdot 10^{-4}$ sec for the larger and smaller traps, respectively).

Accordingly, one result of these plasma-diffusion calculations is a justification for the argument that the plasma decay under the experimental conditions is governed either by neoclassical transverse diffusion or by so-called pseudoclassical diffusion.[7] During the plasma decay the conditions throughout the trap (except near the singularities) are such that the ratio of the local Bohm and classical diffusion coefficients is $D_B/D_c = eH(16\nu_{ei} m_s c)^{-1} > 1$. Accordingly, with $n \cong 10^{12}$ cm^{-3} and $T_e \cong 0.5$ eV, and at the maximum current, this ratio varies from 3 to 30 from point to point in the trap.

---

[1] The degree of dissociation of the hydrogen molecules is assumed to be nearly 100%.

Electron density in an argon afterglow

O. P. Bochkova, R. I. Lyagushchenko, É. A. Sukiasyan, and Yu. A. Tolmachev

A. A. Zhdanov Leningrad University

(Submitted April 12, 1973)
Zh. Tekh. Fiz., 44, 754-758 (April 1974)

A probe-pulse method is used to measure the electron density in the afterglow of a dc discharge in argon at pressures of 0.3-2.5 mm Hg and currents of 30 and 50 mA. An approximate calculation is given for the time rate of change of the electron temperature and the electron density in the argon afterglow. The experimental results are compared with theory.

In the present paper, the electron density is determined in the early afterglow of a dc discharge in argon. The probe-pulse method described in ref. 1 is used to determine the electron density in the decaying plasma of a pulsed electric discharge in helium.

A voltage pulse of amplitude and length such that it does not produce ionization, either direct or stepwise, is applied to the electrodes of the discharge tube after termination of the discharge at some time during the afterglow. The current flowing through the gap during the pulse depends on the number of charged particles remaining in the volume at the given time.

The value of the electron density $\bar{n}_e$ averaged over the volume is related to the current I during the pulse by

$$\bar{n}_e = \frac{I}{e\bar{v}\pi R^2}, \tag{1}$$

where $\bar{v}$ is the electron drift velocity and R is the radius of the discharge tube. The electron drift velocity is a function of the ratio of the field voltage E to the gas pressure p. The experimental relation $\bar{v} = \bar{v}(E/p)$ is given in ref. 2 for argon.

A schematic diagram of the experimental arrangement is given in Fig. 1. The probe voltage pulse is supplied to the electrodes of the 35 mm diameter tube from the delay circuit of a G5-7A generator. The pulse current is measured on the oscilloscope using the voltage drop across the resistance R_2. The field voltage is also measured on the oscilloscope by using two probes placed on the tube axis with a separation of 11 cm.

The length of the probe pulse must be sufficient to establish a value of the electron density corresponding to E/p. This requirement is not very severe for argon: In the range of E/p values of interest the electron drift velocity varies slowly. On the other hand, the variation in electron density should be negligible during the probe pulse. We use a 10 μsec pulse.

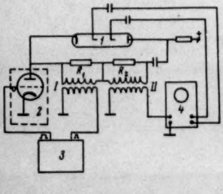

Fig. 1. Experimental arrangement. 1) Discharge tube; 2) circuit for termination of the discharge; 3) G5-7A generator; 4) S1-17 double-beam oscilloscope; I, II) transformers; R_1, R_2) resistances.

In the argon afterglow the electron temperature drops to the atomic temperature in a time of the order of milliseconds. The probe pulse is applied in a way that ensures that the electron temperature is determined by this field, and is of the order of 10,000°K.

According to ref. 3, the electron temperature in argon is related to E/p by

$$T_e = 3.65 \cdot 10^4 \sqrt{\frac{E}{p}} \tag{2}$$

where E is in V/cm and p in mm Hg.

In the experiment, E/p is of the order of 0.2 V/cm · mm Hg and $T_e = 16{,}300$°K.

The increase in electron temperature during the pulse should lead, on the one hand, to an increase in electron density due to ionization, and on the other, to a decrease in n_e due to the increasing rate of electron diffusion to the tube walls. The relative variation in electron density during the pulse is determined by

$$\frac{\Delta n_e}{n_e} = 1 - \exp\left(-\frac{1}{\tau_D} + z_0\right)\tau\,(\mathrm{pul}) = 1 - \exp\left\{-\frac{1}{\tau_D} + \sqrt{\frac{8kT_e}{\pi m}}\left[n_m q_{mi} \exp\left(-\frac{\varepsilon_i - \varepsilon_m}{kT_e}\right) + n_0 q_{0i} \exp\left(-\frac{\varepsilon_i}{kT_e}\right)\right]\right\}\tau_{\mathrm{pul}}, \tag{3}$$

where τ_D is the diffusion time for charged particles, z_0 is the number of ionization events produced by one electron per unit time, q_{mi} and q_{0i} are average cross sections for stepwise and direct ionization, ε_i is the ionization energy of a normal atom, ε_m is the excitation energy of a metastable atom, and n_m and n_0 are the densities of metastable and normal atoms.

Under our conditions $n_0 = 3.2 \cdot 10^{16}\ \mathrm{cm}^{-3}$, $n_m = 2 \cdot 10^{11}\ \mathrm{cm}^{-3}$, $T_e = 16{,}300$°K, $\tau_{\mathrm{pul}} = 10^{-5}$ sec, and $\tau_D = 3.1 \cdot 10^{-4}$ sec. Since $q_{0i} = 10^{-17}\ \mathrm{cm}^2$ and $q_{mi} = 10^{-15}\ \mathrm{cm}^2$, we find that $(\Delta n_e)/n_e \simeq 2\%$.

It can be seen that an increase in electron temperature during the pulse up to 16,300°K has a negligible effect on the electron density during the pulse.

The electron densities averaged over the volume are found experimentally at different times in the afterglow for pressures of 0.3, 0.55, 0.73, 1.0, and 2.5 mm Hg and currents of 30 and 50 mA for each pressure. Figure 2 gives experimental curves for the drop in electron density during the afterglow for three pressures and currents of 30 and 50 mA for each pressure. In this figure the electron densities in the discharge at p = 0.73 mm Hg and currents of 30 and 50 mA are measured using two probes.

The agreement between the values of the electron density in the discharge and in the early afterglow for the same pressure and current is satisfactory.

The curves for the drop in electron density are reproduced to within 5-10%. Systematic errors are the main cause of experimental error, which is of the order of 30-35%.

Under the experimental conditions the charged particles are lost as a result of ambipolar diffusion to the walls of the discharge tube; this is confirmed by the nature of the drop in electron density during the afterglow.

The diffusion time of particles to the walls is determined by $\tau_D = \Lambda^2/D_a$, where Λ is the characteristic diffusion length and D_a is the coefficient of ambipolar diffusion. Under our conditions $\Lambda^2 = 0.53\ \mathrm{cm}^2$. If we use the data of ref. 2 for the argon ion mobility, then

$$D_a = \frac{1220}{p} U_e, \tag{4}$$

where U_e is the electron temperature in volts.

Under our conditions $\tau_D = 0.53\ p/1220\ U_e$ ranges from 50-650 μsec in the discharge. Thus, when p = 0.73 mm Hg and i = 50 mA, $\tau_D = 160$ μsec in the discharge.

If the electron temperature does not decrease with time during the afterglow, assuming that the charged particles are lost only as a result of ambipolar diffusion, the drop in electron density during the afterglow must occur exponentially with a damping constant equal to τ_D. It can be seen from Fig. 3 that there is a slower drop in the electron density. This deviation is due to the fact that the electron temperature decreases with time during the afterglow and, consequently, the diffusion time increases.

We consider an approximate theoretical calculation for the time rate of change of the electron temperature and density after termination of the discharge for the given initial conditions.

The behavior of the electron density is determined by the electron energy balance equation, which can be written

$$\frac{d}{dt}\left(\frac{3}{2}kT_e\right) = e\bar{v}E - \delta_{\mathrm{eff}}\,\nu_{\mathrm{eff}}(T_e)\frac{3}{2}k(T_e - T_a), \tag{5}$$

where $\bar{v}$ is the electron drift velocity, E is the field voltage, $\nu_{\mathrm{eff}}(T_e)$ is the effective collision frequency dependent on the electron energy, $\delta_{\mathrm{eff}} = 2\ m/M$ is the energy lost by an electron in a collision with an atom, m and M are the electron and atomic masses, and T_a is the atomic temperature.

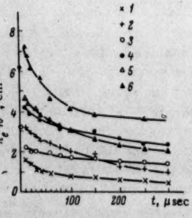

Fig. 2. Drop in electron density during the afterglow of an argon discharge. p in mm Hg: 1, 2) 0.55; 3, 4) 0.73; 5, 6) 2.5. i in mA: 1, 3, 5) 30; 2, 4, 6) 50.

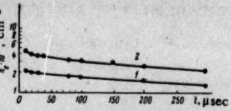

Fig. 3. Drop in electron density on a semilogarithmic scale for p = 0.73 mm Hg. i in mA: 1) 30; 2) 50.

The variation in electron temperature as a function of time during the alterglow can be obtained by solving Eq. (5) with E = 0.

To calculate the effective collision frequency as a function of the electron energy it is necessary to know the dependence of the transport cross section for electron scattering by argon atoms on the electron energy and to allow for the electron energy distribution

$$\nu_{\mathrm{eff}} = \frac{\langle q(\varepsilon)\, n_a v \varepsilon \rangle}{\frac{3}{2}kT_e},$$

where $q(\varepsilon)$ is the transport cross section for electron scattering by atoms, n_a is the atomic density, v is the electron velocity, and ε is the electron energy. In argon $q(\varepsilon)$ differs little from the total cross section for elastic scattering. Graphs of the experimental dependence of these cross sections on the electron energy are given in ref. 2, as is the dependence of the cross section P_c on $(V)^{1/2}$ in argon. The cross section P_c is related to the total elastic scattering cross section by $P_c = 3.53 \cdot 10^{16} q$. A good approximation of the dependence of P_c on V is given by

$$P_c = 35e^{-40V} + 6V.$$

The first term is significant only when V < 0.2 volts; therefore, the following simple approximation can be used:

$$P_c = 6V.$$

Solving Eq. (5) for E = 0, we obtain the following time dependence of the electron temperature during the afterglow:

$$U_e(t) = \frac{U_e(0)}{\left(6 \cdot 10^4 p U_e^{3/2}(0)\, t + 1\right)^{2/3}}, \tag{6}$$

where U_e is the electron temperature in volts and $U_e(0)$ is the electron temperature during the discharge.

Equation (6) is obtained by assuming that $U_e \gg U_a$, where U_a is the atomic temperature in volts.

When p = 0.73 mm Hg and i = 50 mA, $U_e(0) \approx 2$ V. 10 μsec after termination of the discharge, $U_e = 1.18$ V, which corresponds to 13,700°K; after 50 μsec, $U_e = 0.54$ V or $T_e = 6300$°K; after 200 μsec, $U_e = 0.245$ V or $T_e = 2800$°K. The electron temperature falls by a factor of e after ~ 15 μsec.

If the charged particles are lost during the afterglow as a result of ambipolar diffusion, the electron density varies with time as

$$n_e(t) = n_e(0)\exp\left(-\frac{1}{\Lambda^2}\int\limits_0^t D_a(t)\,dt\right)$$

or, according to (4),

$$n_e(t) = n_e(0)\exp\left(-\frac{1220}{\Lambda^2 p}\int\limits_0^t U_e(t)\,dt\right). \tag{7}$$

We substitute $U_e(t)$ into (7) according to (6) and after integrating we get

$$n_e(t) = n_e(0)\exp\left\{\frac{0.061}{\Lambda^2 p^2\sqrt{U_e(0)}}\left[(6\cdot 10^4 p U_e^{3/2}(0)\,t + 1)^{1/3} - 1\right]\right\}. \tag{8}$$

According to Eq. (8), the drop in electron density during the afterglow of a discharge in argon should occur more slowly than is observed in experiment. Thus, when p = 0.73 mm Hg, the electron density from 10 μsec after termination of the discharge to 300 μsec decreases in the experiment by factors of 1.95 and 1.57 for currents of 50 and 30 mA, respectively, but according to the calculation, n_e falls by a factor of 1.43 during this time.

The discrepancy can be explained both by the approximate nature of the theoretical premises and the possible distortion of the experimental results due to induction.

The authors thank S. É. Frish for discussion of the results.

Supersonic plasma jet from a high-power pulsed discharge

M. A. Sultanov

V. I. Lenin Tadzhik University, Dushanbe

(Submitted December 18, 1972)
Zh. Tekh. Fiz., 44, 759-765 (April 1974)

The structure of a single, spatially isolated plasma jet is investigated using a discharge chamber with a cylindrical aperture. A high-power pulsed discharge is used with different parameters for the electric discharge circuit and the diameter of the exit aperture. Under certain conditions (low capacitance and low voltage) a periodic flow of gas from the nozzle is observed in the plasma jet structure under conditions corresponding to a supercritical pressure drop for continuous flow. Different discharge conditions are investigated, the basic parameters of the jet are determined, and an analogy is shown with gasdynamic processes in air at atmospheric pressure.

The structure of the supersonic plasma jet (SPJ) has been investigated in a large number of papers. For example, the hydrodynamic nature of the flow of electrode jets into the discharge gap in a pulsed discharge was first pointed out in ref. 1, and the formation of dark spaces near the electrodes was first discussed in ref. 2. Other authors[3-6] point out the intermittent nature of the flow of electrode material and discuss the formation of the periodic structure.[7-9]

In our view, continuation of research in this direction is of interest to those studying shock-compressed plasma regions produced by the collision of two plasma[10-12] or laser[13-15] jets, those investigating the mechanism for erosion of different solids due to an SPJ,[16-18] and others. Moreover, the study of these jets is of independent interest and also provides additional information on the mechanism for the flow of the electrode material into a discharge.

Certain data given in the present paper indicate that the formation of plasma jets under supersonic conditions is of an intermittent nature. Moreover, there is an analogy between the processes that occur in the flow of a gas from a nozzle with a supercritical pressure drop in air at atmospheric pressure and those in the flow of the plasma jets of a high-power pulsed discharge from a discharge chamber with a cylindrical aperture in air at atmospheric pressure.

The SPJ is produced by the arrangement of electrodes and discharge chamber shown in Fig. 1. The arrangement produces jets with different energy densities and velocities, depending on the diameter of the discharge chamber and the parameters of the discharge circuit. In the present investigation we consider more than 40 regimes for producing plasma jets, varying the capacity of the bank of pulsed capacitors (the capacity ranges from 200-1200 μF in steps of 100 μF), the voltage (0.25-3 kV), and the diameter of the exhaust aperture (3.0-4.8 mm).

Typical time scans and frame photographs are shown in Fig. 2. The photographs are obtained on an SFR-2M streak camera with a scan rate of 1-25 $\cdot$ 10^3 m/sec and a framing rate of 1.25 $\cdot$ 10^5 frames/sec.

The photographs indicate that the plasma jet issuing from the aperture is axially inhomogeneous. Periodic variations in the brightness are evident (Fig. 2a), especially in the center of the pulse (the streak frame in Fig. 2c corresponds to the discharge conditions with continuous scan in Fig. 2a).

The periodic structure of the jet has been noted earlier in refs. 7 and 9, which show that it is due to the formation of compressive shocks. The detailed analysis of the jet structure undertaken in the present paper indicates that the jets exhibit all the basic characteristics of a continuous gas stream flowing from a nozzle with supersonic velocity with a supercritical pressure drop into a motionless medium. For comparison, a Schlieren photograph of the flow of air from a nozzle with a supercritical pressure drop taken from ref. 19 (there is a fourfold drop in pressure at the mouth of the nozzle) is shown in Fig. 2d.

The streak photographs indicate that near the washer surface there is a weakly luminous region similar to a dark cathode space.[1,2,8] It is characteristic that in our case a dark space is observed both for negative and positive polarity of the original electrode. Beyond the dark space there is a separate sharp boundary of an intensely luminous region. Moreover, some of the streak photographs show inclined bands whose formation is evidently due to oscillations in the density of the vapor issuing from the electrode. These oscillations, at a frequency of approximately 5 $\cdot$ 10^5 Hz, determine the fine time structure of the jet, whose formation is not considered in the present paper. Under certain conditions bands can be observed on the negatives not only in the intensity luminous region but also in the dark space. Consideration of these streak photographs indicates that at the boundary between

Fig. 1. Fig. 2. Time scans (a, b), frames of high-speed film (c, e, f, g) of supersonic plasma jets, and a Schlieren photograph of gas flow from the nozzle under conditions of a supercritical pressure drop (d). Discharge circuit: C = 400 μF and U = 0.25 kV (a, c, e); C = 200 μF and U = 2 kV (b); C = 200 μF and U = 6 kV (f); C = 300 μF and U = 3 kV (g).

the dark and light spaces there is a break in the bands toward the side of smaller inclination. This indicates a shock-like decrease in the jet (vapor) velocity in this region. With more powerful discharge conditions (C = 300 μF and U = 2 kV) the vapor velocity in the dark space region is 6-7 km/sec and in the intensely luminous region it is 1.5-2 km/sec (Fig. 2b). In the present case, the period structure disappears, i.e., with a more powerful discharge the compressive jump moves away from the washer. The same pattern is observed in the frames of high-speed scanning for a discharge circuit with C = 200 μF and U = 6 kV (Fig. 2f) and C = 400 μF and U = 3 kV (Fig. 2g). With a stronger discharge the compression region moves comparatively far away, and the streak photographs record only one compressive jump.

A plasma jet structure similar to that described above is also observed in refs. 3 and 7 for an electrical discharge in a closed volume and a plasma flow from a small aperture. The authors show that the boundary between the dark and light spaces is a shock wave generated by a supersonic jet flow into a motionless medium. The supersonic flow of the vapor of the electrode material and the shock-like decrease in velocity in the jet of a pulsed discharge shows that the boundary between the regions of different intensity is a shock wave.

Shock waves are formed in jets flowing from nozzles when the pressure inside the nozzle is much greater than the pressure in the ambient atmosphere. When the pressure inside the nozzle declines, the shock wave should acquire a quasistationary structure. In the jets of a pulsed discharge, a similar structure is sometimes observed in the final stages of the pulses when the energy density at the electrodes, and consequently the vapor pressure in the zone damaged by the discharge, substantially changes their surfaces.

Thus, when vaporized material flows from an electrode with an insulating washer a jet structure is observed which is similar to that for the supersonic flow of a plasma from a nozzle. Extending the analogy, one can assume that region of contact between the discharge and the electrode surface has the properties of a reservoir in which the pressure exceeds the atmospheric pressure appreciably. The flow of the electrode material is similar to a supersonic plasma flow, and the jet is a supersonic plasma stream.

An extremely important feature is the fact that the jet structure does not exhibit random changes during the pulse, as is the case for discharges between open electrodes.[20] There is some a change of direction after a change in the discharge current. This means that the method chosen for localization of the discharge allows us to stabilize the formation and propagation of jets to a significant degree.

A structure similar to that shown in Figs. 2a and 2c should be observed when there is a pressure drop at the

mouth of the nozzle in the direction of decreasing pressure outside the nozzle; the pressure drop must exceed a certain critical value determined by the parameters of the gas in the nozzle and the medium. A supersonic velocity is observed in the flow in the free jet outside the nozzle. In the rarefaction region outside the nozzle the pressure drops to a value below that of the surrounding medium into which the jet flows. In the photographs, this zone is represented by the dark space at the sides of bands of increased brightness which are curvilinear compressive shocks. A good illustration is shown in Fig. 2e. A similar pattern is partially observed in the final stage of the pulse.

It should be noted that with a stronger discharge refractive lines in the background of the opaque plasma region (refraction lines) can be observed on the frames of high-speed film as the plasma jet flows from the aperture of the discharge chamber. A similar pattern is noted in ref. 21, in which a laser-produced jet from a carbon target is investigated using a shadowgraph method. The authors indicate that the angle of inclination of these lines can be used to estimate the plasma density gradient.

Curvilinear compressive shocks can also be observed in the middle of the pulse for more powerful discharges. This is especially clear in Fig. 2f. It can be seen from the photographs that in the center of the flow in the core of the jet and above, the dark space is bounded by a straight compressive shock. The conditions behind this compressive shock are similar to those at the nozzle mouth; thus, the pattern of the pressure flow determines the periodic structure of the jet. In the straight shock the velocity in the center becomes subsonic. In the outer part of the flow the velocity remains supersonic. As a result of the interaction between the jet core and the outer flow the velocity over the entire flow becomes supersonic.

A similar pattern is observed in an investigation of a laser-produced jet[22] using high-speed photography. The authors consider the formation of the compressive shock to be the result of the directed motion of the vapor flow from a crater in the target.

The fundamental relations of thermodynamics[23–25] indicate a sharp increase in temperature, density, and pressure in compressive shocks. This causes an increase in luminosity in the regions behind the compressive shock.

The quantitative parameters characterizing the properties of jets as continuous plasma flows can be obtained by using gasdynamics. One can easily determine the length of the periodic structure (the height of the dark electrode space) from time scans of plasma streams. If the length of the periodic structure is known, one can determine the pressure inside the aperture from which the jet issues, the Mach number in the region ahead of the compressive shock, and the increase in temperature, density, and pressure in this shock.

The periodic structure L is related to the pressure p_1 inside the nozzle by[25]

$$L = 0.89d\sqrt{\frac{p_1 - 1.9p_2}{p_2}}, \tag{1}$$

where d is the nozzle diameter and p_2 is the presure in the ambient medium.

An approximate value of the Mach number in the region ahead of the compressive shock can be obtained from

$$L = 1.3d\sqrt{M^2 - 1}. \tag{2}$$

The velocity of the vapor in the jet ahead of the compressive shock can be measured from time scans of the inclined bands whose appearance is evidently related to fluctuations in the vapor density.

Analysis of spectrograms taken with various values of the parameters in the discharge circuit indicates that the plasma largely consists of erosion products from the discharge chamber and the electrodes and of air components. Therefore, the plasma can be regarded as a diatomic gas and at a discharge temperature of the order of 10^{4}°K the value of γ can be set at ~ 1.25. If the Mach number is known, the temperature and pressure variations in the compressive shock can be determined from the Rankine–Hugoniot relations[23–25]

$$\left.\begin{aligned} \frac{p_2}{p_1} &= \frac{2\gamma}{\gamma+1}M^2 - \frac{\gamma+1}{\gamma-1}, \\ \frac{\rho_2}{\rho_1} &= \frac{(\gamma-1)M^2+2]}{(\gamma+1)M^2}, \\ \frac{T_2}{T_1} &= \frac{[2\gamma M^2-(\gamma-1)][(\gamma-1)M_1^2+2]}{(\gamma+1)^2M^2}. \end{aligned}\right\} \tag{3}$$

We note that the value of γ for the plasma is somewhat smaller than that for a monatomic gas due to the ionization and the emission. For our calculations, however, it is sufficient to obtain just a provisional value for γ since its magnitude does not have a strong effect on the estimates. Therefore, ref. 26 can be used to obtain a value of ~ 1.25.

The results of measurements under some of the discharge conditions considered in this paper are shown in Table 1, which also gives the vapor velocity in the jet, the recession velocity of the luminous front, and the vapor pressure inside the discharge chamber. All the data refer to the middle stage of the pulse, except for the recession velocity of the luminous front, whose value is determined at the onset of the discharge. Analysis of the table indicates that all the parameters of the plasma stream vary with the capacity and voltage of the discharge circuit. Approximately the same dependence applies to the diameter of the aperture. The maximum velocity of the vapor flow appears with increasing pressure in the aperture. In high-power discharges this pressure can be several hundred atmospheres.

It is evident from Fig. 2f that the leading edge of the jet has a relatively sharp boundary which moves from the mouth of the discharge chamber with a velocity that is several times smaller than the vapor velocity in the jet. Under the present conditions the velocity of the leading edge in the initial stage of the pulse is 500 m/sec; the vapor velocity in the jet is 5-6 km/sec.

A similar pattern was first observed in ref. 27 for a spark discharge through a capillary. It was established that a relatively slow-moving luminous front with a limited rate of propagation of the plasma of the shock wave moving from the mouth of the aperture in air also characterizes the initial stage of the pulse. However, the periodic structure was not observed.

A development of the luminous region similar to the one described in the present paper has also been observed in expansion of a spark discharge channel,[28] a discharge in a T-shaped tube,[29] in a high-voltage discharge with an annular electrode,[30],[31] etc. In these cases the rate of propagation of the luminous front is limited by the shock wave formed in the atmosphere surrounding the discharge due to the rapid release of energy in a small volume. It follows that the periodic structure cannot form in the jet sooner than the shock wave can move from the mouth of the aperture to a corresponding distance. The time interval necessary for formation of the complete jet structure is larger, the lower the velocity of the shock wave and the longer the wavelength of the periodic structure.

By analogy with ref. 27, the jet can be considered as a plasma piston produced and fed by the shock wave in the atmosphere. Since the jet emerging from the aperture has a periodic structure, the receding shock wave and the luminous front should interact successively with the compression and rarefaction waves of the jet. Since the rate of propagation of the shock wave is proportional to the square root of the downstream pressure, its velocity should not decrease when interacting with the rarefaction wave, and it should not increase in interacting with the compression wave.

Thus, the formation of supersonic plasma jets in a high-power pulsed discharge is a hydrodynamic detonation process. After the shock wave has moved a large distance from the mouth of the discharge chamber its structure begins to resemble the structure of a continuous gas stream flowing from a nozzle with a supercritical drop in pressure. The interaction between the quasistationary wave structure of the jet and the shock wave in air leads to a periodic variation of the rate of propagation of the luminous front above the jet core during the formation period. A supersonic flow is observed in the region in front of the first compression.

Experimental investigation of microwave radiation produced by hypersonic flows

V. A. Lyutomskii, V. M. Polyakov, and V. G. Testov
Institute of Radio Engineering and Electronics,
Academy of Sciences of the USSR, Moscow

(Submitted May 29, 1973)
Zh. Tekh. Fiz., 44, 766-769 (April 1974)

The temperature of hypersonic flows is measured using their self-microwave radiation. Experimental results are given for the temperature and conductivity of hypersonic waves behind models moving through air with velocities of 4-4.6 km/sec and at an initial pressure of 40-100 torr. The dimensions of the ionization zone in argon are estimated from the measured microwave radiation of the shock wave.

When bodies move with hypersonic velocities through a rarefied gas a complex plasma structure forms around them; the plasma can be arbitrarily divided into the following regions: the ionization region, the shock wave, and the near and far wakes. Laboratory investigations of the microwave radiation from these regions can be carried out in shock tubes or ballistic devices. Consideration of their geometrical dimensions can help clarify the possibility of resolving these regions in space.

The characteristic dimension of the ionization region in the direction of the flow axis is of the order[1] of (Γd)/2, where d is the model (tube) diameter and Γ is the ratio of the characteristic values of radiative and convective transfer

$$\Gamma = \frac{\sigma u^5}{\rho_\infty c_p^4}. \qquad (1)$$

Here, σ is the Stefan–Boltzmann constant, u is the flow velocity, ρ is the flow density, c_p is the specific heat at constant pressure, and the subscript ∞ refers to the flow parameters at infinity.

It can be seen from Fig. 1 that at a pressure of 10 torr, a model diameter of ~ 1 cm, and velocities of ~ 5 km/sec the ionization region in air is approximately 10 cm in the ballistic device. In the shock tube, due to the large dimensions of the contact surface, significantly larger dimensions of this region can be obtained, and the use of argon significantly increases the ionization region.

In the ballistic device the stand-off distance of the shock from the surface of the moving body Δ_s can be taken as the characteristic dimension of the shock region. The following expression:[2]

$$\Delta_s = \frac{d}{3}\left(\frac{\rho_s}{\rho_\infty} - 1\right)^{-1}, \qquad (2)$$

indicates that this dimension is a fraction of the model diameter. For example, with a model of ~ 1 cm, Δ_s does not exceed several millimeters.

In the shock tube the dimensions of the contract surface of the shock-heated gas are several tens of centimeters for pressures of 5-20 torr and velocities[3] of 3-5 km/sec. The geometrical dimensions of the wake exceed those of all the other regions and are more than 1000 diameters of the moving body.[2]

If we assume that the resolution of the directional pattern of the antenna has a lower limit of the order of 1.5 λ, for microwave measurements in the centimeter and millimeter ranges both the ionization and the shock regions can be resolved in shock tubes, and the ionization region and the wake can be resolved in ballistic devices.

The intensity of radiation from the heated gas at frequency f, expressed in terms of the brightness temperature T_B, can be estimated from[4]

$$T_B = [1 - R(f)] \int_0^l T_r(x)\,\varkappa(x)\, e^{-\int_x^l \varkappa(x')\,dx'}\, dx, \qquad (3)$$

where T_r is the radiation temperature, R is the reflection coefficient with respect to the power at the boundary of the plasma structure (it is assumed that the boundary is fairly steep), $\varkappa$ is the absorption coefficient for the low-temperature plasma, and l is the thickness of the plasma layer.

If we assume that the plasma electrons have a Maxwellian velocity distribution and that the electron temperature is equal to the gas temperature, then the radiation temperature is equal to the gas temperature.

The temperature of the air in the wake can be determined from[5]

$$\frac{T}{T_\infty} = 1 + \frac{(\gamma - 1)\, c_x M_\infty^2}{\left[\frac{x}{d}(\gamma - 1)\, c_x + 1\right]}, \qquad (4)$$

where γ is the ratio of the specific heats at constant pressure and constant volume, and c_x is the drag coefficient.

The gas temperature in the shock region (between the shock front and the surface of the body) is determined from[3]

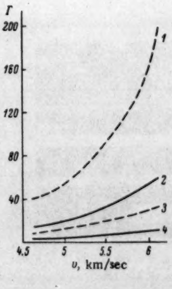

Fig. 1. p_∞ atm: 1, 2) 10^{-2}; 3, 4) $5 \cdot 10^{-2}$; 1, 3) Ar; 2, 4) air.

$$\frac{T}{T_\infty}=\frac{\left(\gamma M^2-\frac{\gamma-1}{2}\right)\left(\frac{\gamma-1}{2}M^2+1\right)}{\left(\frac{\gamma+1}{2}\right)^2 M^2}, \qquad (5)$$

where M is the Mach number.

The absorption and reflection coefficients are determined by the electron density N_e and the electron collision frequency ν.

Calculations indicate that with velocities of the order of 4.5 km/sec the brightness temperature of the shock region in air is about 4000°K. The brightness temperature of the wake can reach ~ 3500° for x/d ~ 20 and 1000°K for d/x ~ 1000. Modern sensitive microwave detectors have a noise temperature of $\delta T \sim 0.1°$ for a time constant $\tau =$ 1 sec. If we assume that measurements of the microwave of a hypersonic flow require a time constant of the order of tens of microseconds and that the sensitivity of the detector depends on the time constant as[4]

$$\delta T=\frac{T_D}{\sqrt{\tau\Delta f}}, \qquad (6)$$

then it becomes clear that a sensitivity of the order of 200° can be attained in the experiments. The calculations and experiments indicate that this sensitivity is sufficient to record microwave radiation from the appropriate regions of a hypersonic flow.

EXPERIMENTAL METHOD AND RESULTS

A ballistic device and a shock tube have been used to measure the characteristics of hypersonic flows.[6]

The self-microwave radiation and conductivity of the wake are measured in the ballistic device at hypersonic velocities of the model. The model is a copper-plated aluminum sphere 5.3 mm in diameter. The experiments are carried out in air at 20-160 torr and ~ 290°K in the pressure chamber. The model is fired from a light-gas gun with a velocity of 3000-4600 m/sec. A synchronization station which measures the velocity and photographs the model during flight is set up along the path of the model. The electron density and the effective frequency of collisions between electrons and neutrals are measured using two-resonator radiointerferometers ($\lambda_1 = 30$ and $\lambda_2 = 60$ cm). The low-frequency conductivity of the wake is measured directly by an electrodynamic method.[7]

The measured antenna temperature of the microwave radiation is related to the brightness temperature by

$$T_A=k\frac{S_W}{S_A}T_B, \qquad (7)$$

where K is the antenna loss, S_W/S_A is the ratio of the area of the wake in the minimum resolution area of the directional pattern to the area of the entire area. The wake dimensions are determined[8] from $d_W/d = 0.87\,(x/d)^{1/3}$. Measurements of a 2.4 cm wave indicate that at velocities of ~ 4 km/sec and a pressure of 40 torr, microwave radiation from the near-wake region is observed (Fig. 2a). With higher velocity and pressure (u = 4.6 km/sec and $p_\infty =$ 160 torr) a delay of the microwave signal is observed with respect to the flight of the model (Fig. 2b). In all likelihood, this is due to the formation of a supercritical plasma density in the wake directly behind the model and the resultant increase in reflection at the boundary. The duration of the microwave signal is determined by the nature of the drop in electron density and temperature along the wake. To estimate these characteristics we use data obtained from interferometer measurements of the conductivity. The measured values of the low-frequency conductivity and the effective collision frequency are used to determine the high-frequency conductivity of the wake:

$$\sigma=\sigma_{lf}\,\frac{1}{1+\frac{\omega^2}{\nu_{eff}^2}}, \qquad (8)$$

where σ_{lf} is related to the electron density and the collision frequency by $\sigma_{lf} = e^2N_e/(m\nu_{eff})$. The high-frequency conductivity thus obtained is used to calculate the absorption and reflection characteristics of the wake in the wavelength region under investigation.

Figure 3 gives theoretical and experimental profiles of the temperature along the wake. It is clear from the figure that they show satisfactory qualitative agreement.

The use of low model velocities and air prevents detection of the ionization region in the ballistic device. Therefore, microwave radiation from this region is measured in a shock tube with an argon atmosphere. The measurements are carried out at pressures of 5 to 10 torr and shock velocities of M ~ 6-7.5. Absorption, reflection, and electric probe current are measured simultaneously with the radiation. The measurements indicate that microwave radiation from the ionization region is observed for Mach numbers greater than 6.5, although it is true that the dimensions of the region are appreciably smaller than the calculated dimensions. In all likelihood, this is due to the

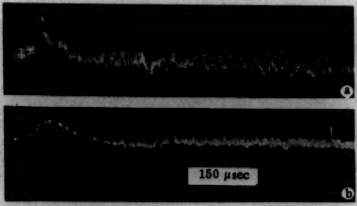

Fig. 2. Microwave radiation of the wake. a) u = 4.3 km/sec, p_∞ = 40 torr; b) u = 4.6 km/sec, p_∞ = 160 torr.

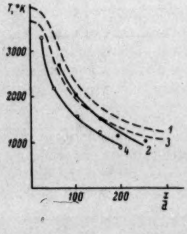

Fig. 3. Temperature distribution in the wake. 1, 2) M = 13.1, p_∞ = 160 torr; 3, 4) M = 12.3, p_∞ = 40 torr; 1, 3) theoretical curves.

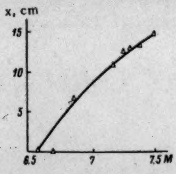

Fig. 4

low electron density at the beginning of the region. Figure 4 gives the dependence of the dimensions of the region ahead of the shock front, from which the microwave radiation is observed on the velocity of the incident shock. The very low absorption in this region (less than 0.1 dB) indicates the nonequilibrium nature of this radiation.

The preliminary results given here indicate that the self-microwave radiation can be used to measure the temperature in the wake and to estimate the variation in the dimensions of the ionization region as a region of the flow parameters.

In conclusion, the authors thank G. I. Mishin and S. N. Palkin for making it possible to carry out this investigation and for their support.

Quantum electronics

Parasitic amplitude modulation of a stabilized Nd $^{3+}$: YAG laser

N. M. Galaktionova, A. A. Mak, and A. P. Khyuppenen

(Submitted April 10, 1973)
Zh. Tekh. Fiz., 44, 770-777 (April 1974)

The dependence of the modulation and noise of a single-mode cw Nd^{3+}:YAG laser on pump-lamp current and loss modulation are investigated experimentally. The results are in good agreement with the solutions of the nonstationary rate equations. The modulation depth at which the continuous lasing mode turns into noise spiked lasing is determined. Stabilization of the laser parameters results in steady lasing with an amplitude-modulation spectral width less than 200 Hz at the 0.1 level; the ratio of noise power to radiation power is below 0.4% between 20 Hz and 600 kHz.

1. One of the most promising trends in the development of radiation sources of high spectral brightness is the reduction of the spectral width of solid state lasers and stabilization of the frequency. One important prerequisite for a successful solution of this problem is stabilization of the radiation power level, i.e., a low amplitude-noise level. One of the causes of random modulation of the intensity is the modulation of resonator loss. It has been shown in refs. 1-4 that such modulation can be caused by fluctuating and homogeneous pumping, by unstable cooling conditions, and by fluctuations of mirror position and the optical length of resonator due to changes in shape. Stabilization of resonator parameters, pumping, and cooling conditions result in a considerable reduction of the modulation in cw Nd^{3+}:YAG lasers.

The purpose of this work is an experimental investigation of the connection between resonator loss and pumping modulation and laser radiation noise, a quantitative estimate of the effect of active element cooling conditions on loss modulation, and the achievement of minimum parasitic modulation in a single-mode CW Nd^{3+}:YAG laser pumped by krypton arc lamps.

2. The dependence of the amplitude modulation on the loss and pump modulation can be found by solving the nonstationary rate equations in which the pump or loss appear as harmonic functions:

$$\gamma=\gamma_0(1+m_\gamma \sin \omega t), \tag{1}$$

$$W=W_0(1+m_{pp}\sin \omega t). \tag{2}$$

where γ is the loss rate; W is the pump rate (proportional to pump power); the subscript "0" denotes stationary values; and m_γ and m_{pp} are the loss and pump modulation indices respectively. Since balance equations and their solutions are well known,[4,5,8] we analyze the solutions. Note that the expressions given below are solutions of kinetic equations for a four-level system with a depleted lower active level and homogeneously broadened emission in the single-mode approximation. To a first approximation in perturbation theory, the solutions of nonstationary equations give expressions for the relative magnitude of the variable component of radiation intensity in the resonator:

$$\frac{U_i(t)}{U_0}=A_i m_i \sin(\omega t+\varphi_i), \tag{3}$$

where U_0 is the steady-state radiation density in the resonator (proportional to the radiation power P_0), the subscript "i" can denote either "γ" or "pp",

$$A_\gamma=\gamma_0\left[\frac{\omega^2+4\beta^2}{(\omega^2-\omega_p^2)^2+4\beta^2\omega^2}\right]^{1/2}, \tag{4}$$

$$\varphi_\gamma=\operatorname{arc\,tg}\left[\frac{\omega(\omega_p^2-\omega^2-4\beta^2)}{2\beta\omega_p^2}\right], \tag{5}$$

$$A_{pp}=\frac{2\beta\gamma_0}{[(\omega_p^2-\omega^2)^2+4\beta^2\omega^2]^{1/2}}, \tag{6}$$

$$\varphi_{pp}=\operatorname{arc\,tg}\left(-\frac{2\beta\omega}{\omega_p^2-\omega^2}\right), \tag{7}$$

$$\omega_p\simeq\sqrt{\frac{\gamma_0(n-1)}{\tau}}, \tag{8}$$

$$\gamma_0=\frac{\sigma c}{2L}, \tag{9}$$

$$\beta=\frac{n}{2\tau}, \tag{10}$$

β and ω_p are the damping constant and the circular frequency of the relaxation oscillations respectively ($\omega_p \gg 2\beta$), σ is the two-pass loss of the resonator, c is the velocity of light, L is the optical length of the resonator, n is the ratio of pump power to threshold power, τ is the lifetime of the excited state, and ω is the circular perturbation frequency.

The solutions have been obtained assuming that

$$U_i \ll U_0,\quad N_i \ll N_0,\quad m_\gamma \ll 1,\quad m_{pp} \ll 1,$$

where N_0 is the steady-state inverted population of the active level, and N_i is the variable component of population inversion.

The radiation power modulation indices are found from (3):

$$m_{P_i}=\frac{P_{a_i}}{P_0}=\frac{U_{a_i}}{U_0}=|A_i|\,m_i, \tag{11}$$

where P_{a_i} is the variable component of laser radiation power; the subscript "a" denotes the corresponding amplitude.

The factors A_i describe the outline of the resonance response of radiation power to small perturbations. The expressions for these factors for three different relationships between ω_p and ω are given below:

$$A_\gamma = \left| \begin{array}{ll} \dfrac{(\omega^2\tau^2+n^2)^{1/2}}{n-1} & \omega^2 \ll \omega_p^2, \quad (12) \\ \dfrac{\gamma_0}{2\beta} & \omega = \omega_p, \quad (13) \\ \dfrac{\gamma_0}{\omega} & \omega^2 \gg \omega_p^2; \quad (14) \end{array} \right.$$

$$A_{pp} = \left| \begin{array}{ll} \dfrac{n}{n-1} & \omega^2 \ll \omega_p^2, \quad (15) \\ \dfrac{\gamma_0}{\omega_p} & \omega = \omega_p, \quad (16) \\ \dfrac{2\beta\gamma_0}{\omega^2} & \omega^2 \gg \omega_p. \quad (17) \end{array} \right.$$

Expressions (12) and (15) indicate that equal loss and pump modulation result in equal radiation modulation, provided $\omega \ll \beta$. In all other cases, radiation modulation is much more affected by less modulation.

Let us estimate the allowable magnitude of m_l for a modulation index $m_p = 10^{-2}$ in the case of a laser with the following parameters: crystal length $l = 5$ cm, crystal diameter $d = 0.3$ cm, resonator length 60 cm, plane mirrors with transmission coefficients $T_1 = 0.05$ and $T_2 = 0.005$, passive crystal loss factor $\sigma_e = 0.005\ \text{cm}^{-1}$, $n = 2$, $\tau = 2 \cdot 10^{-4}$ sec, $\omega_p = 3 \cdot 10^5\ \text{sec}^{-1}$, $\gamma_0 = 1.7 \cdot 10^7\ \text{sec}^{-1}$, $\beta = 0.5 \cdot 10^4\ \text{sec}^{-1}$:

$$\omega^2 \ll 4\beta^2 \ll \omega_p^2, \quad m_\gamma = m_{pp} = 0.5 \cdot 10^{-2},$$
$$\omega = \omega_p, \quad m_\gamma = 6 \cdot 10^{-6}, \ m_{pp} = 1.8 \cdot 10^{-4},$$
$$\frac{\omega^2}{\omega_p^2} = 10, \quad m_\gamma = 6 \cdot 10^{-4}, \ m_{pp} = 6 \cdot 10^{-2}.$$

3. The laser used in the experiments is pumped by two high-pressure krypton lamps in a twin gold-plated elliptical illuminator. The lamp supply is stabilized and the voltage ripple factor is below $2 \cdot 10^{-4}$. The active element is cooled in a closed-loop system with a stabilized pump power supply. To reduce the effect of vibrations, the angle between the element and resonator axes is 15' and the element end faces are coated (R ~ 0.1%). The necessary resonator stiffness is provided by mounting the mirrors on heavy steel plates connected by Invar bars. To damp external vibrations, the entire experimental apparatus is placed on a heavy stiff plate cushioned with pieces of vacuum rubber pipe. Metal pipes are placed between the resonator mirrors and the end faces of the active element to prevent effects due to convective air currents.

The modulation is measured with the circuit shown in Fig. 1. The radiation is detected by an FÉU-62 photomultiplier whose photocurrent is kept constant; the signal across the photomultiplier load is 100 mV. The internal noise of the measuring system is measured by illuminating the photocathode with an incandescent bulb. The measured noise is 0.2 mV between 0.02 and 650 kHz. The alternating component of the photocurrent is amplified and applied to a spectrum analyzer. The spectrum analyzer is calibrated with a standard signal generator. The spectral density of the modulation index is determined from photographs. The radiation noise is analyzed by an ASChKh-1 spectrum analyzer at frequencies from 0.02 to 20 kHz and by an SCh-8 analyzer up to 650 kHz. The circuit makes it possible to measure the modulation index to $5 \cdot 10^{-5}$ at frequencies up to 20 kHz and to $3 \cdot 10^{-4}$ from 20 to 650 kHz. As in the case of radiation modulation measurement, the modulation of the pump lamp current is determined by measuring the voltage across a resistance connected in series with the lamp.

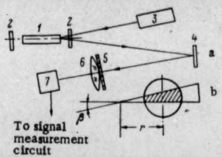

Fig. 2. a: Optical circuit for measuring the vibrations of the active element: 1) active element; 2) resonator mirrors; 3) gas laser; 4) rotating mirror; 5) mask; 6) lens; 7) FÉU-62 photomultiplier. b: Position of gas laser spot relative to the slit.

The noise conditions are strongly affected by vibrations of the active element caused by the perturbing effect of the cooling stream, the magnitude and nature of these vibrations depending on the rate of coolant flow. It has been found that one of the causes of radiation modulation is lateral bending of the active element and changes in the angular position of its axis.

The optical circuit shown in Fig. 2 has been used to estimate the active element vibrations. After reflection from the active element end face and rotating mirror 4, the radiation of a single-mode gas laser passes through slit 5 and is focused by lens 6 on the FÉU-62 photocathode. The slit is triangular with a small vertex angle. The position of the light spot (circle) relative to the slit is shown in Fig. 2b. Changes in the angular position of the element end face, which cause beam displacement along the slit, are determined from the variation of the photomultiplier output signal. The signal spectrum is analyzed with the aid of a spectrum analyzer as in the noise spectrum measurements. Assuming a constant and homogeneous power distribution in the gas laser beam, the vibration spectrum is determined by the spectral density of the alternating component $E(f)$ of the photomultiplier output signal:

$$\alpha(f) = \frac{E(f)}{E_0} \frac{r}{2D}, \quad (18)$$

where E_0 is the dc component of the signal, D is the distance between the element end face and slit, and r is the distance from the center of the light spot on the slit to the vertex of the triangular slit in the absence of vibrations.

In the presence of periodic vibrations, the vibration amplitude can be written

$$a = a_m(f)\,\Delta f, \tag{19}$$

where $\alpha_m(f)$ is the spectral vibration density at the vibration frequency, and Δf is the oscillation bandwidth

To excite relaxation oscillations of laser radiation intensity, the resonator is perturbed by increasing the rate of coolant flow. The frequencies of these oscillations are measured by ASChKh-1 and SCh-8 spectrum analyzers.

All experiments are carried out with the laser lasing in a single transverse mode, the TEM_{00} mode. The longitudinal mode spectrum consists of two to three groups of three to four modes each. The total spectrum width does not exceed 0.2 Å.

4. The experimental f_{ex} and the theoretical f_{th} [calculated from Eq. (8)] frequencies of relaxation oscillations are listed below:

tion $m_p(f)$ and pump lamp current $m_J(f)$ are listed in Table 1. The measurements are taken with exit mirror transmissions at parasitic modulation frequencies of the lamp current. Theoretical values of $m_p(f)$ are calculated assuming that pump power is proportional to the electric power $m_{pp}(f) = 2m_J(f)$. The characteristic modulation spectra of laser radiation and lamp current are shown in Fig. 3, a and b respectively.

The spectra in Fig. 3, c and d clearly show the connection between the modulation of radiation and vibrations of the active element. It has been found that as the coolant flow rate V increases, the element end face starts to vibrate at a low frequency which increases with increasing V. Still further increase of V causes the appearance of periodic oscillations of the end face at about 3 kHz, while the low-frequency random vibrations decay. The dependence of the maximum spectral density $\alpha(f)$ at frequencies up to 500 Hz and of the amplitude of periodic oscillations α of the element end face at 3000 Hz on the Reynolds number Re is shown in Fig. 4 [the solid portion of the $\alpha(Re)$ curve corresponds to experimental data]. In the laser radiation, the periodic component appears at lower Re numbers and is not accompanied by noise. The 3 kHz modulation increases with increasing Re, the frequency bandwidth increases, and the parasitic modulation spectrum becomes almost white (Fig. 3e). Radiation oscillograms indicate that the lasing becomes spiked. The measured frequency of the element end face is in good agreement with the calculated[11] natural frequency of transverse oscillations of the element:

$$f = \frac{b}{2\pi l^2}\sqrt{\frac{EI}{\rho S}}, \tag{20}$$

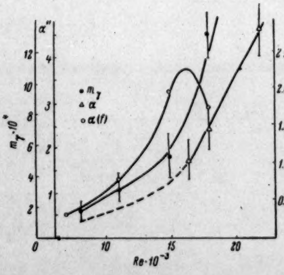

Fig. 4. Dependence of loss modulation index m_γ, angular amplitude of end face oscillations α at 3 kHz; and spectral density of chaotic vibrations $\alpha(f)$ at 20-500 Hz on the Reynolds number.

where E is the elastic modulus, I is the moment of inertia of the element cross-section, S is the cross-sectional area, ρ is the density, and b is a factor which depends on the element mounting. With rigidly mounted end faces b = 22.4, and f = 6.8 kHz, with freely supported end faces b = 9.87 and f = 3 kHz.

5. The experimental results show satisfactory agreement of the relaxation oscillation frequencies and the dependence of radiation power modulation on pump modulation with theoretical values (the spectral density of modulation indices is measured to within ~ 30%). The modulation of radiation caused by element vibrations can be explained by resonator loss modulation. Perturbations by coolant flow cause the active element simultaneously to change the angular position of its axis in the resonator (giving rise to a chaotic vibration spectrum) and to bend at the frequency of its natural transverse oscillations. Coating of the element end faces and removing them from the resonators explains the fact that variations of the angular position of the element do not affect the radiation modulation. At the same time, lateral bending of the rod distorts the resonator geometry, causing an equivalent mirror misalignment by the angle θ:

$$\theta = 2\alpha(\varkappa - 1), \tag{21}$$

where $\varkappa$ is the refractive index of the active element.

Variations of the Q factor of a spherical resonator caused by mirror misalignment are very difficult to determine analytically (in the experiment a spherical resonator derives from the fact that the weak thermal lens formed by the active element is left uncompensated). Thus, the experimental and theoretical data on the connection between laser radiation modulation and loss modulation caused by the perturbing effect of coolant flow have been compared in the following manner. With fixed Re we measure the spectral density of the radiation modulation index $m_p(f)$ at the frequency of transverse element oscillations for different values of n. The spectral density of the loss modulation index $m_\gamma(f)$ is then calculated from (12) at one value of n. This value of $m_\gamma(f)$ is then used to calculate $m_p(f)$ for other n values. The calculated and experimental results are listed in Table 2.

The loss modulation indices m_γ as a function of the Re number, calculated from the corresponding values of $m_\gamma(f)$ at f = 3 kHz, are shown in Fig. 4, where

$$m_\gamma = m_\gamma(f)\Delta f,$$

and Δf is the bandwidth of periodic oscillations of the active element.

At n = 1.15 and $m_\gamma \sim 10^3$, the radiation modulation at f = 3 kHz increases abruptly and spikes appear in the laser oscillations. The radiation modulation spectrum is continuous (Fig. 3e). The amplitude of equivalent angular oscillations of the resonator mirrors θ, corresponding to this value of m_γ, and calculated from Eq. (21) is about 5.5". Extrapolation of $\alpha \sim m_\gamma$ in the direction of small Re numbers indicates that for small n, radiation modulation can be considerable for angular mirror oscillations with an amplitude as small as ~ 0.4".

The noise spectrum of a stabilized laser does not exceed 200 Hz for pumping excesses as large as 1.3. No noise has been detected in this case in the frequency band from 500 Hz to 650 kHz. The noise power does not exceed 0.4% of generation power.

These results indicate that the solutions of nonstationary rate equations can be used in estimating the allowable loss and pumping modulation of a single-mode laser. The dependence of the radiation noise power on the noise of the krypton lamp current can be written as

$$P_{\mathrm{n}} = \frac{2P_0}{J_0} \int_{\omega} A_{\mathrm{pp}}(\omega)\, J(\omega)\, d\omega, \tag{22}$$

where J_0 and $J(\omega)$ are the steady-state value and spectral density of lamp current noise.

In the practically important case

$$P_{\mathrm{n}} = \frac{2P_0 J_{\mathrm{n}}}{J_0} \frac{n}{n-1}, \tag{23}$$

$m_p(f)$ at the frequency of transverse element oscillations for different values of n. The spectral density of the loss modulation index $m_\gamma(f)$ is then calculated from (12) at one value of n; This value of $m_\gamma(f)$ is then used to calculate $m_p(f)$ for other n values. The calculated and experimental results are listed in Table 2. where J_n is the effective value of the pumping lamp noise current.

The authors thank V. Popova, G. E. Novikov, and M. M. Khaleev for helping with the experiment, and V. I. Ustyugov for a discussion of the results.

(Submitted April 17, 1973)
Zh. Tekh. Fiz., 44, 778-783 (April 1974)

The thermal effect of continous radiation from a YAG : Nd^{3+} laser on glassy media and single crystals is studied. Expressions are obtained for the distribution of temperature and thermoelastic stresses in the irradiated sample. Estimates are given for the absorbed power necessary to form melts in the media. The theory agrees with the experimental data obtained with samples made of tinted glasses and single crystals. It is proposed, that in the high-temperature region the thermal effect on glassy media is associated with a change in the macroscopic parameters; while in the case of single crystals, the effect is associated with a microscopic rearrangement.

The thermal effect of continuous laser radiation in weakly absorbing media is observable even at low power levels. Appearing initially as thermal stresses (focusing, defocusing) laser radiation at higher levels of absorbed power causes considerable stress and elastic deformation (induced double refraction), plastic deformation, mechanical failure, and phase transitions.

The nature of the induced thermal effects is essentially determined by the temperature distribution in the medium being irradiated. The temperature field established in the samples under the action of continuous laser radiation depends not only on the level of the incident radiation, but also on the relationship between the geometric dimensions of the cross-section of the laser beam and those of the sample. The clearest thermal effects are manifested in the region of the beam–medium interface. Surface and subsurface effects are the most pronounced in the interaction of continuous laser radiation with strongly absorbing media.

CALCULATION OF THE THERMAL EFFECT

The stationary temperature distribution in a cylindrical sample of radius R can be found from the solution of the homogeneous equation for heat conduction.[1] The source function for the case of a weakly absorbing medium is taken to be of the form

$$W=\begin{cases}\frac{P}{\pi La^2} & \text{for}\quad r\leqslant a,\\ 0 & \text{for}\quad R\geqslant r>a,\end{cases}$$

where a is the radius of the beam of incident radiation, P is the power absorbed in the sample, and L is the length of the sample.

We obtain the following expression for the temperature field:

$$T(r)=\begin{cases}-\frac{P}{4\pi La^2\varkappa}r^2+\Theta_1 & \text{for}\quad r\leqslant a,\\ \frac{P}{2\pi L\varkappa}\ln\frac{R}{r}+\Theta_2 & \text{for}\quad R\geqslant r>a,\end{cases}\tag{1}$$

where $\varkappa$ is the coefficient of thermal conductivity of the medium,

$$\Theta_1=T_0+\frac{P}{2\pi L\alpha R}+\frac{P}{4\pi L\varkappa}\left[2\ln\frac{R}{a}+1\right],$$

$$\Theta_2=T_0+\frac{P}{2\pi L\alpha R},$$

where α is the coefficient of heat transfer.

We note that Θ_2 is the temperature at the surface of the sample, while Θ_1 is the temperature established on the axis of the beam, T_0 is the temperature of the surrounding medium, and

$$\Theta_1-\Theta_2=\frac{P}{4\pi L\varkappa}\left[2\ln\frac{R}{a}+1\right].$$

It is clear that the temperature at the surface of the sample remains constant with decreasing laser beam radius. It is reasonable to expect this behavior, since the boundary conditions are not changed. However, the temperature at the beam axis increases as the beam radius is reduced (for P = const). The temperature difference between the center and the surface of the sample also increases (Fig. 1). The temperature difference between the center and the edge of the beam remains constant.

In order to obtain the distribution of thermoelastic stresses in the sample, we substitute the expressions obtained for the temperature distribution into the equation derived by Timoshenko.[2] After carrying out the integration, and making a correction to the component σ_z for the case of the "free" ends, for $r \leq a$ we get

$$\sigma_r(r)=-K\left[\frac{a^2}{R^2}+4\ln\frac{R}{a}-\frac{r^2}{a^2}\right],$$

$$\sigma_\varphi(r)=-K\left[\frac{a^2}{R^2}+4\ln\frac{R}{a}-\frac{3r^2}{a^2}\right],$$

$$\sigma_z(r)=-2K\left[\frac{a^2}{R^2}+4\ln\frac{R}{a}-\frac{2r^2}{a^2}\right];$$

and for $R \geq r > a$

$$\sigma_r(r)=-K\left[a^2\left(\frac{1}{R^2}-\frac{1}{r^2}\right)+4\ln\frac{R}{r}\right],$$

$$\sigma_\varphi(r)=-K\left[a^2\left(\frac{1}{R^2}+\frac{1}{r^2}\right)+4\ln\frac{R}{r}-4\right],$$

$$\sigma_z(r)=-2K\left[\frac{a^2}{R^2}-2+4\ln\frac{R}{r}\right],$$

$$K=\frac{\beta EP}{16\pi L\varkappa(1-\mu)},$$

where β is the coefficient of linear expansion of the medium, E is Young's modulus, and μ is the Poisson coefficient.

Figure 2 shows the calculated values of $\sigma_2(r)$, $\sigma_\varphi(r)$, and $\sigma_z(r)$ for samples of optical glass. A positive value corresponds to tension, and a negative value corresponds to compression. It is clear from these calculations that the internal stresses for samples made of optical glass can reach hundreds of kilograms per square centimeter.

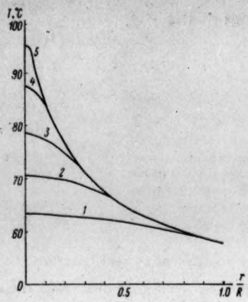

Fig. 1. The stationary temperature distribution in the sample for various values of beam radius a: 1) R; 2) 0.5R; 3) 0.25R; 4) 0.1R; 5) 0.05R.

Under telescopic compression of the laser beam stresses go as high $5 \cdot 10^3$-10^4 kg/cm^2, which is considerably higher than the experimental values of the tensile strengths of glass. The maximum values of σ_r, σ_φ, and σ_z occur at the point r = 0. Estimates of the temperature and stresses at the beam axis give the following results. For given values of R and a, stresses which are greater than the tensile strength of glass are reached at a power level which is larger than that necessary to attain the melting temperature T_1. For temperatures at the axis which are larger than T_1, the temperature distribution is given by the same equations (1), while the character of the stresses changes radically. We will assume that melting occurs for $r \leq b$. As a result, all stresses in this region vanish. Since the temperature difference between the axis of the beam and its boundary is small, the case of $b > a$ is the most common.

For this case, the stresses in the region $b \leq r \leq R$ are treated in the calculation as the stresses of a half cylinder with the given temperature difference between the walls:[3]

$$\sigma_r^* = -4K\left[\ln\frac{R}{r} + \frac{b^2}{R^2 - b^2}\left(1 - \frac{R^2}{r^2}\right)\ln\frac{R}{b}\right],$$

$$\sigma_\varphi^* = -4K\left[\ln\frac{R}{r} + \frac{b^2}{R^2 - b^2}\left(1 + \frac{R^2}{r^2}\right)\ln\frac{R}{b} - 1\right].$$

EXPERIMENTAL RESULTS

A YAG : Nd^{3+} laser, which has been previously described in the literature,[4] is used to supply the continuous radiation for the experimental studies. The glass samples are 3 mm thick and 10 mm in diameter. The coefficient of heat transfer α is $0.002\ \mathrm{W \cdot cm^{-2} \cdot deg^{-1}}$, while the coefficient of thermal conductivity of the glass $\varkappa$ is $7 \cdot 10^{-3}\ \mathrm{W \cdot cm^{-1} \cdot deg^{-1}}$.

The calculation of the temperature field enables one

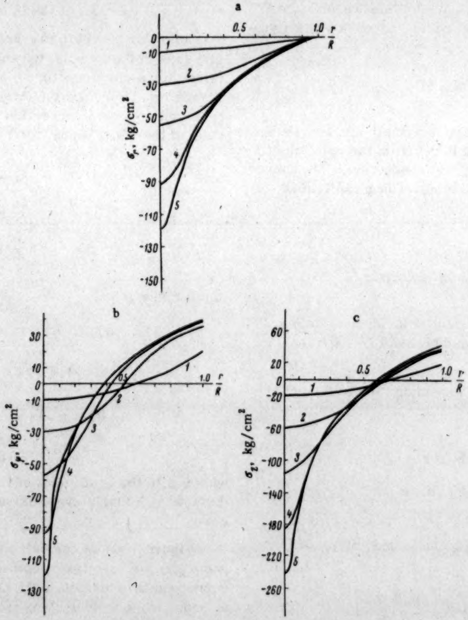

Fig. 2. The distribution of the stationary field of thermoelastic stresses in a sample as a function of a. a) radial; b) angular; c) along z.

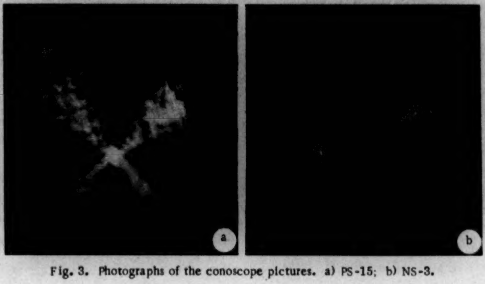

Fig. 3. Photographs of the conoscope pictures. a) PS-15; b) NS-3.

to estimate the value of the absorbed power P_1 necessary to form a melt in the sample at the axis of the laser beam.

Table 1 lists the calculated and experimental values of laser power needed to reach the melting point temperature at the beam axis. To within the accuracy achieved under our conditions (experimental error 30-40% calculation errors ~ 15%), the agreement between the experimental and calculated values can be considered satisfactory.

Measurements of the characteristics of the induced thermal lens are made in order to estimate the temperature distribution. Its parameters are determined by measuring the diameter of the radiation spot in the focal plane of a long-focus lens. In order to take account of the change in the dispersion of the laser radiation itself (in variation of the radiated power level), the measurements are made both with and without the sample. The dimensions of the radiation spot are measured photographically by using electron-optical conversion of its image on a ceramic screen on whose surface is deposited a measuring grid. In certain experiments, the radiation of a He–Ne laser operating in the TEM_{00} mode is used for test purposes. The experimental data are found to be in satisfactory agreement with the theoretical calculation.[5] A discrepancy is observed at high values of P. The reason for this disagreement evidently lies in the change in the parameters of the medium due to the increase in temperature.

The stress distribution is determined by means of induced double refraction. The test radiation of a He–Ne laser is used to observe the induced double refraction. The radiation is passed through classical conoscopes, within which are placed the samples under investigation. Totally reflecting (for $\lambda = 1.06\ \mu$) mirrors and deflecting plates are used to shield the camera from the primary radiation. The conoscope patterns which are obtained for the various samples made of optical glass filters with different amounts of absorption over a laser wavelength closely resemble each other in their essential features (Fig. 3). The stabilization time of the conoscope pictures is 1-2 sec. The relaxation of the conoscope picture takes 3-4 sec. The contrast of the pictures shows a considerable increase at higher power densities. No essential changes in the character of the picture occur, however. Complete relaxation of the induced double refraction takes place right up to melting and disintegration (observations are made on samples made of NS-2, NS-3, FS-7, PS-6, SZS-5, ZS-1, ZhS-16, and PS-15). The photographs are used to estimate the amount of induced double refraction, with the following result:

$$\Delta n_{x,y} = (0.3 \pm 0.1) \cdot 10^{-4}.$$

An investigation of the distribution of double refraction in the samples shows that it reaches its maximum value in the region of the beam–medium interface, rather than on the axis of the laser beam. Relaxation of the stresses

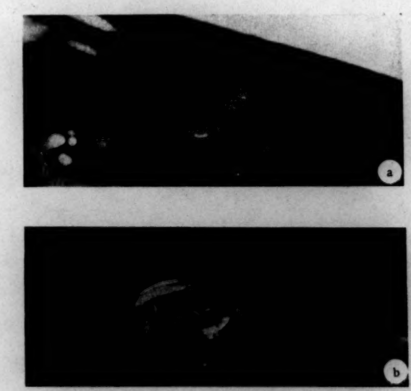

Fig. 4. Photographs of melts at the entrance surface of samples. a) PS-15 b) SZS-22.

in the material within the beam occurs when the softening temperature is reached.

Traces of melts appear at the entrance and exit surfaces of the sample. The form of the melts at both surfaces is the same, but depends essentially on the sample material, the absorbed power, and the focusing. The most common forms of the melts are shown in Fig. 4. The most characteristic form of the initial fissure is that of a circle concentric with the beam. Typical microfissures have a width of from 5 to 20 μ; the diameter of the circles is ~ 3 a. When inhomogeneities are present in the medium, the fissure splits and its shape diverges from that of a circle. Attempts to cut the sample near the fissure cause it to split along the cylindrical surface resting on the fissure.

We have also carried out all of the above-described calculations and experiments for single-crystals made of KDR, ADR, $LiNbO_3$, and others. The results are qualitatively similar to those described above for the case of optical glass. An essential difference does arise, however, in approximating the phase transition temperature. Melting in a single-crystal medium is a very sensitive effect, which depends on a number of factors. In the high temperature region, for glassy media there is a range of softening temperature and the associated changes in the macroscopic parameters of the medium. In crystals, the high temperature region with the presence of thermoelastic stresses is more likely to be associated with a rearrangement of the microscopic structure, rather than being directly related to the macroscopic characteristics.

A model of the CF_3I laser is constructed in which allowance is made for fast reactions of the CF_3 radical; the latest data on the temperature dependences of the rate constants of the chemical reactions are used. The model gives reasonable agreement between the theoretical and experimental characteristics of the stimulated emission of the CF_3I laser over a wide range of pump rates and initial pressures.

1. FORMULATION OF THE PROBLEM

In 1964 Kasper and Pimentel[1,2] obtained laser action on the transition

$$I^1 + h\nu\,(0.942\text{ eV}) \rightarrow I^0 + 2h\nu\,(0.942\text{ eV}) \qquad (1)$$

with the photodissociative pumping mechanism

$$RI + h\nu_{\text{pump}} \rightarrow R + I^1, \qquad (2)$$

where I^1 denotes $I(^2P_{1/2})$, I^0 denotes $I(^2P_{3/2})$, and R denotes the radicals CF_3, C_2F_5, C_3F_7, CH_3, C_2H_5, C_3H_7, etc. However, even for CF_3I and C_3F_7I, the most efficient working materials in terms of power output, the total photon yield of stimulated emission per unit volume G_Σ does not exceed 5-10% of the maximum possible value, $G_{\Sigma\max}$ [see Eq. (64) in ref. 3].

The first mathematically correct treatment of chemical processes leading to quenching in the CF_3I laser is that of Zalesskii and Venediktov,[4] who use Pollack's[5] recombination mechanism for the accumulation of molecular iodine

$$I^l + I^m + M_i \xrightarrow{k_{3ilm}} I_2 + M_i \; (l,\, m=0,\, 1;\; i=1,\, 2) \;\; (3-i,\, l,\, m) \qquad (3)$$

supplemented by the reaction

$$I^1 + I_2 \xrightarrow{k_{21}} I^0 + I_2. \qquad (4)$$

[In (3) M_1 denotes I_2 and M_2 denotes CF_3I]. Zalesskii and Venediktov[4] obtained a certain correlation between the calculated and the experimental values of G_Σ and t_{qu}, the time at which stimulated emission is quenched, but only for weak pumping ($\varphi \leq 10^{20}$ photons/cm^2 · sec in the CF_3I absorption band) and for moderately high pressures ($[CF_3I]_0 \sim 100$ torr). Accordingly, Zalesskii and Moskalev[6] then considered a pyrolysis quenching mechanism in which the quenching is due to population of the lower laser level as a result of the pyrolysis of the working material:

$$CF_3I \rightarrow CF_3 + I^0.$$

In their paper[6] Zalesskii and Moskalev conclude that for trifluoromethane as working substance (unlike, for example, the more thermostable perfluorinated propyl iodide), pyrolysis is quite capable of quenching. We show in ref. 7, however, that if the calculations are not performed for fixed values of the pump power and initial pressure of the working gas, but for the entire experimentally accessible range of these parameters ($[CF_3I]_0$ from 8 to 800 torr, φ from $4 \cdot 10^{20}$ to $4 \cdot 10^{23}$ photons/cm^2 · sec), then the pyrolysis mechanism does not explain existing experimental data on the quenching time and energy output of the CF_3I laser.

Zalesskii[8] later constructed a kinetic model of the CF_3I laser which, for $[CF_3I]_0 = 100$ torr and $\varphi \simeq 4.5 \cdot 10^{21}$ photons/cm^2 · sec, gives good agreement between the experimental and theoretical values of t_{qu} and G_Σ. Nevertheless, there are good reasons for doubting the completeness of the model of ref. 8. First, even when $[CF_3I]_0 = 20$ torr and $\varphi \sim 4 \cdot 10^{21}$, as Zalesskii notes in ref. 8, satisfactory agreement between the calculated and experimental values of t_{qu} and G_Σ does not obtain. Second, the model of ref. 8 consists essentially of processes (1)-(4) used in ref. 4 supplemented by certain insignificant processes (this can be seen from Table 2 of ref. 8, for instance), whereas we had previously pointed out[7] that model (1)-(4) is incomplete as it only works at low pump powers ($\varphi \leq 10^{21}$ photons/cm^2 · sec) and not for all values of $[CF_3I]_0$.

Further, in ref. 8 Zalesskii estimates the rate constant k_{3200} from the boiling point of CF_3I and the resulting value used by him, $2.2 \cdot 10^{-32} \exp(855/T)$ cm^6/mole^2 · sec in the range 20-200°C, is three times greater than the true value, $(1.4 \pm 0.4) \cdot 10^{-33} \exp\,[(1600 \pm 400)/T]$, experimentally obtained[9] by flash photolysis. The high value of k_{3200} must unavoidably create an illusion of validity of model (1)-(4) at higher values of φ. This illusion is heightened by the use of a temperature-independent rate constant $k_{21} = 5 \cdot 10^{-12}$ cm^3/mole · sec (see ref. 10), whereas the true value of $k_{21} = 3.9 \cdot 10^{-14} \exp(1660/T)$ cm^3/mole · sec (ref. 11) is less than $5 \cdot 10^{-12}$ even at 350°K, being only $6 \cdot 10^{-13}$ at 600°K. [These remarks pertain not only to Zalesskii's paper,[8] but also to the papers by Filyukov and Karpov,[12] which are mathematically correct and very interesting, but in which the chemical ideas do not go beyond the model (1)-(4)].

On the other hand, our calculations[7] and the calculations of other investigators[4,8,12] are somewhat out of date. Thus, it is assumed in refs. 4, 12 that $k_{3i11} = k_{3i10} = k_{3i00}$, while in ref. 7 we take $k_{3i10} = k_{3i00}$, $k_{3i11} = 0$. Direct measurements[13,14] have shown, however, that within the limits of experimental error $k_{3i11} = k_{3i10} = 0$. Furthermore, and this is most important, we have previously shown[15,16] that the strong quenching of excited $I(^2P_{1/2})$ atoms at low pressures $[CF_3I]_0$ and at high pump powers cannot be explained by the formation of molecular iodine I_2 through any realistic mechanism, and that this quenching must be ascribed to some other particles. Indeed, Pimentel et al.[17] have recently determined, by flash photolysis, the rate constant of the process

$$I(^2P_{1/2}) + CF_3 \xrightarrow{k_{10}} I(^2P_{3/2}) + CF_3. \qquad (5)$$

At 298°K this quantity is $3.7 \cdot 10^{-12}$ cm^3/mole · sec. Increasing the temperature by a few hundred degrees results in an order of magnitude increase of k_{26}, and it is accordingly 100 times greater than k_{21} (see ref. 11). According to Pimentel et al.[17] the rate constants for the reactions

$$I(^2P_{3/2}) + CF_3 \xrightarrow{k_{60}} CF_3I, \tag{6}$$

$$CF_3 + CF_3 \xrightarrow{k_{700}} C_2F_6, \tag{7}$$

are also very large.

It would thus appear that the operation of the CF_3I laser is governed by reactions (5)-(7), especially at low pressures and high pump powers.

2. CHOICE OF RATE CONSTANTS

In accordance with the ideas of Sec. 1, the main processes occurring in the working volume of the CF_3I laser can be taken to be processes (1)-(7) and the reaction

$$CF_3 + I_2 \xrightarrow{\bar{k}_{900}} CF_3I + I(^2P_{3/2}), \tag{8}$$

the rate constant of which, from ref. 18, is $\bar{k}_{900} = 4.3 \times 10^{-12}$ cm^3/mole · sec. (In the present work we use the notation for the rate constants adopted in our previous papers.[3,7,15,16])

As mentioned in Sec. 1, experimental data[13,14] imply that $k_{3i11} = k_{3i10} = 0$. From ref. 19, $k_{3100} = 1.287 \times 10^{-33} \cdot (T/300)^{3/2} \exp(2676/T)$ cm^6/mole^2 · sec; from ref. 9, $k_{3200} = 1.4 \times 10^{-33} \cdot \exp(1600/T)$ cm^6/mole^2 · sec; and from ref. 11, $k_{21} = 3.9 \cdot 10^{-14} \exp \times (1660/T)$ cm^3/mole · sec. It remains to choose the rate constants for the reactions (6)-(7).

The values given by Pimentel et al.[17] cannot be regarded as completely correct. In mathematical terms, two algebraic equations are obtained in ref. 17 for the three unknowns, k_{26}, k_{60}, and $k_{7300}\,[Ar]_0$, where k_{7300} is the rate constant of the reaction

$$2CF_3 + Ar \rightarrow C_2F_6 + Ar \tag{9}$$

and $[Ar]_0 = 100$ torr. One equation is obtained from photolysis of CF_3I in a kinetic experiment and the second from an analysis of the composition of the final products of the photolysis of CF_3I. The authors of ref. 17, guiding themselves by the analogy with the reaction $Cl + CH_3 \rightarrow CH_3Cl$, take for k_{60} the value $6 \cdot 10^{-10}$ cm^3/mole · sec, after which calculations give for the other two unknowns $k_{26} = 3.65 \cdot 10^{-12}$, $k_{7300}\,[Ar]_0 = 9.8 \times 10^{-12}$ cm^3/mole · sec for 25°C and $k_{26} = 4.5 \cdot 10^{-12}$, $k_{7300}\,[Ar]_0 = 1.18 \cdot 10^{-11}$ for 60°C. A mathematical analysis shows, however, that for such a large value of $k_{60} = 6 \cdot 10^{-10}$ laser action in the CF_3I laser would not be quenched until the temperature of the working mixture reaches ~ 1500°K. The experimental data on the operation of the CF_3I laser accordingly imply that k_{60} is much smaller than $6 \cdot 10^{-10}$. The choice of a new value of k_{60} does not greatly influence the values of k_{26} calculated by Pimentel. Thus, for 25°C the value $k_{60} = 1.5 \cdot 10^{-10}$ corresponds to the value $k_{26} = 4.55 \cdot 10^{-12}$, and $k_{60} = 7.5 \cdot 10^{-11}$ corresponds to $k_{26} = 5.10 \cdot 10^{-12}$. Finally, according to our calculations in conjunction with the experimental results of Pimentel et al.,[17] we find that

$$k_{60} = 1.5 \cdot 10^{-11} \text{ corresponds to } k_{26} = 9.8 \cdot 10^{-11} \sqrt{\frac{T}{300}}\, e^{-581/T}, \tag{10a}$$

$$k_{60} = 2 \cdot 10^{-11} \text{ corresponds to } k_{26} = 7.2 \cdot 10^{-11} \sqrt{\frac{T}{300}}\, e^{-581/T}, \tag{10b}$$

$$k_{60} = 3.75 \cdot 10^{-11} \text{ corresponds to } k_{26} = 4.46 \cdot 10^{-11} \sqrt{\frac{T}{300}}\, e^{-581/T}. \tag{10c}$$

Turning now to the rate constant k_{700} we note that, strictly speaking, there are no experimental data for this quantity. The point is that all measurements of the recombination rate of CF_3 radicals have been made either in the presence of argon[17,20,21] or in the presence of perfluoroacetone,[22] so that the bimolecular constants given in refs. 17, 20-22 are sums

$$k_{700} + k_{7i00}[M_i], \tag{11}$$

where k_{7i00} is the rate constant for recombination of CF_3 radicals on a third body M_i:

$$2CF_3 + M_i \rightarrow C_2F_6 + M_i.$$

A study of the values of the sum (11) given by the various authors gives approximately k_{700} (293°K) = 10^{-11} cm^3/mole · sec; accordingly, in our calculations we use the value

$$k_{700} = 10^{-11} \sqrt{\frac{T}{300}} \quad \text{cm}^3\text{/mole} \cdot \text{sec}$$

Thus, in our model (1)-(8) we utilize the experimentally measured values of all rate constants except k_{60}. The value of k_{60} is found by comparing the characteristics of the CF_3I laser calculated from (1)-(8) with experiment.

3. KINETIC MODEL OF CF_3I LASER

Reactions (2)-(7) listed in Sec. 1, 2 coincide respectively with reactions (6), (10-ilm), (9-1), (9-6), (13-0), (14-00) of our previous paper,[3] while reaction (8) is the inverse of reaction (16-00) of ref. 3. The operation of the CF_3I laser will be described within the framework of the model of Sec. 1 of ref. 3, and we shall assume that the critical inversion is equal to zero (P = 0), $s_{00} = 0$ (see refs. 13, 1), and that the pump pulse $\varphi(t)$ is of the form

$$\varphi(t) = M\Theta(t), \tag{12}$$

where $\Theta(t)$ is the Heaviside function. The rectangular waveform (12) of the pump pulse is chosen so that the effect of the chemical processes on the output radiation pulse should be obscured as little as possible by the shape of the pumping pulse.

Under the stated assumptions, stimulated emission commences at t = 0 and its variation in time G(t), along with the variation in time of the concentrations of all the components, will be described by Eqs. (20)-(26) of ref. 3. In the case of model (1)-(8) these equations acquire the following form:

$$G(t) = \frac{2}{3}\gamma[RI] - \sum_{i=1,6} k_{2i}[M_i][I^1] + \frac{1}{3}[I^0]^2 \sum_{i=1,2} k_{3i00}[M_i]$$

$$+\frac{1}{3}k_{60}[I^0][R]-\frac{1}{3}\bar{k}_{900}[R][I_2], \qquad (13)$$

$$\frac{d[RI]}{dt}=-\gamma[RI]+k_{60}[I^0][R]+\bar{k}_{900}[R][I_2], \qquad (14)$$

$$\frac{d[J^1]}{dt}=\gamma[RI]-G(t)-\sum_{i=1,6}k_{2i}[I^1][M_i], \qquad (15)$$

$$\frac{d[I^0]}{dt}=G(t)+\sum_{i=1,6}k_{2i}[I^1][M_i]-[I^0]^2\sum_{i=1,2}k_{3i00}[M_i]$$
$$-k_{60}[I^0][R]+\bar{k}_{900}[R][I_2]. \qquad (16)$$

$$\frac{d[I_2]}{dt}=\frac{1}{2}[I^0]^2\sum_{i=1,2}k_{3i00}[M_i]-\bar{k}_{900}[R][I_2], \qquad (17)$$

$$\frac{d[R]}{dt}=\gamma[RI]-k_{60}[R][I^0]-k_{700}[R]^2-\bar{k}_{900}[R][I_2], \qquad (18)$$

where M_1, M_2, M_6 denote I_2, RI, and R respectively, R denotes CF_3, and

$$\gamma\equiv s_0 M \ (1/\text{sec}). \qquad (19)$$

Here, s_0 is the mean (over the absorption band) absorption cross section for CF_3I and M is the pump power in the CF_3I band, whence (19) immediately characterizes the pump rate in the chemical system.

The equation for $[C_2F_6]$ can be separated from Eqs. (13)-(18) and has not been written out. In Eqs. (13)-(18) all the constants k are explicit functions of temperature T. The time variation of T is described with the aid of the approximation of Section 2 of ref. 3; accordingly, from Eq. (45) of ref. 3 for the model (1)-(8) considered here

$$T(t)=T_0+\frac{K}{C_{RI}}(1-e^{-\gamma t})=293+4883(1-e^{-\gamma t}), \qquad (20)$$

where C_{RI} = 16.9 cal/deg · mole is the molar specific heat of CF_3I, and K = 82,500 cal = 3.58 eV is the heat input to the system for absorption of a single pump photon in (2).

Numerical integration of Eqs. (13)-(18) is carried out on a BÉSM-6 high-speed digital computer. The calculations are performed for the three variants of model (1)-(8) corresponding to cases (10a), (10b), and (10c) with temperature dependence (20), and also for two variants of model (1)-(4) with the values of k_{3i00} and k_{21} specified in Sec. 2 and with temperature dependence (20) in the one variant and a temperature dependence T(t) = const = T_0 in the other. The results of the calculations are presented in Table 1, which also shows the experimental results obtained in ref. 23.

It can be seen from the table that only calculations according to model No. 2 agree with experiment over the entire range of the parameters $[CF_3I]_0$ and γ. This means that only situation (10b) corresponds to reality as far as rate constants k_{60} and k_{26} are concerned. It was not possible, however, to achieve complete coincidence (within the limits of experimental error). This is hardly surprising since, on the one hand, the presence in the experimental results of hidden systematic errors cannot be excluded. On the other hand, the theoretical calculations for model No. 2 make the manifestly coarse assumption that k_{60} and k_{700} are independent of temperature. Unfortunately, there are no experimental data on the functions $k_{60}(T)$ and $k_{700}(T)$, while the present state of the theory of rate constants does not yield even a guess at the form of these functions.

Thus, on the whole, model (1)-(8) with rate constants (10b) works satisfactorily over a wider range of varia-

TABLE 1. Theoretical and Experimental Dependence of t_{qu} and Γ_Σ of Small-Volume (transparent for pumping radiation) CF_3I Laser on Initial Pressure p_0 of Working Gas and on Pumping Rate γ, Equal to $1.6 \cdot 10^i$ sec^{-1}

Note: Nos. 1, 2, 3 correspond to model (1)-(8) for cases (10a), (10b), and (10c), respectively and temperature dependence (20); No. 4 corresponds to model (1)-(4) with temperature dependence (20); No. 5 corresponds to model (1)-(4) with temperature T(t) = const = T_0 = 293°K. The asterisks denote experimental values obtained through interpolation and extrapolation of the results of ref. 23; the relative error of the experimental data is ± 15% for Γ_Σ and ± 25% for t_{qu}.

tions of the parameters $[CF_3I]_0$ and γ than any other model. The value of $k_{60} = 2.10^{-11}$ cm^3/mole·sec obtained by us is, in fact, a certain "average value" of $k_{60}(T)$ in the temperature interval 300–700°K.

It is clear also from the data of the table that the "recombination mechanism" (1)–(4) (model No. 4) does not give remote agreement between calculation and experiment. It can also be seen that the recombination mechanism with fixed rate constant (model No. 5), which manifestly does not correspond to reality, gives for $160 < \gamma < 1600$ and 50 torr $< p_0 <$ 100 torr the illusion for coincidence of theoretical and experimental data. (The calculations of refs. 8 and 12 pertain to just such values of the parameters γ and p_0.) Model No. 5 does not work, however, for $p_0 <$ 20 torr and $160 < \gamma < 1600$, and gives values of Γ_Σ and t_{qu} that are too high compared with experiment. Mention is made of these high values both in ref. 8 and in ref. 12. This demonstrates again the methodological incorrectness of drawing conclusions on the validity of a given model for the photodissociation laser solely on the grounds that the calculated and experimental data coincidence for certain randomly chosen values of the pressure (p_0) and the pump rate (γ). Before such a conclusion can be drawn it is necessary, at the very least, that the calculated and experimental data coincide in the entire experimentally accessible range of variation of the parameters p_0 and γ.

This remark also applies to the recent paper by Hohla and Kompa.[24] The merit of the kinetic model of the CF_3I laser constructed in ref. 24 is that it incorporates reactions (5)–(7) [but not (8)]. However, all rate constants in ref. 24 are assumed to be temperature independent, most of them differ appreciably from their true values, and the calculation is carried out only for a single value of the parameters p_0 and γ.

The development of a volume discharge excited by a beam of fast electrons is studied at pressures $P \geq 1$ atm. The current characteristics are calculated allowing for the parameters of the discharge circuit and the energy input to the gas is analyzed. For $P \approx 2$ atm the specific energy introduced into a mixture of N_2 and CO_2 is $W_g \sim 1$ J/cm^3. These values are achieved at a current density in the electron beam $j_{beam} \sim 5$-10 A/cm^2 and a beam lifetime $\tau_{beam} \sim 4 \cdot 10^{-8}$ sec. It is shown that maintenance of the discharge by ionization processes permits a substantial reduction in the beam current while maintaining acceptable energy characteristics and sparkless operation. For example, $W_{gas} \sim 0.1$ J/cm^3 with $j_{beam} \sim 0.1$ A/cm^2 amd $\tau_{beam} \sim 2 \cdot 10^{-8}$ sec.

1. INTRODUCTION

The problem of constructing a gas laser with a high light energy per unit volume is closely linked to the problem of obtaining a volume discharge at pressures of the order of an atmosphere or higher. Such discharges have been obtained with the aid of a beam of fast electrons.[1] Lasers that use a volume discharge are called electrical ionization lasers.[2,3] In the design of such lasers it is important to find regimes in which large specific energies are dissipated in the gas, a matter to which a number of papers have been devoted.[3-6]

Until now, however, little attention has been given to the effect of the characteristics of the discharge circuit on the passage of the current. An understanding of this feature is necessary in order to optimize the transfer of energy to the gas. An analysis of the introduction of energy into the gas volume allowing for the parameters of the discharge circuit is given in the present paper.

THE FUNDAMENTAL EQUATIONS

The equations that describe the input of energy into the gas are

$$\frac{dn}{dt} = (\alpha - \eta)\mu E n - \beta n^2, \tag{1}$$

$$j = en\mu E, \tag{2}$$

$$j = -C\frac{d}{S}\frac{dE}{dt}, \tag{3}$$

$$W_g = \int_0^t E j dt, \tag{4}$$

where n is the electron density, E is the electric field in the gap, μ is the electron mobility, α, η, β are the coefficients of ionization, attachment, and combination, j is the discharge current density, W_{gas} is the specific (i.e., per unit volume) energy released in the gas, C is the capacitance of the condenser bank, d/S is the ratio of the height of the discharge column to its area, and e is the electron charge.

The equations are subject to the following limitations. Equations (1)-(2) are valid for $n > 10^{11}$ cm^{-3}, since it is only at high electron densities that a cathode drop is formed with length $l_{cath} \ll d$ and the conductivity of the gap is determined by electron drift.[4]

For most cases of practical importance the resistance of the plasma is ohmic in character so that the effect of inductance can be neglected in the Kirchhoff equation (3).

In the experiments, the discharge is initiated by a beam of short lifetime $\sim 10^{-8}$ sec, and the ionizing effect of the beam is allowed for in the initial conditions $n(0) = n_0$, $E(0) = E_0$, $j(0) = j_0$.

There are two regimes of interest in connection with the introduction of energy into the gas, namely: 1) no impact ionization in the gas, $(\alpha - \eta)\mu E \ll \beta n$; and 2) ionization operates and the incremental electron density due to electron multiplication in the gas is important.

DISCHARGE WITHOUT IMPACT IONIZATION IN THE GAS

This regime can be realized in practice at low values of the electric field E, for example, when $E \leq 0.3E_{st}$ (E_{st} is the static breakdown electric field).

However, remembering that the energy introduced into the gas increases with increasing field, there is clearly practical interest in the possibility of operating at high E up to the breakdown value E_{bd}. In order to realize a regime without ionization enhancement the electron density must be large.

Subject to the condition $(\alpha - \eta)$ vn = 0 Eqs. (1)-(4) can be solved analytically to give

$$E = E_0(1 + \beta n_0 t)^{-\frac{Se\mu}{Cd\beta}}, \tag{5}$$

$$j = en_0\mu E(1 + \beta n_0 t)^{-\left(1 + \frac{Se\mu}{Cd\beta}\right)}, \tag{6}$$

$$W_g = \frac{CE^2}{2}\frac{d}{S}\left[1 - (1 + \beta n_0 t)^{-\frac{2Se\mu}{Cd\beta}}\right]. \tag{7}$$

It is meaningful to consider the energy released only up to a certain critical time $t_{cr} = [(n_0/n_{cr}) - 1]/\beta n_0$, when the electron density has fallen to n_{cr}, the value of n at which the length of the cathode drop becomes comparable with the length of the discharge gap. The input of energy to the gas then effectively ceases.[4-6] Experimental estimates give $n_{cr} \sim 5 \cdot 10^{10}$-$10^{11}$ cm^{-3}.

The energy introduced into the laser medium is obtained by inserting the expression for t_{cr} into (7):

$$W_g = \frac{CE_0^2}{2}\frac{d}{S}\left[1 - \left(\frac{n_{cr}}{n_0}\right)^{A/\theta}\right], \tag{8}$$

where $A = (2se\mu)/d\beta$.

The energy input increases in proportion to E^2. If $E_0/P = \text{const}$, then, remembering that $\mu \sim 1/P$ and that $U_0 \sim P$, the function $W_g = W_g(P)$ varies somewhat more slowly than a quadratic. Let us consider in more detail the dependence of W_g on C. It is readily seen that when $n_{cr}/n_0 \ll 1$ and $A > C$, the energy input increases linearly with increasing C. This result means that the conductivity of the gap is sufficient to allow the capacitor to discharge completely in a time t_{cr}. Strictly speaking, the discharge time of the capacitor depends on the relationship between the geometrical dimensions of the discharge column and the value of the capacitance. A universal parameter characterizing the rate of voltage drop is given by (Cd)/S. When this parameter is increased (e.g., by increasing C) the linear growth of W_g is maintained so long as $(n_{cr}/n_0)^{A/C} \ll 1$, after which it slows down. The limiting energy as $C \to \infty$ can be written

$$W_{\text{lim}} = \frac{e\mu E_0^2}{\beta} \ln \frac{n_0}{n_{cr}}. \tag{9}$$

The input energy is thus effectively increased with increasing C up to a certain value slightly greater than the parameter A. The energy can be increased at larger values of C by increasing n_0, although this dependence is very weak since n_0 appears under the logarithm sign. This means that increasing the beam current density is not accompanied by a growth of the input energy. Experiments have shown that it is pointless to increase the current density of the beam beyond 5 A/cm², which corresponds to a density $n_0 \sim 5 \cdot 10^{13}$ cm^{-3} at P = 1 atm.

Curves of specific energy versus E/P are shown in Fig. 1 for various mixtures. Spark breakdown is absent in all cases. It is characteristic that by suitably choosing the values of C a sparkless discharge regime can be obtained for values of E/P close to breakdown. This fact acquires special significance in the case of a discharge in a mixture with a large CO_2 content. Data on the initiation of a discharge at high pressures but at low values of $E/P \leqslant 20$ V/cm · mm Hg are given in ref. 7, where it is shown that electrons are lost from the discharge mainly through attachment to CO_2 molecules. The high values of $E/P > 20$ V/cm · mm Hg in our case and the resulting insignificant losses due to attachment[8] mean that more effective use can be made of the electron beam. The drop of electron density to n_{cr} takes place over a longer time and the energy introduced into the volume increases. For example, with a 5 A/cm² electron beam the energy input to a CO_2-N_2 (1:3) mixture at P = 2 atm is $W_g \sim 1$ J/cm³. A laser operating in the described regime gave an output light energy of ~ 2.5 J. The total volume of the active region is ~ 40 cm³ with a length of 40 cm (see ref. 9).

DISCHARGE WITH ELECTRON MULTIPLICATION IN THE GAS

The main advantage of a discharge without ionization enhancement is its stability in all mixtures at pressures up to tens of atmospheres. The production of high specific energies, however, requires the use of electron beams of high current density, j_{beam}. The values of j_{beam} can be reduced if the initial electrons participate in ionization enhancement.

Let us consider the energy input process, allowing for impact ionization and assuming the field in the gap remains constant during the discharge, i.e., $E(t) = E_0$, or, what is the same thing, $C \to \infty$. The time variation of electron density can then be written

$$n = n_{st} \frac{e^{(\alpha-\eta)vt}}{e^{(\alpha-\eta)vt} - 1 + \frac{n_{st}}{n_0}}, \tag{10}$$

where n_{st} is the stationary electron density, determined from the condition $t \to \infty$,

$$n_{st} = \frac{\alpha - \eta}{\beta} \mu E. \tag{11}$$

The energy introduced per unit volume of the laser medium is given by

$$W_g = \frac{e\mu_- E^2}{\beta} \ln \frac{e^{(\alpha-\eta)vt} - 1 + \frac{n_{st}}{n_0}}{\frac{n_{st}}{n_0}}. \tag{12}$$

It follows from (12) that the energy introduced into the gas increases with time the more rapidly, the larger the quantity $(\alpha - \eta)v$.

An experimental study of this regime has been reported by Korolev and Khuzeev[10] for pure nitrogen and for a mixture of CO_2, N_2, and He. In all cases there is a definite time delay t_d between the time at which the beam is injected and the time at which spark breakdown occurs; a volume discharge exists during this time and energy input to the gas takes place. The time t_d varies from fractions to tens of microseconds and depends strongly on E/P and the gas pressure P. For optimum values of these parameters and an injection current density of 0.1 A/cm² the experimentally measured energy introduced into a

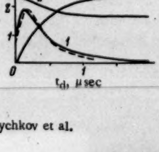

Fig. 2. Theoretical (solid curves) and experimental (dashed curve) variation with delay t_d of (1) current density, (2) voltage, and (3) specific energy input for: $n_0 = 5 \cdot 10^{12}$ cm^{-3}, S = 80 cm², d = 1 cm, C = 10^{-7} F.

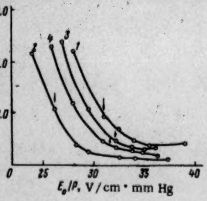

Fig. 3. Delay t_d under various conditions. 1) N_2, $C = 5.6 \cdot 10^{-9}$ F, d = 0.85 cm, S = 5 cm^2, P = 1 atm, $n_0 = 10^{13}$ cm^{-3}; 2) as for curve 1 but with $n_0 = 2 \cdot 10^{12}$ cm^{-3}; 3) $CO_2:N_2 \cdot 10^3$, $C = 5.6 \cdot 10^{-9}$ F, d = 0.85 cm, S = 5 cm^2, P = 1 atm, $n_0 = 6 \cdot 10^{12}$ cm^{-3}; 4) as for curve 3 but with $C = 3.9 \cdot 10^{-9}$ F.

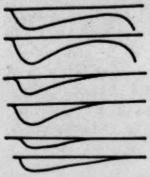

Fig. 4. Oscillograms of discharge current for conditions in the table.

CO_2-N_2 mixture is 0.1-0.2 J/cm^3 for a discharge lifetime 10^{-6}-10^{-5} sec.

Thus, by keeping the field in the gap constant and utilizing electron multiplication it is possible to reduce the current density of the electron beam substantially and to obtain a uniform discharge for times up to 10 μsec. A serious disadvantage of this regime, however, is the fact that the discharge goes over into the spark phase.

With a view to investigating conditions under which the spark phase can be avoided we have analyzed the case with a varying voltage across the capacitor. The initial intensity is high to assure electron multiplication; the field intensity falls as the discharge proceeds. Equations (1)-(4) are solved numerically for these conditions.

A solution for a mixture of the gases CO_2, N_2, and He would be of the greatest interest. However, since the values of the ionization and recombination coefficients are not known over a wide range of variation of E/P for such mixtures, the analysis is performed for nitrogen. The recombination coefficient $\beta = \beta(E/P)$ is taken from the experimental data of Korolev and Khuzeev[10] ($\beta \sim 10^{-6}$ cm^3/sec). The tabulated values are used for α. Typical curves for $n_0 = 5 \cdot 10^{12}$ cm^{-3} are shown in Fig. 2. For sufficiently small n_0, where $(\alpha - \eta)\, vn_0 > \beta n_0^2$, in accordance with (1) we have an increase of electron density and current (curve 1 of Fig. 2).

Recombination losses subsequently begin to balance ionization multiplication, and the drop in voltage is accompanied by a drop in current.

Experiments conducted in pure nitrogen and also in a $CO_2:N_2$ mixture show that a real fivefold enhancement of current can be obtained by impact ionization. The delay t_d before the onset of spark discharge falls sharply when the enhancement is large. Figure 3 shows experimental curves of t_d versus /P for a 1:3 mixture of $CO_2:N_2$.

Discharges in mixtures containing helium prove to be more interesting for practical use. Oscillograms of the discharge current are shown in Fig. 4. In a 1:3:10 mixture of $CO_2:N_2:He$ it is possible to achieve a current enhancement of 10 without spark breakdown.

Table 1 lists the experimental data on the delay t_d, the maximum electron density n_m obtained in the discharge, and the specific energy introduced into the discharge, for various values of E/P and capacitance C. In this experiment the initial electron density produced by the injected beam is $5 \cdot 10^{11}$-10^{12} cm^{-3}, i.e., the current density is 0.1 A/cm^2. It can be seen from the table that at this small value of beam current the energy input to the gas is ~ 0.1 J/cm^3.

The idea of preventing spark discharge by rapidly reducing the voltage across the gap can be realized by means of special circuits. The results of experiments are shown in Figs. 4 and 5. Here, a voltage $U_0 < U_{st}$ is applied to the gap. At beam injection a pulse ΔU of length $\Delta\tau$ is applied so that the total voltage across the gap is $U_0 + \Delta U$. Ionization multiplication occurs for a time $\Delta\tau$. It can be seen that the enhancement k of the initial electron density can be varied by varying ΔU and $\Delta\tau$, and regimes occur ($U_0 \le 0.3U_{st}$) in which spark breakdown does not occur.

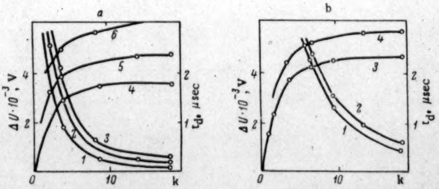

Fig. 5. Curves of ΔU and t_d versus enhancement k for various conditions. a: $n_0 = 5 \cdot 10^{11}$ cm^{-3}, $U_0 = 5.53 \cdot 10^3$ V, d = 0.3 cm, P = 1 atm, $CO_2:N_2$ = 1:3; $\Delta\tau$, nsec: 1) 80; 2) 40; 3) 20; 4) 80; 5) 40; 6) 20. b: As for a, but with $U_0 = 4.5 \cdot 10^3$ V; $\Delta\tau$, nsec: 1) 80; 2) 40; 3) 80; 4) 40.

TABLE 1

C, F	E/P, V/cm · mm Hg	t_d, μsec	$\sim n_{max}$, cm^{-3}	W, J/cm^3	W_{store}, J/cm^3
$5.9 \cdot 10^{-9}$	18.4	1.1	$7.8 \cdot 10^{12}$	0.10	0.173
	19.7	1.0	$1.3 \cdot 10^{13}$	0.13	0.20
$3.9 \cdot 10^{-9}$	18.4	2.6	$7 \cdot 10^{12}$	0.08	0.115
	19.7	$\geqslant 3$	$1.1 \cdot 10^{13}$	0.10	0.132
$2.6 \cdot 10^{-9}$	18.4	> 3	$5.1 \cdot 10^{12}$	0.06	0.0765
	19.7	> 3	$8.3 \cdot 10^{12}$	0.07	0.088

In effect, here a high-power electron injector is replaced by a low-power injector combined with a special circuit for powering the gap. The pulse ΔU can be fed to the gap several times at ~ 1 μsec intervals, when the electron density can fall on account of recombination. Experiments with two pulses have demonstrated the possibility, in principle, of increasing the energy input to the gas by this method.

Pulsed neodymium-glass laser with periodic Q switching

T. A. Kuzovkova, E. V. Nilov, V. A. Rusov, I. N. Semenov, and A. A. Chertkov

(Submitted January 11, 1973; resubmitted July 5, 1973)
Zh. Tekh. Fiz., 44, 797-802 (April 1974)

A pulsed neodymium-glass laser with periodic Q switching is described; high-frequency giant pulses are generated by this laser. The operation is analyzed and approximate expressions are derived to relate the laser parameters to the apparatus parameters. Experimental investigations are described.

1. INTRODUCTION

In many physics problems it is useful to have a source of light which gives a series of short, high-frequency, high-power pulses. This kind of operation can be obtained by means of a pulsed solid-state laser that uses multiple Q switching of the laser resonator. Well-known examples of such lasers are the ruby laser,[1-4] the neodymium-glass laser,[5,6] the neodymium-doped YAG laser,[7-9] and also neodymium lasers in which infrared radiation is converted into the second harmonic.[5-9] The resonators of these lasers are periodically Q-switched by devices similar to those used for Q switching under single-pulse conditions; optomechanical,[1,5,7] electrooptical,[2-4,8] and optoacoustic[6,9] devices are used for this purpose.

Pulsed lasers operating with a periodically Q-switched resonator have so far only been used in practice for high-speed filming,[2,3,5] but they can also be used for plasma diagnostics,[10] for microprocessing materials[9] and in other cases where giant light pulses and high repetition frequencies are required over comparatively short time intervals.

It should be noted that since no other methods of obtaining high repetition frequencies of giant pulses exist presently (insufficient mean source powers of the pump and the power limitations of the active material), the problem of designing and developing periodically Q-switched pulsed lasers is an urgent one.

The present paper gives an analysis of certain processes which occur in lasers in which neodymium glass is used as the active medium.

2. ANALYSIS OF PERIODIC LASING OF A NEODYMIUM LASER WITH A PULSED PUMP

When the resonator is subjected to periodic Q switching, while the quasistationary pumping pulse is acting, a synchronous process of pulse generation occurs which is accompanied by an alternate rise and fall in the population inversion. At low Q-switching frequencies ($f < 1/\tau$, where τ is the lifetime in the metastable level) the amplitude of the pulses generated remains constant. This result is due to the constancy of the population inversion until each pulse starts, which is ensured by stabilizing the pumping power level, and is achieved in practice by using as the pumping tube supply the discharge of a long artificial line matched to the internal impedance of the tube during the period in which it flashes. Under these conditions the parameters of the pulses generated are similar to the parameters of the pulses obtained under single-pulse conditions.

As the Q-switching frequency is increased the lasing frequency increases; beginning at a certain frequency $f \approx 1/\tau$, the amplitude decreases. At a certain frequency ($f = f_t$), which depends on the laser parameters, the value of the initial population inversion becomes equal to the threshold value. A further increase in the Q-switching frequency will cause gaps to occur in the lasing.

The analysis of the processes which occur when the laser is periodically Q-switched applies for the single-mode approximation. It enables us to explain the physical behavior of periodic high-frequency lasing, and to make positive estimates of the expected power characteristics of the laser from the known parameters of the apparatus.[9,11]

The process of the periodic generation of pulses which have parameters close to the parameters of giant pulses, is described by the well-known rate equations for the relative density of the population inversion and the density of the radiation emitted.[11]

Values of the relative density of the population inversion at the beginning of each pulse, y_0, and at the end $y_{\min}$, for a rectangular pump pulse, can be obtained from the following set of equations:

$$y_0 - y_{\min} = \frac{k_1}{\varkappa} \ln \frac{y_0}{y_{\min}}, \tag{1}$$

$$y_0 = \frac{G}{D}\left(1 - e^{-D/2f}\right) + y_{\min} e^{-D/2f}, \tag{2}$$

where f is the repetition frequency of the pulses, k_1 is the overall loss factor, $\varkappa$ is the maximum gain, and G and D are quantities which are proportional to the pump power, being given by the following expressions:

$$D = 2(\eta B U_H + P_{32} + P_{31}), \tag{3}$$

$$G = 2\eta B U_H. \tag{4}$$

In these expressions $\eta = P_{43}/(P_{43} - P_{41})$, U_H is the density of the pump radiation, P_{ij} is the probability of the corresponding interlevel transition, and B is the Einstein coefficient.

It is difficult to obtain accurate values of y_0 and $y_{\min}$, in Eqs. (1) and (2), because of the complexity of the calculations. For practical purposes, however, it is sufficient to use approximate values of these quantities, which can be obtained as follows.

Consider the region of lasing frequencies in the range 10-100 kHz. Below 10 kHz the processes by which the pulses develop are identical with the processes under single-pulse conditions. The number of pulses in this case is small, due to the power limitations of the flash tube. Above 100-150 kHz the development of the pulses is similar to the development of pulses under regular free-running conditions.

At frequencies $f \geq 10$ kHz the quantity $D/(2f)$ in Eq. (2) is very much smaller than unity. Expanding the function $\exp(-D/2f)$ in a Taylor series, and using the first three terms of this expansion, we can transform expression (2) as follows:

$$y_0=\frac{G}{2f}\left(1-\frac{D}{4f}\right)+y_{\min}\left(1-\frac{D}{2f}+\frac{D^2}{8f^2}\right). \qquad (5)$$

The quantity $y_{\min}$ is found from Eq. (1) by substituting Eq. (5):

$$\delta \ln \frac{a+by_{\min}}{y_{\min}}=a-y_{\min}C, \qquad (6)$$

where

$$\delta=\frac{k_1}{\varkappa};\ a=\frac{G}{2f}\left(1-\frac{D}{4f}\right);$$

$$b=1-\frac{D}{2f}+\frac{D^2}{8f^2};\ C=\frac{D}{2f}-\frac{D^2}{8f^2}.$$

Since $a \gg y_{\min}C$, we can write expressions for y_0 and $y_{\min}$ which depend on the frequency,

$$y_{\min}=\frac{a}{e^{a/\delta}-b}, \qquad (7)$$

$$y_0=a+\frac{ab}{e^{a/\delta}-b}. \qquad (8)$$

Using these equations, expressions can be derived to relate the energy, the power, the pulse length and the laser efficiency with the parameters of the apparatus. These are

$$W_{1a}=\frac{nh\nu lS}{2}\frac{k_r}{k_1}\left(a-\frac{aC}{e^{a/\delta}-b}\right); \qquad (9)$$

$$\overline{P_{\max}}=\frac{nh\nu\mu vk_r lS}{2}\left(a+\frac{a}{e^{a/\delta}-b}-\delta-\delta\ln\frac{a+\frac{ab}{e^{a/\delta}-b}}{\delta}\right); \qquad (10)$$

$$\Delta t=\frac{a-\frac{aC}{e^{a/\delta}-b}}{\mu vk_1\left(a+\frac{aB}{e^{a/\delta}-b}-\delta-\delta\ln\frac{a+\frac{ab}{e^{a/\delta}-b}}{\delta}\right)}; \qquad (11)$$

$$\eta=\frac{nh\nu lSNk_r}{2k_1E_p}\left(a-\frac{aC}{e^{a/\delta}-b}\right), \qquad (12)$$

where n is the density of the active particles, h is Planck's constant, ν is the frequency of the emission, v is the velocity of light in the active medium, μ is the filling factor of the resonator, l is the length of the active element, S is the transverse cross-section, k_r is the transmittance of the exit mirror, N is the number of pulses in a series, and E_p is the pump power.

The error involved in using these equations is below 25%.

Using Eq. (9) we can find the transmittance of the exit mirror for maximum output energy:

$$k_r=\sqrt{\frac{G\varkappa\rho}{D}\left(1-\frac{D}{4f}\right)}-\rho, \qquad (13)$$

where ρ is the loss the resonator.

It should be noted that for the region of high frequencies in the band used (f = 40-100 kHz), Eqs. (9)-(13) can be simplified considerably without increasing the error, if we neglect the quantities $D/2f$ on account of their smallness. We obtain

$$W_{1a}=\frac{nh\nu lS}{2}\frac{k_r}{k_1}\frac{G}{2f}; \qquad (14)$$

$$\overline{P_{\max}}=\frac{nh\nu\mu vk_r lS}{2}\left[\frac{G}{2f}-\delta\ln\left(1+\frac{G}{2f\delta}\right)\right]; \qquad (15)$$

$$\Delta t=\frac{\frac{G}{2f}}{\mu vk_1\left[\frac{G}{2f}-\delta\ln\left(1+\frac{G}{2f\delta}\right)\right]}; \qquad (16)$$

$$\eta=\frac{nh\nu lSN}{2}\frac{k_r}{k_1E_p}\frac{G}{2f}. \qquad (17)$$

3. EXPERIMENTAL INVESTIGATIONS OF A PERIODICALLY Q-SWITCHED LASER

The purpose of the experimental investigations is to establish the relationship between the main power parameters of the laser and the Q-switching frequency.

The arrangement consists of the usual solid-state laser system with a controlled Q. The active element consists of GLS-1 neodymium glass ($n = 2 \cdot 10^{20}$ cm^{-3}) of diameter 15 mm and with a length of the active part of 240 mm. The ends of the element are tapered at the Brewster angle.

An IFP-8000 flash tube is used for pumping. A long artificial line consisting of capacitors and inductors matched to the internal impedance of the tube is discharged through the tube.

The limiting value of the discharge energy is 5 kJ. The pumping light pulse length is 1.5 μsec.

The resonator is Q switched using a quarter-wave Pockels cell, which uses the transverse electrooptical effect in a KDP crystal. The cell is controlled by means of a high-voltage rectangular pulse generator similar to that described in ref. 12.

A total-internal-reflection prism and a stack of glass plates with reflectance 30% are used as the resonator mirror.

The experimental investigations are made at a pumping power of 3 kJ, which corresponds to a threefold excess over the lasing threshold for the case when the Q switch introduced into the resonator is completely trans-

Fig. 3. Oscillogram of a series of laser pulses with repetition frequency 25 kHz.

mitting, and is in fact one of the sources of passive loss.

It is established that the emission is a regular sequence of giant pulses, the envelope of which quite accurately repeats the time behavior of the light pump pulse. When the Q-switching frequency is increased from a few kilohertz to tens or even hundreds of kilohertz, the power parameters change from values which are specific for single-pulse operation to values close to free-running conditions. In the latter case, the emission is regular free-running emission. The frequency dependences of certain power parameters are shown in Fig. 1.

The experimental results, agree with the theoretical curves calculated using Eq. (9) and (12).

The values of a number of the parameters in these equations are measured or calculated. Thus, the total losses in the resonator are found using the method described in ref. 11, and are as follows: $\rho \approx 0.07\ \text{cm}^{-1}$, maximum gain $\varkappa \approx 6.7\ \text{cm}^{-1}$, cross section of stimulated absorption measured using the method described in ref. 13, $\sigma_{32} = 3.35 \cdot 10^{-20}\ \text{cm}^2$; the threshold pump power is $\cdot \eta B U_{H_k} \simeq 20\ \text{sec}^{-1}$, and the energy characteristics are measured for a threefold excess of the pump power above the threshold value.

The dependence of the efficiency on the frequency is worth noting. At frequencies higher than 20 kHz the value remains unchanged and approximately 2.5 times higher than the efficiency under single-pulse conditions. The efficiency obtained in the experiments for a 5.5-fold excess above the threshold is 0.6%. This is due to the high losses introduced into the resonator by the KDP crystal. Thus, without the crystals, the power under free-running conditions is 100 J for a pump power of 5 kJ. When the crystals are introduced into the resonator, the power is reduced to 30 J.

The stability of the amplitude of the emitted pulses is investigated from oscillograms taken at different lasing frequencies.

It is established that as the Q-switching frequency is increased the level of fluctuations increases, and starting at a frequency of the order of 100 kHz, gaps in the emission occur. This is shown in Fig. 2, in which the frequency dependence of the change in the fluctuation intensity and the change in the number of pulse gaps is shown in relative units. The curves are constructed by processing the results of a large number of oscillograms.

As an illustration, Fig. 3 shows one of the oscillograms corresponding to a Q-switching frequency of 25 kHz.

Characteristics of the electrical ionization CO_2 laser

Yu. I. Bychkov, Yu. A. Kurbatov, and V. V. Savin

Institute of Atmospheric Optics, Siberian Branch,
Academy of Sciences of the USSR, Tomsk

(Submitted May 21, 1973)
Zh. Tekh. Fiz., 44, 803-807 (April 1974)

Theoretical estimates of the input energy to the gas are derived and oscilloscope traces of the current and voltage of a pulsed electrical ionization CO_2:N_2 laser and the output pulses are analyzed. The experimental and theoretical dependence of the spectral composition and efficiency on the pumping energy are obtained. The effect of helium efficiency is indicated. Threshold and cutoff values of the pump power are considered for different cavities.

The recent development of electrical ionization CO_2 lasers[1,2] has stimulated interest in the processes involving delivery of energy to the gaseous medium at high pressure as well as the energy and spectral characteristics of the laser emission. We have investigated these problems and have also studied the dependence of the threshold and cutoff pumping energy of an electrical ionization CO_2 laser on the parameters of the cavity and the gaseous mixture.

To analyze the energy and spectral characteristics of the electrical ionization CO_2 gas laser we employ a system of equations which describes the energy input to the gaseous medium, the energy distribution among the vibrational levels of CO_2 and N_2, and lasing at transitions of the P branch of the 00^01-10^00 and 00^01-02^00 bands. The variation in electron density n and electric field E in the discharge gap for a storage capacity C is described by the equations

$$\left.\begin{aligned}\frac{dn}{dt}&=(\alpha-\eta)\mu nE-\beta n^2,\\ \frac{dE}{dt}&=-\frac{Se\mu En}{Cd},\end{aligned}\right\}\tag{1}$$

where α, β, and η are the (field-dependent) coefficients of impact ionization, recombination, and attachment, μ is the electron mobility, e is the electron charge, S is the cathode area, and d is the electrode spacing.

The initial conditions for (1) are

$$n|_{t=0}=n_0,\quad E|_{t=0}=\frac{U_0}{d},$$

where n_0 is the electron density in the gap after injection of a short-duration high-energy electron beam and U_0 is the charging voltage of the pump circuit.

Thus, the specific pumping power (per unit volume) is $P_g = Ej_-$, where $j_- = enE\mu$ is the current density.

The quantity N is the total number of particles per unit volume and N_μ is the population of the μ-th energy level; we introduce the variables $n_\mu = N_\mu/N^\mu$. Let $dP_0(\nu)/d\nu$ be the spectral density of the laser output power.

We set

$$\varphi(\nu)=\frac{[dP_0(\nu)/d\nu]}{S_a NCh\nu},$$

where S_a is the active cross section of the laser and $Ch\nu$ is the energy of a photon at frequency ν cm^{-1}. Then

$$\frac{d\varphi}{dt}=\frac{S_a}{4\pi L^2}\sum_{\mu\mu'}A_{\mu\mu'}n_\mu\frac{\Delta\nu_{\mu'\mu}}{(\Delta\nu_{\mu'\mu})^2+(\nu-\nu_{\mu'\mu})^2}+[\varkappa(\nu)-\alpha(\nu)]\varphi(\nu).\tag{2}$$

Here, L is the cavity length $A_{\mu'\mu}$, $\nu_{\mu'\mu}$, and $\Delta\nu_{\mu'\mu}$ are the Einstein coefficient, the frequency, and the Lorentz half-width of the spectral line $\mu'-\mu$,

$$\varkappa(\nu)=\frac{lN}{8\pi L\nu^2}\frac{\Delta\nu_{\mu'\mu}\left(\frac{g_\mu n_{\mu'}-g_{\mu'}n_\mu}{g_\mu}\right)}{(\Delta\nu_{\mu'\mu})^2+(\nu-\nu_{\mu'\mu})^2},$$

$$\alpha(\nu)=-\frac{1}{2L}\ln[r_1(\nu)r_2(\nu)],$$

l is the length of the active medium, g_μ is the multiplicity of the degeneracy of the μ-th level, and $r_1(\nu)_1r_2(\nu)$ are the reflection coefficients of the cavity mirrors, which, in the general case, depend on the frequency.

The population of the vibrational and, consequently, the vibrational–rotational levels can be determined by using the method proposed in refs. 3 and 4, which involves the determination of the populations of the vibrational levels in the i-th mode of the Boltzmann distribution, characterized by a vibrational temperature T_i. If the vibrational temperature is known, the population of any CO_2 or N_2 vibrational level can be determined. The equations for $x_i = \exp\{-E_i/kT_i\}$, where i = 1, ..., 4, E_i is the photon energy of the i-th mode (i = 1, 2, 3 refs to CO_2, i = 4 to N_2), and k is the Boltzmann constant, are similar to those given in ref. 3 and contain extra terms to describe the variation in x_i due to the emission processes. The system also includes an equation to describe the variation in the translational temperature of the gaseous medium. The rate constants for relaxation and exchange of vibrational energy are taken from ref. 4.

A computer solution of the above system of equations, which is not given in full because of its complexity, gives the time dependences of the discharge characteristics $j_-(t)$ and E(t), and the laser output:

$$P_0(t)=\int\limits_\nu\left(\frac{dP_0(\nu)}{d\nu}\right)d\nu,\quad W_0(t)=\int\limits_0^t P_0(t)\,dt,$$

as well as the spectral composition of the output energy:

$$\frac{dW_0}{d\nu}=\int\limits_\nu\left[\frac{dP_0(\nu)}{d\nu}\right]dt.$$

The calculations are performed for a laser with the parameters l = 40 cm, L = 100 cm, $r_1 = 0.9$, $r_2 = 0.4$, $S_a = 1$ cm^2, S = 80 cm^2, and d = 1 cm; these correspond to the parameters of the experimental device described in ref. 2.

Figure 1 gives a solution of the system of equations for a laser with $CO_2:N_2:He = 1:3:0$ at a pressure of 1 atm, excited by a $C = 10^{-7}$ F discharge with $U_0 = 15$ kV for an initial electron density $n_0 = 5 \cdot 10^{12}$ cm^{-3}. The dependence of $(\alpha - \eta)$ and β on E is obtained by interpolation of the experimental data of ref. 2 for $CO_2:N_2$ mixtures. The density of the input energy is 0.1 J $\cdot$ cm^{-3}, and the output energy is $W_0 \sim 5.6 \cdot 10^{-3}$ J $\cdot$ cm^{-3} with a peak power of $2.7 \cdot 10^5$ W. It is assumed in the calculations that the cavity does not have mode-selecting properties and lasing occurs at transitions in the 00^01-10^00 band. The spectral density of the output energy for this case is shown in Fig. 2a. Lasing occurs in practice, at one rotational line of the 00^01-10^00 band, and the ratio of the energy input into the gas to the threshold pumping energy is $W_g/W_{th} \sim 2.5$. At high threshold pump energy lasing occurs on several lines; because of the increase in gas temperature, the maximum $dW_0/d\nu$ shifts toward higher j. In Fig. 2b the emission spectrum is calculated for $U_0 = 25$ kV, giving $W_g = 0.3$ J $\cdot$ cm^{-3} and $W_g/W_{th} \sim 7.5$. Thus, the calculations indicate that even in a non-mode-selecting cavity the frequency of laser emission can be regulated by varying just the pump energy. The experimental values for laser efficiency $\tilde{\eta} = W_0/W_g$ are given in Fig. 3 for different compositions of the gas mixture at a pressure of 1 atm. Variation of W_g is accomplished by varying the charging voltage U_0 for a fixed electron beam, or by varying the beam density for a fixed U_0, i.e., by varying n_0. The calculation performed for a $CO_2:N_2 = 1:3$ mixture indicates that the decrease in efficiency for high W_g values is due to the more intense heating of the gas due to a transfer of a portion of the discharge energy through symmetric and bending vibrations of CO_2 to translational degrees of freedom. The presence of He in the mixture shifts the maximum $\tilde{\eta}(W_g)$ toward smaller W_g. This is due to the increase in the gain, and, consequently, to the reduction in the threshold pump energy as a result of the decrease, by comparison with CO_2, in the broadening of the spectral lines of the laser transitions. For large W_g a gaseous mixture containing He is heated more strongly due to the smaller specific heat of He; consequently the dropoff in efficiency occurs for smaller W_g values.

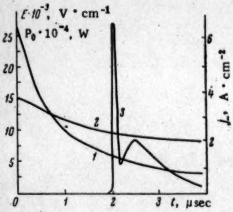

Fig. 1. Time characteristics of the discharge and laser output. A mixture $CO_2:N_2 = 1.3$ for P = 1 atm: 1) discharge current density j_-; 2) field voltage E; 3) laser output power P_0.

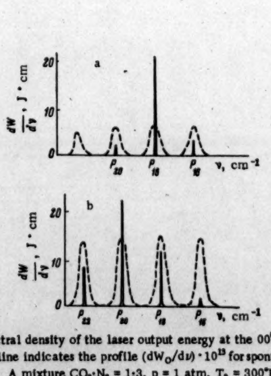

Fig. 2. Spectral density of the laser output energy at the 00^01-10^00 band. The dashed line indicates the profile $(dW_0/d\nu) \cdot 10^{13}$ for spontaneous emission $r_1r_2 = 0$. A mixture $CO_2:N_2 = 1:3$, p = 1 atm, $T_0 = 300$°K. a) $U_0 = 15$ kV, $W_g = 0.1$ J $\cdot$ cm^{-3}; b) $U_0 = 25$ kV, $W_g = 0.3$ J $\cdot$ cm^{-3}.

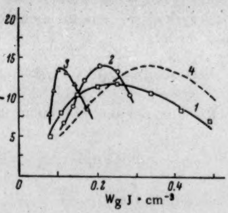

Fig. 3. Laser efficiency as a function of energy input to the gas. The experimental data are for a $CO_2:N_2:He$ mixture. 1) 1 : 3 : 0; 2) 1 : 3 : 3; 3) 1 : 3 : 10; 4) calculation for a 1 : 3 : 0 mixture.

The experimental[2] and calculated data indicate that with increasing W_g, W_0 also passes through a maximum more appropriate to higher W_g than to a maximum $\tilde{\eta}(W_g)$. Therefore, the operating modes of a CO_2 laser with maximum efficiency and with maximum output energy correspond to different ranges of W_g values.

We also investigate the dependence of the threshold pumping energy of an electrical ionization CO_2 laser on the parameters of the cavity and the composition of the gas mixture. It is noted that the gas temperature increases with increasing W_g, and this increases the threshold pump energy. If one continues to increase W_g after the threshold has been reached a situation can arise in which the gas will be heated to a temperature for which the population inversion threshold cannot be attained due to the large population of the lower-lying laser level, the population being determined by the Boltzmann distribution with a translational gas temperature T. This is indirectly indicated by the dropoff in efficiency for high W_g. The equations giving the threshold and cutoff values of the pump energy for the CO_2 laser are

$$\left.\begin{aligned} W_0 &= P1.25\Phi_1 \frac{1}{2}\left\{\frac{1-x_1-\delta(a+1)}{\delta}\right. \\ &\quad \times \left.\left[1 \pm \sqrt{1-4\frac{(a\delta - x_1)\delta}{1-x_1-\delta(a+1)}}\right]\right\}, \\ T &= T_0 + \frac{\Phi_2 W_0}{C^*}. \end{aligned}\right\} \qquad (5)$$

Here, Φ_1 is the portion of the discharge energy exciting the 00^0v levels of CO_2 and N_2, Φ_2 is the portion of the discharge energy exciting the symmetric and bending vibrations of

CO_2, $\bar{x}_i = \exp\{-E_i/kT\}$ ($i = 1$ is the symmetric and $i = 2$ is the bending mode),

$$a = 1 + x_1(1 - x_1)^{-1} + 2x_2(1 - x_2)^{-1},$$

C^* is the specific heat per unit volume of the gas mixture,

$$\delta = 1.25 \cdot 10^{-2}\psi \frac{Z}{fC_3},$$

$$f = 1.12(2j + 1)\exp\left\{-\frac{0.56j(j + 1)}{T}\right\}T^{-1},$$

f is the population distribution function of the vibrational level with respect to the sublevel j, $\psi = C_3 + 0.78C_4 + 0.5C_5$ is a function determining the broadening of the spectral line of the laser transition in the gas mixture, C_3 is the concentration of CO_2, C_4 of N_2, C_5 of He, P is the pressure of the gas mixture (atm), and $Z = -[\ln(r_1r_2)]/l$.

The square root in Eq. (5) gives two values of W_0. It is clear from physical considerations that taking the square root in (5) with the minus sign yields the threshold pump energy – with the plus sign it yields the cutoff value. The system of equations (5) is solved on a computer by successive approximations. Figure 4 gives the threshold and cutoff values of the pump energy as a function of the cavity parameter Z for a $CO_2 : N_2 : He = 1 : 3 : 0$ mixture at a pressure of 1 atm and with different initial temperatures T_0 of the gas mixture. The range of allowable values for W_0, limited below by the threshold and above by the cutoff, narrows with an increasing Z. At a certain value Z_n we have $W_{th} = W_{cut}$, which means that for $Z > Z_n$ lasing can be obtained for a lower initial temperature T_0.

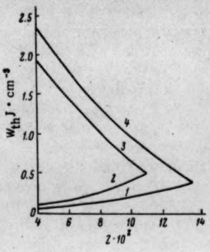

Fig. 4. Threshold (1, 2) and cutoff (3, 4) values of the pump energy vs the cavity parameter Z. T_0, °K: 1, 4) 300; 2, 3) 400.

A satisfactory agreement between the calculated and experimental values of W_{th} is observed for different mixtures.[2] The cutoff values of the pump energy are not attained in the experimental apparatus because of the limitations of the pump source. The estimates given above indicate the upper and lower limits of the pump energy for specific CO_2 laser cavities.

Linear accelerator for beam injection into a slowly rising magnetic field

D. G. Borisov, A. I. Gryzlov, V. M. Levin, and A. V. Ryabtsov

(Submitted December 26, 1972)
Zh. Tekh. Fiz., 44, 808-811 (April 1974)

A linear electron accelerator is described which is intended for the injection of a relativistic beam into the slowly rising magnetic field of a synchrotron. Monochromatization of the particle beam is accomplished in each bunch along with modulation of the mean energy in each bunch with the energy increasing from bunch to bunch. A high-frequency field is used for modulation of particle energy. The disparity between the curve for energy modulation and the curve for the rise in the magnetic field is insignificant for the slowly rising steering magnetic field in a synchrotron. This situation offers an opportunity to excite the modulating and equalizing sections from a single source at a frequency different from the excitation frequency of the main accelerator sections.

It is well known that the best results for particle injection into a circular accelerator can be obtained when the energy of the injected particles varies synchronously with the rising magnetic field of the circular accelerator.[1] This problem has been solved for nonrelativistic injection energies.[2] This problem has, in general, also been solved for proton accelerators.[3-5]

However, this problem has not yet been solved in a practical way for electrons with energies of the order of 10 MeV and above. There is a well-known proposal[6] to use for modulation of particle energy a section of a linear induction accelerator in which the amplitude of the eddy field rises continuously over the duration of a pulse in accordance with a specified relation. This solution is ideal from the standpoint of a match between the energy modulation curve and the magnetic field variation. As was shown,[6] its application in this case (despite the low efficiency of a linear induction accelerator at low currents) is more suitable than the use of a linear waveguide accelerator of excessive length.

However, the situation shifts in favor of a traveling-wave accelerator when the rise in the steering magnetic field in a circular accelerator is small over the injection time. Assuming the rise in the field is linear in such a case, one can use the linear portion of the sinusoidal accelerating field in the traveling-wave accelerator for modulation of particle energy.

Linear electron accelerators at the exit of which particle beams can be produced with energies rising during the pulse are well-known.[7] One of their characteristic features is the inequality of the electromagnetic field frequencies in the main accelerating sections and the sections for particle energy modulation.[8]

The advantage of such an accelerator can be realized even more completely during injection if the instantaneous width of the beam energy spectrum is made smaller. The most convenient solution for the problem of beam spectrum compression is the use of special monochromatizing devices, which ensure in their operation an unchanged beam intensity relative to the original values.

There are several monochromators that are used in electron accelerators at the present time.[9-11] A characteristic feature is excitation of the sections for equalizing particle energy, or of a resonator, at the frequency of the main accelerating sections.

However, the latter situation is unsuitable for an accelerator with modulation of beam energy. We first show that it is necessary to carry out modulation of mean bunch energy before bunch monochromatization. Equalization of particle energies in the bunches in both proton and electron accelerators is carried out after considerable elongation of the bunches. On the other hand, it is clear that with modulation of the mean energy of a bunch the quality of the monochromatization will be so much the worse the more a bunch is elongated. Also in favor of modulation before monochromatization is the fact that the energy spread introduced by modulation for bunches narrow in phase is not outside the limits acceptable for a monochromator, i.e., it can be compensated for in the monochromator.

Returning to the question of the choice of excitation frequency for the equalizing section, it is timely to emphasize that bunches with different mean energies either pass through a drift space in different times (for nonrelativistic energies) or pass through the magnetic channel of a debuncher along trajectories of different lengths at identical velocities. This means that in an accelerator with modulation, the equalizing section must be excited at a frequency different from the main section frequency and matching the frequency of bunch arrival, which is in contrast to the generally accepted method for monochromatization.

Otherwise, additional modulation of the mean bunch energy is initiated in the equalizing section with monochromatization being different for each bunch and completely absent for some bunches.

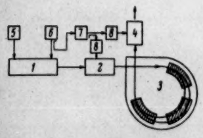

Fig. 1. Block diagram of accelerator. 1) Main section of accelerator; 2) modulation section; 3) magnetic debuncher; 4) equalizing section; 5, 6) klystron amplifiers; 7) phase modulator; 8) phase shifter.

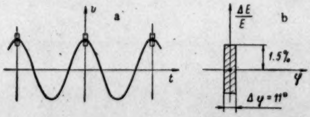

Fig. 2. Bunch position relative to accelerating wave (a), and energy and phase distribution of bunch particles (b).

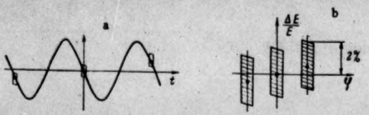

Fig. 3. Bunch position relative to modulating wave (a), energy distribution of bunches in a pulse, and phase and energy distribution of bunch particles (b).

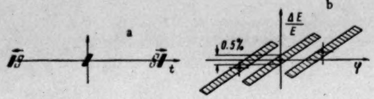

Fig. 4. Energy and phase distribution of particles after the magnetic debuncher.

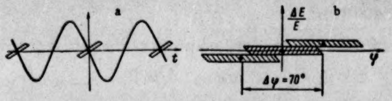

Fig. 5. Bunch position relative to equalizing wave (a), and phase and energy distribution of particles after equalizing section (b).

A linear electron accelerator intended to achieve optimal multiturn injection of a beam into a slowly rising steering magnetic field in a 1.2 MeV synchrotron can be pictured in the following form (Fig. 1). Element 1 is a linear traveling-wave electron accelerator with an energy of 40-50 MeV, a relative spectral width at exit $\Delta E/E = \pm 1.5\%$, in which $f_0 = 1818$ MHz in the sections. Figure 2a shows schematically the position of electron bunches relative to the accelerating wave at the accelerator exit. Figure 2b shows the idealized distribution of bunch particles over energy and phase. Element 2 is a section for modulation of mean bunch energy. The rise in mean energy during a pulse is + 1% and the length of the section is 40 cm. The electromagnetic frequency in the section, $f_1 = f_0 - 11$ kHz, is chosen to match the frequency in the equalizing section. Because of this choice, a rise in energy from bunch to bunch is provided in an accelerating field decreasing with time, as shown in Fig. 3a. The energy distribution of the bunches in a pulse at the exit section and the phase and energy distributions of bunch particles are shown in Fig. 3b for the first, middle, and last bunches in a pulse. Element 3 is a magnetic debuncher occupying an area of 1 m^2. Three magnets with uniform field and tapered pole tips provide a beam deflection of 270°, a sevenfold longitudinal dispersion of the bunches, establish a correlation between particle phase and energy, and provide vertical stability of the beam. Energy and phase distributions of the particle beyond the magnetic debuncher are shown in Fig. 4. Element 4 is the section which equalizes the energy of particles in a bunch. At the exit the relative spectral width $\Delta E/E = 0.25\%$, and the length of the section is 60 cm. The electromagnetic frequency in the section, $f_1 = f_0 - 11$ kHz, is determined by the need for delaying higher-energy bunches relative to bunches with lower energies during passage through the debuncher of a pulse of particles with energies which increase with time. The energy and phase distribution of the particles in the first, middle, and last bunches of a pulse are shown in Fig. 5b. Figure 5a shows the position of electron bunches relative to the traveling wave in the equalizing section. Equalization of particle energy in the bunches is provided by location of the bunches in a field decreasing with time. Elements 5 and 6 are klystron amplifiers, 7 is a phase modulator, and 8 is a phase shifter.

Use of an accelerator with beam energy modulation and bunch monochromatization as an injector for a synchrotron makes it possible to double the injection time in comparison with a monochromatic beam, to optimize the conditions for particle capture in the circular chamber of the synchrotron, to reduce the Coulomb interaction because of longitudinal dispersion of the bunches, and, in the final analysis, to increase the particle current emerging from the synchrotron.

Use of the distribution function to describe free molecular beams

I. G. Neudachin, B. T. Porodnov, and P. E. Suetin

S. M. Kirov Ural Polytechnic Institute, Sverdlovsk

(Submitted May 15, 1973)
Zh. Tekh. Fiz., 44, 812-817 (April 1974)

We have determined the characteristics of molecular beams shaped by cylindrical and infinitely wide channels under free molecular conditions. The density, flux, and temperature have been calculated by using the molecular velocity distribution function. It has been established that Clausing's angular distribution is obtained at large distances from the source. The effect of the nonlinearity of the distribution of molecular collisions with the channel walls on the beam characteristics has been estimated.

1. INTRODUCTION

The molecular beam method has been widely used in studies of the interaction of gas molecules with solid surfaces in masers[1-3] and therefore a detailed study of beam characteristics is of interest. Investigations of this kind have been performed under free molecular conditions using the cosine law, as in refs. 4 and 5, to calculate fluxes. Gadamer[6] attempted to calculate the molecular density close to the exit cross section of a cylindrical channel by using the distribution function.

We propose a calculational method using the distribution function which enables one to find any macroscopic characteristics of gas flow in the collisionless regime both inside and outside the channel. The shaping of beams by circular and little-studied slotted channels of finite length is discussed.

2. STATEMENT OF THE PROBLEMS

We consider the free molecular flow of a gas from a chamber with a gas density n_1 and temperature T_1 through a channel into a chamber with gas density n_2 and temperature T_2. Since the molecules do not collide it is sufficient to consider the case $n_2 = 0$. The results can easily be generalized for an arbitrary gas density in the second container. The chambers are so large in comparison with the channel that the gas in the chambers is in equilibrium and the molecules are incident on the channel with an equilibrium Maxwellian distribution f_{00}:

$$f_{00}=n_1\left(\frac{m}{2\pi kT_1}\right)^{3/2}\exp(-c^2),\quad c=\sqrt{\frac{m}{2kT_1}}\,v, \tag{1}$$

where c is the dimensionless velocity. Under stationary conditions equilibrium is established between the flux of incident molecules and those reflected from the walls. Molecules which are diffusely scattered by the channel surface are described by a distribution function f_0 of the form

$$f_0=Nf_{00}. \tag{2}$$

The quantity N in Eq. (2) is a solution of the equation for the blance of fluxes normal to the wall, or the well known Clausing equation.[7]

Consequently the problem consists of two parts: the solution of the Clausing equation, which enables to find the distribution function f_0, and the subsequent use of the distribution functions f_0 and f_{00} to calculate various characteristics of the molecular beam shaped by the channel.

Under free molecular conditions of flow in the absence of external forces the Boltzmann equation can be written in the form

$$\mathbf{c}\frac{\partial f}{\partial \mathbf{r}}=0. \tag{3}$$

Consequently the distribution function is preserved along the molecular trajectories. In order to determine the distribution function of molecules with velocities in a given direction at a given point a ray must be constructed in the opposite direction. If this ray intersects the channel surface the distribution function for such molecules will be f_0; if the molecules came from the volume their distribution function will be f_{00}. Knowing the distribution function we use the kinetic definitions of density n, flux nu, and temperature T

$$(n,\ n\mathbf{u},\ nkT)=\left(\frac{2kT_1}{m}\right)^{3/2}\int f\left(1,\ \mathbf{c},\ \frac{2kT_1(\mathbf{c}-\mathbf{u})^2}{3}\right)d\mathbf{c}, \tag{4}$$

where $\mathbf{u} = (m/2kT_1)^{1/2}\mathbf{V}$ is the dimensionless macroscopic velocity of the gas at the given point.

Because of symmetry the problem can be solved for one quarter of the plane of an axial cross section of the channel.

3. PLANE SOURCE

We introduce a rectangular coordinate system. We consider the outflow of gas from a plane channel into a vacuum. Let the x axis be directed along the gas flow with the plates confining the flow placed at the planes y = ± 0.5. The molecules are incident on the channel through the cross section x = 0, and emerge from it through the cross section x = L. All lengths are measured in units of the distance between the plates.

The integration in velocity space in Eq. (4) is performed in cylindrical coordinates, in which the element $d\mathbf{c} = c_\rho dc_\rho dc_z d_\varphi$ and $c_\rho = (c_x^2 + c_y^2)^{1/2}$. At points with coordinates $0 \le y \le 0.5 + (x - L)/L$ the total molecular flux density is determined not only by the molecules scattered by the walls but also by those traversing the channel without colliding with the walls. Therefore it is more convenient to transform from the integration over the angle φ to integration over x_1 by the obvious relation

$$x_1=x-(0.5+y)\operatorname{ctg}\varphi. \tag{5}$$

In accordance with this the flow field outside the chan-

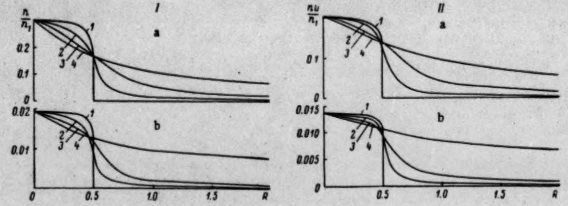

Fig. 1. Plane source. I) Normalized density; II) reduced flux. Here and in Fig. 2 φ in deg : 1) 90; 2) 80; 3) 60; 4) 0; a) L = 1; b) L = 100.

nel is divided into three zones with the following ranges of y: $0 \le y \le 0.5$, $0.5 \le y \le 0.5 + (x - L)/L$, and $0.5 + (x - L)/L \le y$. The results are too cumbersome to be written down in detail, and therefore, in the example below we give only the expression for the molecular number density in the $0 \le y \le 0.5$ zone:

$$n = \frac{n_1}{2\pi}\left[\operatorname{arc\,tg}\frac{0.5+y}{x} + \operatorname{arc\,tg}\frac{0.5-y}{x} + \int_0^L \left(\frac{0.5-y}{(0.5-y)^2+(x-x_1)^2} + \frac{0.5+y}{(0.5+y)^2+(x-x_1)^2}\right) N(x_1)\,dx_1\right]. \quad (6)$$

Since the solution of Clausing's equation[8] obtained by a variational method converges well,[9] N(x) can be determined in the linear approximation:

$$N(x) = 0.5[1 + A(0.5L - x)],$$
$$A = \frac{6(L - \operatorname{Arsh} L)}{L^3 + 3L^2 + 4 - (L^2+4)\sqrt{1+L^2}}. \quad (7)$$

The results of a machine calculation of the molecular number density and the molecular flux at points a distance R along rays from the point (x = L, y = 0, z = 0) making various angles φ with the x axis are shown in Fig. 1, I and II respectively. The molecular flux density is given by

$$nu = \sqrt{(nu_x)^2 + (nu_y)^2}. \quad (8)$$

4. CYLINDRICAL SOURCE

We consider the flow field from a cylindrical pipe. We take the z axis along the channel of length L, and the x and y axes in the entrance cross section. All lengths are measured in units of the radius of the pipe. The determination of the macroscopic moments (4) requires integrating the distribution function with various weights in velocity space, but for convenience in introducing the limits of integration it is necessary to transform the integration variables.

We transform from the cylindrical coordinate system in velocity space used in the last section to polar coordinates at the center of the entrance cross section z = 0. Then the contribution of "straight-through" molecules, i.e., molecules which traverse the channel without colliding with the walls, is taken into account by integrating over the area S of the entrance opening visible from the observation point (ρ, φ, z)

We introduce new variables ρ_1 and φ_1 by the relations

$$c_z = \frac{z}{m} c_\rho, \quad \varphi = 2\pi - \arcsin\left(\frac{\rho_1}{m}\sin\varphi_1\right), \quad (9)$$

where $m^2 = \rho^2 + \rho_1^2 - 2\rho\rho_1\cos\varphi_1$.

Then the element of volume in velocity space is

$$dc = c_\rho dc_\rho dc_z d\varphi = \frac{z\rho_1}{m^3} c_\rho^2 dc_\rho d\rho_1 d\varphi_1. \quad (10)$$

The fraction of the molecules reflected from the walls is found by integrating over the part of the inner surface of the cylinder C visible from the point of observation. We define the transformation of integration variables by

$$c_z = \frac{z - z_1}{m_1} c_\rho, \quad \varphi = -\arcsin\frac{\sin\varphi_1}{m_1}, \quad (11)$$

where $m_1^2 = 1 + \rho^2 - 2\rho\cos\varphi_1$.

Then the element of volume dc for molecules reflected by the wall is

$$dc = c_\rho dc_\rho dc_z d\varphi = \frac{1 - \rho\cos\varphi_1}{m_1^3} c_\rho^2 dc_\rho dz_1 d\varphi_1. \quad (12)$$

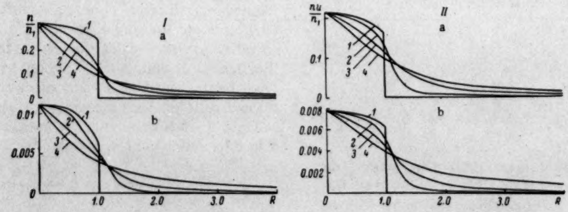

Fig. 2. Cylindrical source. I) normalized density; II) reduced flux.

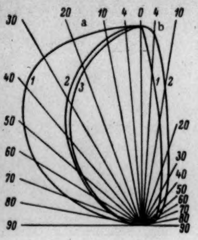

Fig. 3. Cylindrical source. Asymptotic behavior of normalized flux $nu(\varphi)/nu(0)$. a: L = 1; 1) R = 2; 2) 20; 3) ∞. b: L = 10; 1) R = 20; 2) ∞.

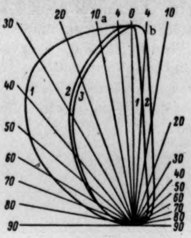

Fig. 4. Plane source. Asymptotic behavior of normalized flux $nu(\varphi)/nu(0)$. a: L = 1; 1) R = 1; 2) 10; 3) ∞ b: L = 10; 1) R = 10; 2) ∞.

The molecular density, for example, is given by

$$n=\frac{n_1 z}{4\pi}\iint_S \frac{\rho_1}{A_1^3}\,d\rho_1 d\varphi_1+\frac{n_1}{4\pi}\iint_C \frac{1-\rho\cos\varphi_1}{A_2^3}N(z_1)\,dz_1 d\varphi_1, \qquad (13)$$

where $A_1^2 = z^2 + \rho_1^2 + \rho^2 - 2\rho\rho_1 \cos\varphi_1$ and $A_2^2 = (z - z_1)^2 + 1 + \rho^2 - 2\rho\cos\varphi_1$.

The flow field is divided into several zones. Since a detailed report of the results would be too cumbersome we present below as an example only the expression for the molecular flux density in the axial direction for $0 \le \rho \le 1$:

$$nu_z=\frac{n_1}{4\sqrt{\pi}}\left[1-\frac{\rho^2+z^2-1}{\sqrt{(1+\rho^2+z^2)^2-4\rho^2}}\right.$$
$$\left.+4\int_0^L\frac{a-2\rho^2}{(a-4\rho^2)^{3/2}}(z-z_1)N(z_1)\,dz_1\right], \qquad (14)$$

where $a = (z - z_1)^2 + \rho^2 + 1$.

Using a variational method[8] we find for N(z)

$$N(z)=0.5+A(0.5L-z),$$
$$A=\frac{1}{3}\,\frac{(0.5L)^3-2+(2-0.25L^2)\sqrt{1+0.25L^2}}{0.5L\sqrt{1+0.25L^2}-\operatorname{Arsh}(0.5L)}. \qquad (15)$$

The results shown in Fig. 2 are obtained with a computer program written to calculate macroscopic characteristics of a molecular beam. This figure shows the molecular density n and the molecular flux

$$nu=\sqrt{(nu_\rho^2)+(nu_z^2)} \qquad (16)$$

as functions of the distance R along a ray from the point (x = 0, y = 0, z = L) making an angle φ with the z axis.

Calculations show that the computing time depends strongly on the position of the point of observation and increases significantly close to the edge of the exit opening of the pipe.

It is interesting to note that for both plane and cylindrical channels the temperature T as a function of the average molecular velocity u is given by

$$T=T_1\left(1-\frac{2}{3}u^2\right). \qquad (17)$$

The same result was obtained by Narasimha[10] for flow through an opening, and by Shakhov[11] for a spherical source.

5. DISCUSSION OF RESULTS AND CONCLUSION

The fluxes obtained by using the distribution function and making a change of variables are identical with those obtained by using the cosine law.[4,5] However, the introduction of this method of describing molecular beams leads to considerably more information on the flow field outside the channel (density, velocity, temperature) on the basis of the usual kinetic definitions of macroscopic characteristics (4).

We consider limiting cases. For L = 0 our results agree with Narasimha's equation[10] for a circuit opening and for a slot in a thin wall. Clausing's angular distribution[4,12] is asymptotic in comparison with ours, i.e., it is valid for $R \gg 1$ and $R \gg L$. This must be taken into account in experiments with molecular beams.

A comparison of the results, part of which are shown in Fig. 3, shows that the normalized flux density $nu(\varphi)/nu(0)$ differs from the limiting Clausing diagram for an axisymmetric beam by less than 7% for R = 20L ($L \ge 1$). The limiting angular diagram for a plane source and the normalized flux density $nu(\varphi)/nu(0)$ given by our calculations (Fig. 4) differ by no more than 10% for R = 10L($L \ge 1$). The fluxes in actual and limiting cases differ the most (by about 5%) on the axis for R = 20L (cylindrical source) and for R = 10L (plane channel). The direction of the fluxes varies from axial in the output cross section to radial when the limiting diagram is reached at large distances.

The average molecular velocity u and the temperature T in a beam with axial symmetry approach the limiting values

$$u'=\frac{2}{\sqrt{\pi}},\quad T'=T_1\left(1-\frac{8}{3\pi}\right) \qquad (18)$$

as $R \to \infty$.

The macroscopic velocity u differs from the limiting velocity u' at R = 20 by less than 0.1%. The corresponding limits in the plane case are

$$u''=\frac{\sqrt{\pi}}{2},\quad T''=T_1\left(1-\frac{\pi}{6}\right). \qquad (19)$$

At R = 10 the velocity differs from its limiting value by less than 0.1%.

The flux parameters are also calculated using the second approximation of the variational method for N[9,12] [cf. Eq. (7)] in order to estimate the accuracy of the quantities obtained. For short and rather long channels the results are practically the same. A difference is observed only for intermediate length channels and large angles. For example, for a cylindrical source the difference in the two approximations for the flux density nu ($\varphi = 80°$) is 2.3% for L = 8, 4.6% for L = 32, and 3.7% for L = 80.

(Submitted May 14, 1973)
Zh. Tekh. Fiz., 44, 818-823 (April 1974)

An experimental study has been made of the flow of the gases He, Ne, Ar, Kr, Xe, H_2, D_2, N_2, CO_2, and CH_4 over the Knudsen-number range $5 \cdot 10^{-1}$-10^4. The experiments are carried out at room temperature with a capillary grid made from glass capillaries with fused walls. The free-molecule values of the reduced flow rates are determined for all the gases. The accommodation coefficients for the tangential momentum of the molecules incident on the wall are calculated under the assumption that the xenon molecules are scattered diffusively by the wall. The accommodation coefficients found for He, Ne, and Ar agree with the values found previously with single capillaries.

INTRODUCTION

Berman and Maegley[1,2] have recently attempted to explain a phenomenon observed by them and other investigators:[3,4] the experimental flow rates in the free-molecule regime and in intermediate regimes are found to be lower than the theoretical values based on the assumption of complete diffuse scattering of molecules by the walls. Channels with artificially roughened walls were used in these experiments.

Berman and Maegley have suggested that among the molecules scattered by a smooth wall it is possible to distinguish a group which are probably scattered predominantly backward, in the direction opposite the direction of incidence. They describe this group of molecules by means of a "back-scattering coefficient." This coefficient is incorporated into the boundary conditions in a numerical solution of the Boltzmann equation with the Bhatnager–Gross–Krook collision operator.

We believe that the use of the concept of backscattering of molecules by a smooth wall in boundary-value problems of the kinetic theory of gases is not justified, for the following reasons.

First, it has been shown[5] that a Monte Carlo description of free-molecule flow of gases in circular capillaries with artificial regular wall corrugations with various shapes and parameters agrees with the observed flows, within the experimental and theoretical errors, if the rough walls are assumed to scatter molecules completely diffusely. An analogous result has been obtained[6] for a planar channel with triangular roughness features.

Second, analysis of the molecular-scattering characteristics obtained from experiments on the interaction of molecular beams with solid surfaces[7] supports the Maxwell-boundary condition scheme, according to which some of the molecules incident on a smooth wall undergo specular reflection.

Third, it follows from experimental studies of the intermediate flow regime and of viscous flow with slip in various channels[4,8-10] that the observed slip flows are larger than the theoretical flows calculated for diffuse scattering of molecules by the rigorous methods of the kinetic theory of gases. In this case, the discrepancy between theory and experiment can be attributed to the introduction of a diffuse-mirror boundary-condition scheme or an accommodation coefficient for the tangential momentum of the molecules incident on the walls.

Accordingly, the available experimental and theoretical information shows that each smooth element of the wall surface apparently is responsible for the mirror-reflection of a certain fraction of the molecules incident on it.

It is therefore worthwhile to carry out a systematic study of free-molecule and intermediate flow regimes for a wide range of gases. Under these conditions the interaction of the gas with the surface has the clearest effect on the macroscopic flow characteristics. These experiments are extremely difficult to carry out, primarily because it is necessary to detect very small flows if a single capillary or a packet of capillaries is used; the problem can be simplified considerably by using a capillary microscreen as the channel.

We report here on an experimental study of free-molecule and intermediate flow regimen for several inert and polyatomic gases in a capillary screen. We compare the results with the other information available.

EXPERIMENTAL PROCEDURE

The measurement procedure and the experimental apparatus for this study of intermediate and free-molecule flow regimes are described in detail in ref. 10. The only difference in the apparatus is that slight structural changes have been made in the injection system and in the working chamber in connection with the use of a different channel. Accordingly, we describe only the basis features of the working channel and the procedure for determining the flows.

The working channel is a capillary screen, fabricated

TABLE 1. Purity of the Gases Studied

from a set of thin-walled capillaries of the same diameter placed in a glass tube, heated, and stretched. The average capillary diameter is $(1.35 \pm 0.01) \cdot 10^{-3}$ cm, the capillary length is ~ 5.0 cm, the transparency of the screen is ~ 90%, and there are ~ 640 capillaries.

The screen is mounted in the following manner: A silver film of the necessary thickness is deposited on the outer surface of the glass tube of the screen. Then the screen is soldered by means of Wood's metal to a Kovar disk, soldered with ordinary solder beforehand to a stainless steel flange. This flange divides the working volume of the experimental apparatus into two approximately equal parts. This method for mounting the screen in a flange provides a good thermal contact between the flange and the metal and prevents the possible leakage of gas around the capillaries; it also permits experiments to be carried out over a broad temperature range, from 70 to 350°K.

We have studied the free-molecule and intermediate flow regimes of a wide variety of inert, diatomic, and polyatomic gases; the purity of the gases is shown in Table 1.

The results of the experiments carried out with spectrally pure helium and nitrogen and with samples of these gases of ordinary purity (an impurity of ~ 2%) agree within the experimental error.

All the gases are passed through a liquid-nitrogen trap before they enter the experimental apparatus. All measurements are carried out at room temperature, 290-292°K.

EXPERIMENTAL RESULTS AND CONCLUSIONS

The experimental results are analyzed on a computer by means of a nonlinear method of least squares, by the procedure described in ref. 10. The quantity which is the immediate result of the computer analysis of the experimental data is the constant C, which is related to the flow rate of the gas through the channel per unit pressure difference across the ends of the channel, M:

$$C = \frac{M}{V\left(1 + \frac{a}{V} p\right)}. \tag{1}$$

Here $V = V_1V_2/(V_1 + V_2)$ is the reduced volume of the system, 146.5 cm^3, which is measured by a comparison method within 0.1%; the quantity $a = 0.136 \pm 0.002$ c^3/torr is the correction for the membrane curvature of the differential capacitance micromanometer. Since the measurements are carried out over an intermediate pressure range, $\bar{p} \simeq (5 \cdot 10^{-4}\text{–}10^{-1})$ torr, their contribution to the flow rate of the term associated with this membrane curvature is negligibly small over the entire $\bar{p}$ range.

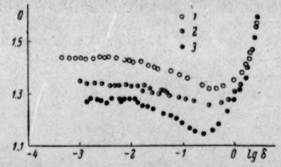

Fig. 1. Reduced gas flow rate Q as a function of the parameter δ. 1) He; 2) H_2; 3) Xe.

The relative error in the calculation of the gas flow rate M is less than 0.5% for He, Ne, and D_2 or 1% for the other gases in the entire pressure range studied. All the measurements were repeated after an interval of about two months; the results agree within the specified errors.

The experimental data for the various gases are conveniently compared on the basis of the reduced volume flow rate Q as a function of the parameter δ, which is related to the Knudsen number Kn by

$$\delta = \frac{\sqrt{\pi}}{2} \frac{R}{\lambda} = \frac{\sqrt{\pi}}{2} \frac{1}{\mathrm{Kn}}, \tag{2}$$

where R is the average capillary radius and λ is the mean free path of the molecules; this mean free path is calculated on the basis of the hard-sphere model and the equation for the viscosity coefficient in the second Chapman–Enskog approximation.

Since there is an uncertainty in the channel geometry for the capillary screen used here (the cross sections of several of the capillaries are not circular), and since we do not know the exact number of capillaries, we use the following definition of the reduced flow rate, in contrast with that used in refs. 9 and 10:

$$Q = \frac{M}{\left(\frac{T}{\mu}\right)^{1/2}}, \tag{3}$$

where T is the experimental temperature and μ is the molecular weight. This definition of Q suppresses a sensitivity of the gas flow rate in the free-molecule and intermediate flow regimes to the temperature and the nature of the gas. It also allows all the differences in the values of Q for the various gases in these flow regimes to be attributed to interactions of the gases with the surface alone.

To illustrate the results we show in Fig. 1 the reduced flow rate Q as a function of the parameter δ for He, H_2, and Xe.

In the intermediate flow regime (δ ~ 1) as well as in the free-molecule and adjacent regimes (δ < 0.1), there is

TABLE 2. Experimental Values of the Reduced Free-Molecule Gas Flow Rate Q_{fm} and of the Tangential-Momentum Accommodation Coefficient α

	He	Ne	Ar	Kr	Xe	H_2	D_2	N_2	CO_2	CH_4
Q_{fm}	1.442	1.471	1.337	1.312	1.289	1.354	1.372	1.351	1.296	1.309
$\pm\Delta Q_{fm} \cdot 10^3$	7	7	13	10	15	13	5	14	13	11
α	0.944	0.934	0.982	0.991	1	0.976	0.969	0.977	0.998	0.992
$\pm\Delta\alpha \cdot 10^3$	4	4	6	5	—	7	3	7	6	6

a significant difference between the values of the reduced flow rates Q for the various gases.

To calculate the free-molecule flow rate Q_{fm} we use

$$Q = Q_{fm}(1 + 0.7\delta \lg\delta). \tag{4}$$

The functional dependence of Q on δ described by (4) is analogous to the theoretical function $Q(\delta)$ for approximately free-molecule flow ($\delta \leqslant 10^{-2}$) (refs. 11, 12). Calculations show that the values of Q calculated from Eq. (4) agree with the exact values[11,12] within $< 0.2\%$ for $\delta < 5 \cdot 10^{-2}$.

We analyze all the experimental data in this range of δ by the method of least squares, using Eq. (4). Table 2 shows the values of Q_{fm} and the corresponding standard deviations found for the various gases.

We see from Table 2 that Q_{fm} is a strong function of the nature of the gas; the most pronounced difference, ~ 16%, is observed between the results for Ne and Xe.

According to ref. 10, the experimental data for xenon agree with the theoretical data within the experimental error for both viscous flow with slip (with a slip constant) and for approximately free-molecule flow (a reduced flow rate), provided that all the molecules are assumed to be scattered diffusely by the wall in the theory. Since a screen of glass capillaries with fused walls is used in our experiments, and since the lowest value of Q_{fm} found is that for xenon, we can quite confidently assert that the xenon molecules in our experiments are scattered diffusely by the fused glass surface. Then all the differences among the values of Q_{fm} for these gases can be attributed to differences in the relative number of molecules which are scattered diffusely by the wall, Q_{fm}. This relative number can be calculated from the experimental values of Q_{fm} through the equation[12]

$$Q_{fm}(\alpha) = Q_{fm}(\alpha = 1)\frac{2-\alpha}{\alpha}. \tag{5}$$

According to our assumptions, the quantity $Q_{fm} \cdot \alpha = 1)$ in (5) is the reduced flow rate for xenon. In this procedure, the values of α calculated for all the gases are relative values.

The observed values of α are shown along with the corresponding errors in Table 2. The error in the determination of α is governed solely by the error ΔQ_{fm} for each gas since the error in the determination of Q_{fm} for xenon is a systematic error.

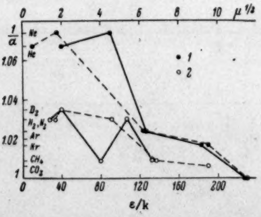

Fig. 2. The quantity $1/\alpha$ as a function of the molecular weight μ and the depth of the potential well, ε/k. 1) Inert gases; 2) polyatomic gases. Dashed lines) $1/\alpha = f_1(\varepsilon/k)$; solid lines) $1/\alpha = f_1(\mu^{1/2})$.

In ref. 10 the values $\alpha = 0.935$, 0.929, and 0.975 are founde for He, Ne, and Ar, respectively, in good agreement with the data in Table 2. This agreement strengthens our confidence in the interpretation of these experimental results.

Figure 2 shows $1/\alpha$ as a function of the molecular weight μ of the gases studied. We see that as the molecular weight is increased the quantity $1/\alpha$ falls off monotonically for the inert gases, except for helium. For the polyatomic gases the functional dependence $1/\alpha = f_1(\mu^{1/2})$ is satisfied on the whole, although there are anomalous values of $1/\alpha$ for hydrogen and methane.

It seems worthwhile to attempt to find another parameter characterizing either the individual or collective properties of the atoms or molecules and which could be used to eliminate this anomalous behavior of the values of $1/\alpha$. Such a parameter could be, e.g., the diameter of the molecule or the depth of the potential well, ε/k, in the Lennard Jones (6-12) potential. An attempt to use the molecular diameter as this parameter has been unsuccessful.

For comparison, Figure 2 shows the experimental values of $1/\alpha$ as a function of the depth of the potential well, ε/k. These depths, given in ref. 13, are determined from the functional dependences of the viscosity coefficients on the temperature, in which the quantum-mechanical corrections are taken into account. We see that the anomalous behavior for methane vanishes, although that for helium and hydrogen does not.

We can draw the following conclusions from these experimental results.

First, it has been shown experimentally that the observed flow rates for all the gases in free-molecule and adjacent flow regimes in glass capillaries with fused walls are higher than the theoretical values obtained under the assumption of completely diffuse scattering of molecules by the wall. This difference supports the Maxwell diffuse-mirror scheme for the interaction of gases with a surface.

Second, the agreement between the calculated values of the coefficient α and the available data from single capillaries is evidence in favor of the procedure of extracting these coefficients from the experimental data by a relative method, in which xenon is chosen as a diffusely scattered gas.

Third, the fact that α does not behave anomalously as a function of the depth of the potential well for the inert and polyatomic gases studied here, except for helium and hydrogen, allows us to conclude that heavy-gas molecules, for which the depth of the potential well is greater, are reflected more diffusely than light-gas molecules, since they spent more time interacting with the wall (and thus have a longer lifetime in the adsorbed state).

Taking account of surface diffusion would undoubtedly improve the agreement between the experimental and theoretical results. However, at present it is difficult to distinguish between mirror reflection and surface diffusion in the absence of appropriate experimental information, in particular, information obtained at various temperatures.

(Submitted April 17, 1973; resubmitted October 8, 1973)
Zh. Tekh. Fiz., 44, 824-829 (April 1974)

Numerical solutions are found for several two-dimensional problems in the Knudsen pressure range using the Langmuir adsorption model in the transient state: These include the distribution of the molecular flow within a cylindrical effusion vessel, the distribution of coverage of the adsorbed film on the walls of this vessel, and the signal from an ideal detector for molecular flows from the cylinder for various geometries. The time constants of the vessel–collimator–detector systems are functions of the ratio of the angular dimensions of the collimator and vessel and of their relative arrangement. The time constant of this system is also a function of combinations of characteristic times involved in this problem, e.g., the transit time in the vessel, the lifetime on the wall, the frequency of particle–wall collisions, and the time constant of the detector. The characteristics (like the real characteristics) deviate significantly from one-dimensional behavior and are transient. Programs which have been worked out provide realistic simulations of the evolution of the effusion characteristics over a broad range of the governing parameters.

The use of molecular effusion from various vessels and the closely related problems of the molecular distribution within these vessels play an important role in applied physics. An understanding of these processes is important in high-temperature evaporation, in the use of molecular guns in molecular-beam experiments, in problems that arise in ion engines and vacuum communication systems, and in problems involving porous adsorbents, deposited films, and catalysts.[1-4] Clausing's work in the 1930's has apparently been the most important in this field, although there has been some recent work.[5,6]

In this work we use a system of transient equations [Eqs. (1)-(3)], introduced previously,[7] which relate the distribution of the incident particle flux per surface position per unit time, $\sigma = \sigma(P, t)$, the distribution of the departing particle flux, $\varphi = \varphi(P, t)$; and the distribution of the degree of coverage, $\theta = \theta(P, t)$. Here, t is the time and P specifies a point on the internal surface of the cylinder. The lifetime of the particles on the surface and the time spent in flight (in the single-velocity approximation) are taken into account. In constructing these equations we adopt the Knudsen cosine law and neglect collisions between particles (we assume Knudsen flow). We assume the unknown distributions to be axisymmetric, so the problems solved here are two-dimensional, being much more complicated than the one-dimensional ones solved by Clausing[8] but simpler than actual three-dimensional systems. We do not use Clausing's[9] replacement of approximation integral equation (2) by a partial-derivative diffusion equation; this simplification is valid only for infinitely long (or very long) capillaries.[3]

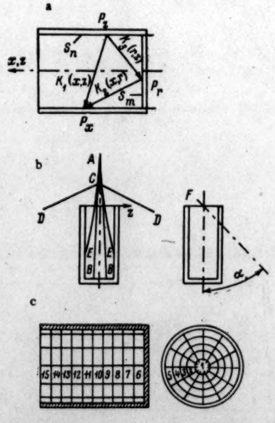

Fig. 1. The coordinate systems. a) For Eqs. (1)-(4). Here S_m is the base and S_n is the lateral surface of a cylinder; b) relative arrangement and motion of the vessel and the collimator. Here, point F is the intersection of the z axis and the plane of the figure; c) scheme for partitioning the internal surface into mutual-irradiation zones.

The system of equations which we use below can be written:

$$\varphi = (\sigma + \mu)\,\Theta, \tag{1}$$

$$\sigma(P,\ t) = \int_s \varphi\left(P',\ t - \frac{\|P' - P\|}{v}\right) K(P,\ P')\,dS(P'), \tag{2}$$

$$\dot{\Theta} = \sigma - \varphi, \tag{3}$$

$$\Theta(P,\ 0) = \begin{cases} \Theta_0, & P \in S_m, \\ 0, & P \in S_n. \end{cases} \tag{4}$$

Fig. 2. Distributions of the degree of coverage θ and the intensity of the incident flux σ over the internal surface of the cylinder. Here (m + n) is the index of the zone (see Fig. 1c). t = 0.116 sec: 1) θ; 2) σ. t = 1.15 sec: 3) θ; 4) σ.

where

$$K(P,\ P')=\begin{cases}K_1(x,\ z);\ P,\ P'\in S_n;\ P=P_x;\ P'=P_z,\\ K_2(x,\ r);\ P\in S_n;\ P'\in S_m;\ P=P_x;\ P'=P_r,\\ K_3(r,\ z);\ P\in S_m;\ P'\in S_n;\ P=P_r;\ P'=P_z.\end{cases}$$

$$K_1(x,\ z)=\frac{1}{2}\left[1-\frac{|x-z|(6R^2+|x-z|^2)}{(4R^2+|x-z|^2)^{3/2}}\right];$$

$$K_2(x,\ r)=\frac{2xr\,(R^2-r^2+x^2)\,R^2}{[(R^2+r^2+x^2)^2-4r^2R^2]^{3/2}};$$

$$K_3(r,\ z)=\frac{2z\,(R^2-r^2+z^2)\,R^3}{[(R^2+r^2+z^2)^2-4r^2R^2]^{3/2}}.$$

In Eqs. (1)-(3), μ is the average rate at which particles leave the surface. This quantity is a function of the temperature and the heat of adsorption and is assumed to be constant in these calculations. Also, v is the particle velocity, R is the cylinder radius, r is the radial coordinate, and x and z are the axial coordinates. All the numerical examples are calculated for $\mu = 1\ \mathrm{sec}^{-1}$, R = 1 cm, and $v = 10^4$ cm/sec for a cylinder 5 cm long; the other dimensions are chosen according to scale on the basis of Fig. 1. The quantity K(P, P') is the probability that a particle will be incident from the region near point P' on the region near point P. The nature of this probability has been discussed widely (see, e.g., ref. 3). Equation (1) describes the balance between the fluxes arriving at and departing from a given point, Eq. (2) describes the balance between the fluxes between a given point and other points on the cylinder, taking account of the delays involved, and Eq. (3) is found from the ordinary Langmuir equation for the adsorption φ kinetics. The departing flux φ consists of the reflected part of the incident flux $\sigma(\Theta)$ (we assume that a particle incident on a filled position is reflected, while one incident on a vacant position is captured), and the desorbed flux, $\mu(\Theta)$; and Eq. (4) is the initial condition. If we set $\Theta = 0$ in Eq. (3) (corresponding to the steady state), we find $\sigma = \varphi$, and Eq. (2) becomes a an integral Fredholm equation of the second kind (if we also assume $\|P'-P\|/v = 0$), which we manipulate in the ordinary manner with the Clausing times. If we do not assume $\|P'-P\|/v = 0$, we find from Eq. (2), in the case of sufficiently rapid adsorption, integral equations with a retarded argument, introduced in ref. 3. Surface diffusion, which has been discussed from time to time in the literature (beginning with Volmer) is inconsequential in our problem; According to the Clausing criterion,[9] this process is negligible when the quantity

$$\frac{3D_s}{4R^2\mu},$$

where D_s is the surface-diffusion coefficient, is small in comparison with unity.

We assume that the cylinder has been brought to

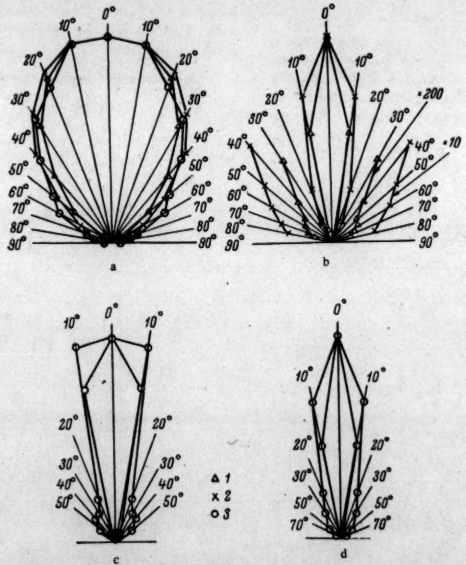

Fig. 3. Time evolution of the characteristics for various collimators. a) CDD; b) CEE; c) ABB according to Fig. 1b; d) "infinitely" remote collimator. a (CDD): 1) z = 0, t = 0.116 sec; 2) z = 0, t = 1.4 sec; 3) z = 2.66 cm, t = 0.116 sec. c) (ABB): inner curve) z = 0, t = 0.116 sec; outer curve) z = 0, t = 1.99 sec. d("infinitely" remote collimator): inner curve) z = 0, t = 0.116 sec; outer curve) z = 0, t = 1.99 sec.

that temperature at which the average particle lifetime in the adsorbed film is μ^{-1} sec. Then, as in ref. 7, we place a certain amount of the material, Θ_0, at the base of the cylinder (Fig. 1). The numerical examples are carried out for $\Theta_0 = 0.1$ monolayer.

Using a difference approximation of Eqs. (2) and (3) we can calculate the values of σ, φ, and Θ in all zones of the cylinder in successive time layers; the results of such a calculation for σ and Θ are shown in Fig. 2. However, it is difficult to compare these results with the measured values of Θ and σ within the cylinder because of the difficulty in carrying out such experiments. It is simpler to measure the fluxes I from the cylinder through some collimator system to a detector. The rest of this paper is devoted to a calculation of such effusion fluxes, but this calculation can be carried out only after σ and Θ are found).[1)]

Figure 1b shows the relative arrangement of the effusion cylinder and the three samples used as collimators in the calculations. The collimators are a system of two coaxial circular irises which determine the right circular "visibility cones" ABB, CDD, and CEE in the figure. These cones bound that part of the surface of the cylinder from which particles capable of passing through the collimator into the detector (among other particles) are desorbed. We assume that all the particles which pass through the collimator are detected.

Here, we have introduced a realistic collimating system. On the other hand, to match the system for which calculations were first carried out by Clausing[10] and for which many subsequent calculations have been carried out (see, ref. 6 and the bibliography there), we must construct something similar to the faceted eye of an insect. No such collimators have been described in the literature; nevertheless, our analysis of the emission characteristics of various points on the cross section of a cylinder is an important supplement to previously published work. This analysis converts the one-dimensional characteristics of Clausing and many of his successors into the two-dimensional characteristics of the present paper.

The program that we have worked out makes it possible to calculate the number of particles incident on the detector for various specified geometries of the cylinders and collimators, and it is possible to alter the relative arrangement of these units, e.g., by moving the cylinder a specified distance along the z axis with respect to the collimator and then rotating the cylinder around this axis through a specified angle α, while the other replaceable collimators are held in position.

We also calculate the signals from our ideal detector as a function of the time.

The detector signal is calculated for fixed values of all the parameters in the following manner: The internal surface of the cylinder is partitioned into hoops m, n and into a specified number of angular sectors (see Fig. 1c, where m = 5, n = 10 hoops, and there are 12 sectors for concrete calculations). The exit-window iris of the collimator is also partitioned into a specified number of radial and angular regions. We calculate the probabilities for incidence from each such region of the cylinder (assuming a cosine law) on all regions of the collimator in succession. We take into account only those pairs of regions which are in the line of sight. Then, through a summation over the corresponding regions, we find the probabilities for incidence on the detector of particles from each of the (m + n) regions of the cylinder. The detector signal is found through a summation (with these probabilities) of the distribution of the escaping flux, $\varphi(P)$, calculated by the program described above.

Figure 3 shows the effusion characteristics $I = I(\alpha)$ for various collimator schemes and for various relative arrangements of the cylinder, collimator, and detector. The curves in this figure are obtained by connecting points for which the coordinates are calculated, so the curves may differ slightly from those which would be calculated with a finer calculation step (this refinement can be made where necessary). Figure 3d shows data for an "infinitely" remote collimator (the cylinder–collimator separation used in the calculation is 50 cm), having the same dimensions as the collimator for CDD. This scheme is also a good approximation of the ideal Clausing collimator,[10] which we have discussed above.

In Fig. 3 we see a gradual broadening of the emission patterns and a broadening of the "pupil" of the collimator as time elapses; this behavior is, of course, a manifestation of an increase in the entropy of the system.

Figure 4 shows the detector signal as a function of the time for the various collimator versions and for various

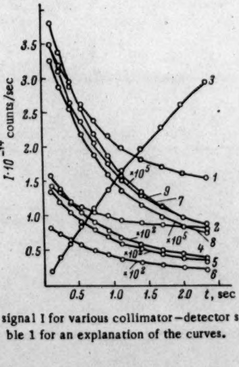

Fig. 4. Detector signal I for various collimator–detector systems. See Table 1 for an explanation of the curves.

TABLE 1. Signal Decay Over the Observation Interval from One to Two Seconds (from the data in Fig. 4)

*No decay; instead, the signal increases.

positions of the cylinder along the z axis (Fig. 1b) (but without rotation). Particularly noteworthy is the increase in the detector signal in the case of curve 3, in the face of a decay of this signal for all other cases. This singular case is attributed to the combination of the wide "vision" angle of collimator CDD (Fig. 1b) and the extreme position of the cylinder, displaced 2.66 cm along the z axis. In this position the detector "sees" only the time-increasing emission from the mouth of the cylinder, where particles from the base of the cylinder are incident. Subsequently, of course, this signal must decay.

A direct analysis of Eqs. (1)-(4) does not yield any conclusions regarding the time constants of the system. On the basis of general considerations we conclude that the time characteristic of the system is a function of several characteristic times – the time a particle spends in flight, the time it spends at the surface, the time which elapses between collisions with the surface – as well as of the number of such collisions. The frequency and number of collisions with the surface are functions of the geometry of the system.

Let us analyze the curves in Fig. 4 as if we had obtained them experimentally. One possible result of this analysis is shown in Table 1.

Table 1 shows how the detector signal varies from 1 to 2 sec on the scale in Fig. 4 for various geometric arrangements. These data show that the time constants of the overall cylinder–collimator system are different, even though the same processes occur in the same cylinders and with the same boundary and initial conditions (Fig. 2). Accordingly, the construction and arrangement of the collimator affect the time constant of the system; this constant is shorter, the "stiffer" the collimation.

The significance of these results is clear. It would be useful to analyze the metrological features of these systems, which must also be taken into account in measurements and which may be used in further studies.

The authors thank V. Fedosimov for consultation on the calculations, and they thank the participants of the seminar supervised by É. Ya. Zandberg and N. I. Ionov for a detailed discussion of this work.

---

[1] We recognize that the inverse problem must be solved, but at the present stage we do not know how to proceed.

A transaxial lens

V. M. Kel'man, L. M. Nazarenko, and E. M. Yakushev

(Submitted July 23, 1973)
Zh. Tekh. Fiz., 44, 830-834 (April 1974)

An experimental study has been made of a transaxial lens operating in the anamorphic regime. The focal length of the lens and the aberrational broadening of the image line in the focal point have been measured. Good agreement is found with calculated data.

Transaxial lenses, studied theoretically in refs. 1 and 2, have been suggested for use as collimators and focusing devices in symmetric prism energy focusing mass spectrometers.[3] An advantage of such lenses is the fact that the spherical aberration in the dispersion direction of the instrument is small; structurally, these lenses combine well with the reflecting elements of the instrument. We report here on an experimental test of such lenses. We have tested the lenses along with the electrostatic deflecting elements (three-electrode telescope systems) of a mass spectromer; in this way we are able to determine simultaneously the quality of the entire electrostatic part of the mass spectrometer (without the magnetic prism). Furthermore, the deflecting elements make it possible to construct an electron-optics bench, which is particularly useful for testing transaxial lenses.

Figure 1 shows the experimental apparatus, which consists of two identical systems, I and II, divided in this figure by line mm. In a symmetric prism mass spectrometer these systems lie in symmetric positions with respect to the magnetic prism and serve as its arms. In the mass spectrometer the edges of electrodes 6 of the two systems, which touch each other along line mm in this apparatus, are parallel to the direction in which the field of the magnetic prism is constant. Each arm (I or II) consists of a transaxial lens with electrodes 1-4 and a deflecting telescope system with electrodes 4-6. A single electrode consists of two identical plates arranged symmetrically with respect to the median plane of the system. The distance between the plates in each electrode d = 8 mm.

To avoid disturbing the desired field distribution we place all the supporting parts between the electrode plates at a distance of at least 5d from the axis of the ion beam. The lens electrodes are L = 100 mm in size. The gap between neighboring electrodes of the lenses and telescope systems is 1 mm. Limiter D, with a rectangular aperture, is placed 309 mm from ion source E. The dimensions of this aperture are 2.7×9 mm^2; the long dimension is parallel to the median plane of the system.

In the arrangement of electron-optics elements shown in this figure the gaps between the electrodes of the two telescope systems are parallel to each other. Accordingly, the two telescope systems together constitute an electron-optics analog of a plane-parallel plate, and for the case of a parallel beam in the median plane, these telescope systems are free of all types of geometric and angular chromatic aberrations.

Figure 2 shows a photograph of one part of the electron-optics bench (one arm of the mass spectrometer). All the electrodes are mounted on plate 7. Electrodes 1-5 and plate 7 are made of a nonmagnetic material (stainless steel). The plates of electrode 6 are made of soft magnetic materials, because this electrode is also a magnetic shield, used to keep the field of the deflecting magnet two-dimensional. Here we are concerned with this electrode only in regard to its effect in shaping the electrostatic field of the telescope system.

Certain requirements are imposed on the elements of an arm of a mass spectrometer,[3] and the parameters of the telescope system are chosen to meet these requirements. The incidence angle (Fig. 1) $i = 64°40'$, the refraction angle $j = 31°15'$, and the width of the intermediate electrode $l = 41$ mm. The ratio of the potentials at the extreme electrodes of the telescope system is $V_4/V_0 = 0.330$, while the potential at the central electrode is $V_{ce} = 0.530\ V_0$. The point at which the ions appear is assumed to be at zero potential, and the potential of grounded electrodes 1 and 6 is V_0. The effective refraction plane of the telescope system, bb, lies near central electrode 5, 9 mm from the plane passing through the center of the gap between electrodes 4 and 5. With these parameters of the telescope system the mass spectrometer is achromatic, and its spectral lines are straight when the beam enters the magnetic prism at an angle $\alpha = 51°$.

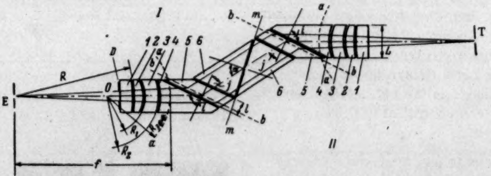

Fig. 1. Arrangement of the apparatus for testing transaxial lenses. 1-4) Electrodes of the transaxial lenses; 4-6) electrodes of the electrostatic telescope systems; E) exit slit of the ion source; T) detector slit of the recording instrument. Lines aa show the effective refraction surfaces of the transaxial lenses, while lines bb show the effective refraction planes of the telescope systems.

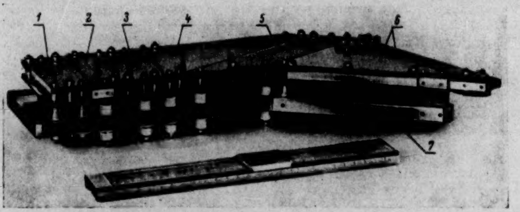

Fig. 2. Transaxial lens and deflecting telescope system. 1-4) Electrodes of the lens; 4-6) electrodes of the telescope system; 7) supporting plate.

The transaxial lenses, whose task is to produce a parallel, three-dimensional beam from the ions emerging from a point source and to then focus this beam to a point in the object plane, operate in the anamorphic regime. Accordingly, the calculations carried out for cylindrical transaxial lenses[4,5] can be used only as rough estimates. The parameters of the lenses used here are determined accurately through numerical computer calculations. For this purpose we assume electrodes 1 and 2 to be grounded, i.e., we assume the lenses to be three-electrode lenses. With potential V_4, given above, on the electrode 4, and with $R_1 = 121$ mm and $R_2 = 161$ mm, the potential of the central electrode of the transaxial lens, electrode 3, which provides lens operation in the anamorphic regime is calculated to be $V_3 = 2.19\ V_0$. Here R_1 and R_2 are the radii of curvature of the edges of electrode 3 with center at point 0. The corresponding focal length on the concave side of the lens is $f = 460$ mm, and the effective refracting surface is found to lie at a distance $R_{\text{eff}} = 195$ mm from the center of curvature of the transaxial lens, 0. This information is sufficient for determining the paths of rays in the median plane of the entire system. We note that this system has unit magnification in both the horizontal and vertical directions.

Electrode 2 is added to correct the position of the focus. The gap between electrodes 1 and 2 is cut along the arc of a circle of radius R = 350 cm, centered at the slit of the ion source E (or at that of the detector, T). Accordingly, the field in this gap does not alter the rectilinear nature of the ion trajectories from the source to the median plane of the system (or from this plane to the detector). When there is a slight change ΔV_2 in potential $V_2 = V_0 + \Delta V_2$ at electrode 2, the field in this gap also has essentially no effect on the vertical course of the trajectories because when the ratio $\Delta V_2/V_0$ is small the optical power of the lens in the vertical direction is proportional to the square of this ratio. Accordingly, the role of the extreme electrode of the three-electrode transaxial lens is assumed by electrode 2, and a change in the potential of this electrode leads to a change in the refractive index of the lens, providing the desired control of the position of the focus.

In preliminary experiments we observe the images visually by means of an ion-optical image converter. In these experiments the exit slit of the source is 1 × 0.1 mm^2 in size. The calculated potentials are supplied (within 0.1%) to the electrodes, and electrode 2 is grounded. The ion energy eV_0 is 2870 eV. Because of the low resolution of the image converter, the shape and dimensions of the image on the screen are governed largely by the quality of the converter. The observed image is a spot whose brightest part is a circle about 1 mm in diameter (Fig. 3a). This result is evidence that this ion-optics system is operating in the anamorphic regime when the source and detector are placed in their calculated positions. A change of ± 100 V in the potential on electrode 2 causes a significant expansion of the beam in the horizontal direction (parallel to the median plane), while a like change of the potential at electrode 3 has essentially no effect on the image shape. In addition to the central bright spot on the screen we observe fainter vertical bands issuing upward and downward from this bright spot; the intensity of these bands falls off rapidly from the central spot, and the bands essentially vanish at a distance of 10-12 mm from it. These bands may be due to vertical aberrations of the transaxial lenses and the telescope systems, as is implied by the circumstance that a reduction of the potential on electrode 3 can significantly contract the vertical dimension of the pattern as a whole, while the central bright spot stretches out in the vertical direction (Fig. 3b). This behavior corresponds to a coincidence of the plane in which the vertical spherical aberration is minimal[6] with the grid plane of the image converter. In this adjustment, the height of the image as a whole is about 10 mm, and that of the bright spot is about 6 mm.

When there is a simultaneous change in the potentials on both electrodes 4, the image does not move. It does move when the potential on only one of electrodes 4 is changed. In that case, the additional potential is fed to electrode 4 of system II, which is the one closer to the ion detector T. Measuring the resulting image displacement δl and the additional potential supplied to electrode 4, δV, we can determine experimentally the focal length of the transaxial lens:

$$f = 2 \operatorname{ctg} \iota \sqrt{V_0 V_4}\, \frac{\delta l}{\delta V}. \tag{1}$$

The focal length found in this manner turns out to be 468 ± 10 mm, in agreement with the calculated value.

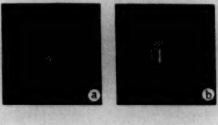

Fig. 3. Photograph of the image line. a) In the anamorphic regime; b) with the system adjusted for the shortest image.

We use the following procedure for a precise measurement of the width of the image line. We detect the ions with an SI-03 counter, the slit of whose detecting head is placed in the image plane. By smoothly changing the potential on electrode 4 of system II, we cause the image to move in the horizontal direction; we measure the intensity of the ion current passing through the detector slit as a function of the additional voltage fed to the electrode, δV. From the width of the peak ΔV determined in this manner and from Eq. (1) we determine the image width:

$$\Delta l = \frac{f\,\mathrm{tg}\,t}{2\sqrt{V_0 V_4}}\Delta V. \qquad (2)$$

The basic voltage on both electrodes 4 is supplied by a single source, so the deflection angle is independent of fluctuations in this voltage. In this manner we eliminate the errors due to the instability of the high-voltage source. On the other hand, the instability of the additional voltage fed to electrode 4 of system II, δV, cannot introduce any important errors since it is so small (up to 1 V).

We carry out measurements as argon is injected into the ion source. To improve the accuracy, we choose a slit width of 5 μ for both the source and the detector. In these experiments the apparatus is not shielded from the earth's field, so the apparatus has a certain slight mass dispersion. As a result, a small amount of residual gas causes a significant expansion of the base of the peak. Accordingly, in determining the image width from Eq. (2) we use twice the peak width at half-height as ΔV.

Measurements show the broadening of the image line per arm of the mass spectrometer to be 13 μ. This broadening is caused by aberrations of the transaxial lens, errors in the assembly of the ion-optics system, errors in adjustment, and all other experimental errors.

For comparison, the resultant calculated aberration of this transaxial lens in the horizontal direction, with the specified position of the aperture limiter, is

$$\Delta y = B_1 y_0^3 + B_2 y_0^2 y_D + B_3 y_0 y_D^2 + B_4 y_D^3 + B_5 y_0 z_0^2 + B_6 y_0 z_0 z_D + B_7 y_0 z_D^2 + B_8 y_D z_0 z_D + B_9 y_D z_0^2 + B_{10} y_D z_D^2. \qquad (3)$$

Here we have adopted a Cartesian coordinate system y, z with origin at the main optical axis of the lens. The y axis is in the median plane of the lens and runs perpendicular to the main optical axis. Coordinates in the object plane are given a subscript "O," while those in the limiter plane are given a subscript "D." The aberration coefficients B_1–B_{10}, which characterize the aberrations in the focal plane of this lens (i.e., in the object plane for the collimator lens or in the image plane for the focusing lens), are, in reciprocal square millimeters (mm^{-2}): $B_1 = 1.16 \cdot 10^{-6}$, $B_2 = 7.63 \cdot 10^{-6}$, $B_3 = 8.76 \cdot 10^{-6}$, $B_4 = 1.72 \cdot 10^{-5}$, $B_5 = 5.20 \cdot 10^{-5}$, $B_6 = 2.67 \cdot 10^{-5}$, $B_7 = 1.39 \cdot 10^{-4}$, $B_8 = 1.55 \cdot 10^{-4}$, $B_9 = 3.05 \cdot 10^{-4}$, $B_{10} = 8.20 \cdot 10^{-44}$ mm^{-2}.

Since the slit of the ion source (or detector) is very narrow, and the center of this slit is assumed to lie at the main optical axis of the lens, the terms in Eq. (3) containing y_0 are negligibly small. With the dimensions specified above for the ion source and the limiter, the total contribution of the other terms to the line width at its base is $2\Delta y$ = 18 μ. Most of this contribution is from spherical aberration, described by the two terms $2B_4 y_D^3$ = 3 μ and $2B_{10} y_D Z_D^2$ = 13 μ.

The theoretical broadening of the image in the transaxial lens (18 μ) turns out to be slightly higher than the experimental image broadening (13 μ). The explanation lies in the circumstance that the aberrations are calculated for the image in the Gaussian plane, while the image width is measured in the plane of the best focus, where the spherical aberration is known to be much less than in the Gaussian plane. Furthermore, the theoretical calculation neglects the distribution of the ion current density over the image width; i.e., the peak shape is not taken into account. A more accurate calculation shows that the width of the peak at its base is more than double its width at half-height. Accordingly, the assumption that the width of the peak at its base is equal to twice its half-height width, used in the experimental determination of ΔV, leads to an estimate of the image width which is slightly too low.

We note that the aberrations of the transaxial lenses fall off rapidly with decreasing limiter dimensions. For example, the calculated aberrations of the ion-optics system shown in Fig. 1 are about 1 μ when a circular limiter 2 mm in diameter is used; under these conditions the elements of this system (I and II) are completely suitable for use in a high-resolution prism mass spectrometer.

Differential electromagnetic characteristics at the interface between ice and water in the ocean

V. V. Bogorodskii and V. P. Tripol'nikov

Arctic and Antarctic Scientific-Research Institute, Leningrad

(Submitted July 31, 1973)
Zh. Tekh. Fiz., 44, 835-838 (April 1974)

Experimental data on the electromagnetic contrast of the interface between ice and water in the ocean are reported. The experiments were carried out on pack ice and ice one year old by the SP-19 drifting station through the use of video pulses of various length and radio pulses at 200 MHz.

A knowledge of the electromagnetic contrast at the interface between ice and water in the ocean is of fundamental importance for assessing the feasibility of radar sounding of ice formations in the ocean from various vehicles.

The power required for probing ice in the ocean is reported in ref. 1.

In calculations of the total loss it has been assumed that there is no electromagnetic matching between ice and water. The Fresnel reflection coefficient of an ice–water interface has been assumed equal to unity, since the modulus of the impedance of sea water is about 25 Ω, while that of ice is 180-220 Ω. This model is only approximate, and objections can be raised against it, since the complicated physical processes involved in the crystallization of sea water always provide a transitional ice layer having relatively high liquid-phase and salt content at the interface. It therefore becomes necessary to study the quantitative characteristics of the electromagnetic contrast between ice and water in the ocean under natural conditions.

An experimental study has been made of the electromagnetic contrast of the ice-water interface at the most typical formations of pack ice and 1-year ice in the Arctic.

Figure 1 shows the experimental arrangement. Two holes 10 mm in diameter, 10 cm apart, and parallel to each other are melted by a hot needle in the ice. Metal rods 5 mm in diameter with length greater than the thickness of the ice are inserted into the holes. The lower ends of these rods extend below the ice-water interface. After a certain time, the metal rods become frozen into the ice and form a two-conductor "ice" line with a characteristic impedance of about 200 Ω, short circuited by the sea water at the boundary of the ice. It has been established that this technique for preparing the holes does not alter the structure of the ice between the rods of the ice line. Then this line is sounded with video and radio pulses, through the use of an apparatus having an air delay line matched to the ice line (Fig. 1).

Figure 2 shows the pulses reflected from the short circuit of the ice line by the sea water and from a short circuit produced by the operator at the air–ice interface. These pulses are recorded through a multiple exposure of the film: First, the pulse reflected from the short circuit produced by the operator at the ice–air interface is recorded; then, with the camera shutter open, the short-circuit at the air end is removed, and the pulses due to reflection at the short circuit in the ice line are recorded. No additional amplification is used.

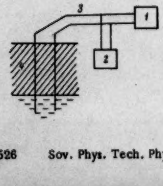

Fig. 1. Experimental apparatus for determining the electromagnetic contrast at the interface between ice and water in the ocean. 1) Oscillator; 2) detector; 3) delay line (400 nsec); 4) metal rods.

By comparing the signals reflected from the artificial short circuit at the air–ice interface with those reflected from the short circuit formed by the sea water we can evaluate the total loss in the ice line. This loss is due to absorption in the dielectric (natural sea water) and the loss due to reflection at the air–ice and ice–water interfaces. The latter can be adopted as a measure of the electromagnetic contrast at the lower boundary of the ice. Figure 3 shows the experimental values of the attenuation as a function of the ice thickness. Here the dashed curves correspond to the specified values of the specified absorption N (in decibels per meter). The measurements are carried out on pack ice many years old, with thickness up to 10 m, on 2-yr pack ice ranging in thickness from 2 to 3 m, and on young ice 1 m thick. The three groups are distinguished by different thickness distributions of the temperature and

22	8.04	6.0
32	7.98	1.8

*Number of grams of salts per kilogram of ice.

salinity.[2] Despite the variety in the general characteristics of these ice formations, the results found by sounding with video pulses 25 nsec long show that the specific absorption usually lies in the range 0.9-0.2 dB/m. The reflection coefficient at the lower interface can be assumed equal to unity; otherwise the curves of N (in decibels per meter) would intersect the ordinate at values above unity. This is also true for the radial pulses at 200 MHz, and the specific absorption in this case is 4-5 dB/m. In sounding the lines described above with radial pulses at 440 MHz, we have also verified the existence of an appreciable electromagnetic contrast at the ice-water interface (Fig. 2b). However, it is difficult to quantitatively evaluate this difference at 440 MHz in this line arrangement. The preparation of ice lines in which the conductors are closer together would require a more complicated drilling technique.

These results do not tell us whether the actual reflecting interface is the sea water proper or the upper boundary of the layer in which the highly concentrated brine appears. This question is of practical importance in radar measurements of the thickness of ice in the ocean. To study this question further we have carried out a radar sounding of an ice island (at the ST-19 drifting station). This ice island, a fragment of an ice shelf, has been floating in the Arctic basin for many years. Its thickness was measured during the thermal drilling and found to range from 28 to 34 m. Samples of the ice were removed for salinity tests from various depths, from cores obtained during the thermal drilling with an annular thermal drill. The temperature of the ice was also measured at various depths.1) Table 1 shows the temperatures and the salinities of the ice at certain depths.

Since the temperature at depths of 17 mm below is higher than the eutectic temperature for most salts in sea water, the presence of salts at these depths implies the presence of a liquid phase in the ice.

The relative content of the liquid phase increases with increasing temperature and increasing salinity of the ice.[3]

The radar sounding of the ice island was carried out at a frequency of 200 MHz, a pulse length of 50 nsec, and a locator potential of 140 dB.

The antennas, half-wave radiators, were embedded in the ice 25 m apart; their lengths were reduced by a factor of $(\varepsilon)^{1/2}$. The reflectors were pieces of sheet metal 1.5 × 1.5 m in size, mounted behind the antennas on the surface of the ice. The results of the probing are shown in Fig. 4. Here pulse 1 is the forward signal in the air, 2 is the forward signal in the ice, 3 is the signal reflected from the salinity boundary at a depth of 17 m, 4 are the reflections due to the discontinuity in salinity at depths on the order of 20-22 m, and 5 is the reflection from the bottom of the ice. This interpretation is supported, in particular, by the circumstance that the amplitudes of the reflected signals fall off with decreasing directionality of the antennas (Fig. 4). To calculate the depth of the first reflecting boundary we use the equation

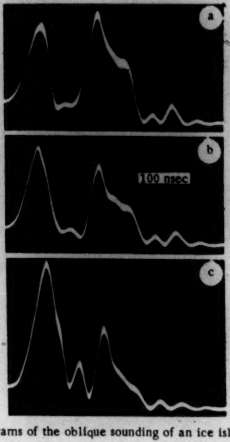

Fig. 4. Oscillograms of the oblique sounding of an ice island. a) Reflectors on both antennas; b) reflector on the transmitting antenna only; c) antennas without reflectors.

$$\Delta t = \frac{\sqrt{R^2 + (2H)^2}}{v} - \frac{R}{c},$$

where Δt is the delay of the reflected signal with respect to the forward signal in air, H is the height of the reflected boundary, c is the wave velocity in air, v is that in fresh-water ice (170 m/μsec), and R is the distance between antennas. To determine the depth of the lower boundary we use the approximate equation

$$2h \approx v_1 \Delta t_1,$$

where h is the thickness of the ice layer below the 17-m level, Δt_l is the delay between signals 3 and 5, and v_l is the wave velocity in the layer. If we assume the velocity in the layer to have an average value of[4] 100 m/μsec over the prevailing temperature and salinity distributions, we find a layer thickness of 11.5 m for the measured delay of Δt_l = 0.23 μsec. Accordingly, the total thickness of the ice according to the radar at our measurements is 28.5 m, in satisfactory agreement with the drilling results.

These experiments show that, despite the lack of contrast in terms of certain physical characteristics (e.g., the density and temperature), there is a good electromagnetic contrast between the layers in ice, which are characterized by variations in salinity and simultaneous variations in the relative amounts of liquid phase. Similar conditions arise at the lower boundary of ice in the ocean. In this connection, the signal received after the reflection from the lower boundary of the ice during radar sounding may begin to be formed slightly above this lower boundary: at the top of the transition layer. The thickness of this layer is governed by the temperature at the time of the ice formation as well as the temperature at the time of the radar sounding.

Evolution of monochromatic whistler and plasma-wave packets in a collisionless plasma

Ya. N. Istomin
Institute of Terrestrial Magnetism,
Ionosphere, and Radiowave Propagation,
Academy of Sciences of the USSR

(Submitted January 30, 1973)
Zh. Tekh. Fiz., 44, 839-840 (April 1974)

The evolution of wave packets is considered. The effect of the velocity spread on the electron distribution function is investigated. Expressions are found for the adiabatic invariants of the motion of the resonant particles taking the spread in velocity into account.

In refs. 1 and 2, the evolution of monochromatic wave packets (whistlers and plasma waves) due to the interaction with resonant particles is treated. This is a bounded problem, in contrast to the problem of the damping of an unbounded plane monochromatic wave.[3,4] A number of aspects of this problem are discussed in the present paper.

To be definite, we introduce the plasma-wave packet $E(x, t) = E_0(x, t) \sin (kx - \omega t + \varphi)$. We write the collisionless kinetic equation for the plasma electrons as

$$\frac{\partial f}{\partial t} + v\frac{\partial f}{\partial x} - \frac{eE_0(x, t)}{m}\sin(kx - \omega t + \varphi)\frac{\partial f}{\partial v} = 0. \tag{1}$$

In the nonlinear case [$\gamma_L \tau \ll 1$, where γ_L is the linear growth rate and τ is a characteristic oscillation time of the resonant particles, $\tau = (m/eE_0k)^{1/2}$], the wave amplitude $E_0(x, t)$ changes very slowly with time and it is therefore convenient to go over from the variables t, x, and v in (1) to the new independent variables: x, $2\xi = kx - \omega t + \varphi$, $2\dot{\xi} = kv - \omega$, and

$$\left(v_0 + \frac{2}{k}\dot{\xi}\right)\frac{\partial f}{\partial x} + \dot{\xi}\frac{\partial f}{\partial \xi} - \frac{1}{2\tau^2}\sin 2\xi\frac{\partial f}{\partial \dot{\xi}} = 0, \tag{2}$$

where $v_0 = \omega/k$ is the phase velocity. A similar kinetic equation is obtained for whistlers by introducing the analogous variables defined by Eq. (2.5) of ref. 1. In this reference, the divergence of the resonant particles is neglected, i.e., the first term in the kinetic equation (2) is written as $v_0 \partial f/\partial x$. The solution to (2) is found here without this simplification.

If the packet is rectangular, i.e., τ is constant in the packet, the particles move in such a way that the quantity $\varkappa = (\tau^2\dot{\xi}^2 + \sin^2 \xi)^{-1/2}$ is conserved. If $|\varkappa| < 1$, the particle is free and if $|\varkappa| > 1$, the particle is trapped by the wave. We now find the average values over x of the particle velocity and the square of this velocity for the cases above:

$$\bar{\psi} = \frac{\int \psi dx}{\int dx} = \frac{\int \psi\left(v_0 + \frac{2}{k}\dot{\xi}\right)\frac{d\xi}{\dot{\xi}}}{\int\left(v_0 + \frac{2}{k}\dot{\xi}\right)\frac{d\xi}{\dot{\xi}}},$$

$$\bar{\dot{\xi}} = \frac{\pi}{2\tau\varkappa K(\varkappa)}\,\frac{1 + \frac{4E(\varkappa)}{\pi k v_0 \tau\varkappa}}{1 + \frac{\pi}{kv_0\tau\varkappa K(\varkappa)}}, \quad \bar{\dot{\xi}^2} = \frac{E(\varkappa)}{\tau^2\varkappa^2 K(\varkappa)}\,\frac{1 + \frac{\pi}{kv_0\tau\varkappa E(\varkappa)}}{1 + \frac{\pi}{kv_0\tau\varkappa K(\varkappa)}}; \; |\varkappa| < 1,$$

$$\bar{\dot{\xi}} = \frac{2}{kv_0\tau^2}\,\frac{E\left(\frac{1}{\varkappa}\right) - (1 - \varkappa^{-2})K\left(\frac{1}{\varkappa}\right)}{K\left(\frac{1}{\varkappa}\right)}, \quad \bar{\dot{\xi}^2} = \frac{kv_0}{2}\bar{\dot{\xi}}; \quad |\varkappa| > 1, \tag{3}$$

K(ϰ) and E(ϰ) are elliptical integrals of the first and second kinds. We note that the expressions for the average quantities in the bounded problem are different from those in the initial-value problem by a quantity of the order of $1/kv_0\tau$, i.e., by the ratio of the spread in velocities $1/k\tau$ to the phase velocity. This difference is due to the fact that the oscillation period of the resonant particles depends only on τ and on the energy (i.e., on $\varkappa$) while the spatial period also depends on the particle velocity.

We now find the distribution function $f(x, \xi, \dot{\xi})$. From Liouville's theorem we obtain

$$f(x, \xi, \dot{\xi}) = f(0, \xi_0(x, \xi, \dot{\xi}), \; \dot{\xi}_0(x, \xi, \dot{\xi})), \tag{4}$$

where the right side contains the distribution function at the origin of the packet (x = 0). Assuming that $1/k\tau \ll v_T$, we expand v_0 in powers of $\dot{\xi}_0$ and limit ourselves to the first two terms:

$$f(x, \xi, \dot{\xi}) = f_0(v_0) + f_0'(v_0)\frac{2}{k}\dot{\xi}_0(x, \xi, \dot{\xi}), \tag{5}$$

where f_0 is the unperturbed distribution function.

Complete phase mixing of the particles takes place in a time of the order of a few τ, and a so-called ergodic state is established.[4] In order to find this ergodic distribution function, we substitute the average velocity $\bar{\dot{\xi}}$ into (5). Owing to the fact that $\bar{\dot{\xi}}$ contains a small correction which is even in $\varkappa$, the average resonant particle density over a wave period

$$\frac{2}{\pi k}\int\limits_{-\pi/2}^{\pi/2} d\xi \int\limits_{-\infty}^{\infty} (f - f_0)\, d\dot{\xi}$$

is nonzero. Knowing the particle distribution function, we can easily show that

$$\int\limits_{-\pi/2}^{\pi/2} d\xi \int\limits_{-\infty}^{\infty} (f - f_0)\, d\dot{\xi} = -\frac{2}{kv_0}\int\limits_{-\pi/2}^{\pi/2} d\xi \int\limits_{-\infty}^{\infty} (f - f_0)\,\dot{\xi}\, d\dot{\xi}. \tag{6}$$

Equation (6) is a result of the continuity condition, which can be obtained directly from the kinetic equation (2).

We consider a long packet ($l \gg v_0\tau$) of arbitrary shape. We will show how, even in this case, corrections which are even functions of the velocity appear in the distribution function as a result of the spread in velocity of the resonant particles. If the amplitude changes, the magnitude of $\varkappa$ is altered. However, as in ref. 1, we can find the adiabatic invariants.

$$\left.\begin{aligned} &\frac{E(\varkappa)}{\varkappa\tau}+\frac{\pi}{2kv_0\tau^2}\left(\frac{1}{\varkappa^2}-\frac{1}{2}\right)=\text{const}, \quad |\varkappa|<1; \\ &\frac{E\left(\frac{1}{\varkappa}\right)-(1-\varkappa^{-2})K\left(\frac{1}{\varkappa}\right)}{\tau}\equiv\frac{\nu(\varkappa)}{\tau}=\text{const}, \quad |\varkappa|>1. \end{aligned}\right\} \tag{7}$$

By using (7), we can easily find the distribution function for the particles in transit:

$$f(x,\varkappa)=f_0(v_0)+f_0'(v_0)\frac{2}{k}\left\{\frac{2}{\pi}\frac{E(\varkappa)}{\varkappa\tau}+\frac{1}{2kv_0\tau^2}\left[\frac{1}{\varkappa^2}-\frac{1}{2}-\frac{4}{\pi^2}\frac{E^2(\varkappa)}{\varkappa^2}\right]\right\}. \tag{8}$$

In order to find the distribution function for the trapped particles we recall that into a given region of the phase space of these particles, there enter particles which were originally in two different regions of transit-particle phase space, i.e., the regions $\varkappa_0^+ > 0$ and $\varkappa_0^- < 0$. We make use of the differential form of the particle conservation law (see ref. 5):

$$\begin{aligned} f(x,\xi)\left(v_0+\frac{2}{k}\xi\right)d\xi d\xi &= f(0,\xi_0^+)\left(v_0+\frac{2}{k}\xi_0^+\right)d\xi d\xi_0^+ \\ &+ f(0,\xi_0^-)\left(v_0+\frac{2}{k}\xi_0^-\right)d\xi d\xi_0^-. \end{aligned} \tag{9}$$

Transforming to the variables ξ and $\varkappa$, integrating (9) over ξ and using (7), we obtain

$$\begin{aligned} f(x,\nu) &= \frac{1}{2}f(0,\varkappa_0^+)\left(1+\frac{\pi\nu}{2kv_0\tau}\right)+\frac{1}{2}f(0,\varkappa_0^-)\left(1-\frac{\pi\nu}{2kv_0\tau}\right) \\ &= f_0(v_0)+\frac{2}{k}f_0'(v_0)\frac{\nu^2}{kv_0\tau^2}\left(\frac{3}{2}-\frac{4}{\pi^2}\right). \end{aligned} \tag{10}$$

To get a closed equation for the amplitude of the packet we use conservation of energy:

$$\frac{\partial}{\partial t}\left(\frac{E_0^2}{8\pi}\right)+\frac{\partial}{\partial x}I=0, \tag{11}$$

where I is the energy flux of the resonant particles:

$$I=\frac{m}{\pi k}\int_{-\pi/2}^{\pi/2}d\xi\int_{-\infty}^{\infty}(f-f_0)\left(v_0+\frac{2}{k}\xi\right)^3 d\xi.$$

Using (6) we get

$$I=\frac{2m}{\pi k}v_0\int_{-\pi/2}^{\pi/2}d\xi\int_{-\infty}^{\infty}(f-f_0)\frac{2}{k}\xi d\xi. \tag{12}$$

Substituting (8) and (10) into (12), and then (12) into (11), we obtain the equation

$$\frac{\partial E_0}{\partial t}-C(E_0)\frac{\partial E_0}{\partial x}=0,$$

where $C(E_0)$ is identical with expression (5.11) from ref. 1. Thus allowance for the term $2\xi/k$ in (2) does not affect the form of the final equation for the field as obtained in ref. 1. This is because the inclusion of this term leads to even corrections in the distribution function and these do not make any contribution to the integral (12).

The author is grateful to V. I. Karpman for suggesting the problem and for useful discussions.

Diffraction of a plane electromagnetic wave by a conducting plane with a projection

A. A. Zilbergleit

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad

(Submitted August 6, 1973)
Zh. Tekh. Fiz., 44, 841-844 (April 1974)

The diffraction of an E-polarized electromagnetic wave incident at an arbitrary angle on a conducting plane with a perpendicular projection of height a is discussed. The dual integral equations of the problem are reducted to a Fredholm integral equation of the second kind with a symmetric kernel, which is solved by an expansion in terms of the small parameter $(ka)^{-1} \ll 1$, where $k = 2\pi/\lambda$ is the wave number, which corresponds to short waves. Equations are derived for the current density and the coefficient of scattering from the projection, and asymptotic expansions of these quantities which are applicable for any angle of incidence are found.

A method for solving certain problems in the diffraction of short waves based on the use of dual integral equations was proposed recently.[1,2] We employ a variation of this method to solve the problem of the diffraction of a plane electromagnetic wave by a conducting plane with a projection. Equations are obtained for the current density on the projection and for the scattering factor, and the short-wave asymptotic forms of these quantities are presented.

1. Suppose a plane wave polarized with its E vector along OZ is incident on the system shown in Fig. 1 at the angle of incidence γ, $0 < \gamma \leq \pi/2$. The calculation of the plane field produced is reduced to finding the function $E_z = E(x, y)$:

$$\Delta E + k^2 E = 0, \quad -\infty < x < \infty, \quad 0 < y < \infty \tag{1}$$

where $k = 2\pi/\lambda$ is the wave number. The solution of Eq. (1) which goes to zero at infinity and vanishes at y = 0 has the form

$$E(x, y) = E_0 \Big\{ e^{ik(x\cos\gamma + y\sin\gamma)} - e^{ik(x\cos\gamma - y\sin\gamma)} - 2i \int_0^\infty A(\nu)\, e^{\mp x\sqrt{\nu^2 - k^2}} \sin \nu y\, d\nu \Big\}, \quad x \gtrless 0. \tag{2}$$

By using (2) to satisfy the condition on the projection and the requirement of the continuity of $\partial E/\partial x$ on the ray $x = 0$, $a < y < \infty$, and making the substitutions

$$A(\nu) = \frac{2}{\pi} f(\nu) - N(\nu), \quad \varkappa = k \sin\gamma, \tag{3}$$

$$f(\nu) = \frac{k}{2} \Big\{ \frac{(\varkappa - \nu)\cos(\varkappa - \nu)a + k \sin(\varkappa - \nu)a}{(\varkappa - \nu)[k^2 + (\varkappa - \nu)^2]} - \frac{(\varkappa + \nu)\cos(\varkappa + \nu)a + k\sin(\varkappa + \nu)a}{(\varkappa + \nu)[k^2 + (\varkappa + \nu)^2]} \Big\} \tag{4}$$

we obtain the dual integral equations for $N(\nu)$:

$$\int_0^\infty N(\nu) \sin \nu y\, d\nu = 0, \quad 0 < y < a; \tag{5}$$

$$\int_0^\infty N(\nu) \sqrt{\nu^2 - k^2} \sin \nu y\, d\nu = g(y), \quad a < y < \infty, \tag{6}$$

where

$$g(y) = \frac{2}{\pi} \int_0^\infty f(\nu) \sqrt{\nu^2 - k^2} \sin \nu y\, d\nu. \tag{7}$$

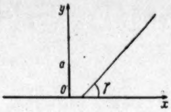

Fig. 1

2. When $ka \gg 1$ we seek the solution of Eqs. (5) and (6) in the form

$$N(\nu) = \sqrt{\frac{ik}{\pi}} \int_a^\infty \psi(t) \Big[\frac{e^{i\nu t}}{\sqrt{k - \nu}} - \frac{e^{-i\nu t}}{\sqrt{k + \nu}} \Big] dt. \tag{8}$$

Here, $\psi(t)$ is a continuous differentiable function for $a < t < \infty$; it is to be determined so that $\psi(t) \to 0$ as $t \to \infty$. Starting from the relations on p. 201 of ref. 3

$$\frac{i}{\sqrt{\pi}} \int_0^\infty \Big[\frac{e^{i\nu t}}{\sqrt{i(k - \nu)}} - \frac{e^{-i\nu t}}{\sqrt{i(k + \nu)}} \Big] \sin \nu x\, d\nu = \begin{cases} 0, & x < t, \\ -\dfrac{e^{-ik(x-t)}}{\sqrt{x - t}}, & x > t, \end{cases} \tag{9}$$

$$\frac{i}{\sqrt{\pi}} \int_0^\infty \Big[\frac{e^{i\nu t}}{\sqrt{i(k + \nu)}} - \frac{e^{-i\nu t}}{\sqrt{i(k - \nu)}} \Big] \sin \nu x\, d\nu = \begin{cases} \dfrac{e^{-ik(t+x)}}{\sqrt{t + x}} - \dfrac{e^{-ik(t-x)}}{\sqrt{t - x}}, & x < t, \\ \dfrac{e^{-ik(t+x)}}{\sqrt{t + x}}, & x > t, \end{cases} \tag{10}$$

it can be shown that Eq. (8) satisfies (5) identically, and it follows from (6) that $\psi(t)$ is the solution of a Fredholm integral equation of the second kind with a symmetric kernel. After transformation to the dimensionless quantities

$$\tau = t/a; \quad \psi(\tau) = \psi(t)$$

$$\Psi(\tau) = e^{-ka(\tau - 1)} [v_+ e^{i\varkappa a\tau} + v_- e^{-i\varkappa a\tau}] \tag{11}$$

the latter takes the form

$$+ \frac{ka}{2} \int_1^\infty \Psi(\sigma) [H_0^{(2)}(ka(\tau + \sigma)) + iH_1^{(2)}(ka(\tau + \sigma))]\, d\sigma, \quad 1 \leqslant \tau < \infty; \tag{12}$$

$$v_\pm(\gamma) = 0.5 (1 + i \pm \sin\gamma)^{1/2} (\pi i)^{-1/2}. \tag{13}$$

Solving (12) by the method of asymptotic iteration ($ka \gg 1$) gives

$$\Psi(\tau) = \Psi_+(\tau) + \Psi_-(\tau); \quad \varphi_\pm(\gamma) = 1 \pm \sin\gamma;$$

$$\Psi_\pm(\tau) = v_\pm \Big[e^{\pm i\varkappa a\tau - ka(\tau - 1)} + \frac{1}{(ika)^{1/2}} \frac{e^{-ika\tau}}{(\tau + 1)^{1/2}} \frac{e^{-ika\varphi_\mp}}{2\sqrt{2\pi}(i - \varphi_\mp)} + \ldots \Big]. \tag{14}$$

Equations (2)-(4), (8), and (14) completely determine the solution of the problem.

3. We calculate the current density $j_z(y)$ induced on the projection. Starting with the expression

$$j_z(y)=\frac{c}{4\pi ik}\left[\frac{\partial E}{\partial x}\bigg|_{x\to+0}-\frac{\partial E}{\partial x}\bigg|_{x\to-0}\right],\quad 0<y<a \tag{15}$$

we use (2), (3), and (8)-(10) to find

$$\begin{aligned}j_z(y)=\frac{cE_0}{\pi}\Bigg\{&k^{-1}g(y)+k^{-3/2}\psi(a)\left[\frac{e^{-ik(a+y)}}{\sqrt{a+y}}-\frac{e^{-ik(a-y)}}{\sqrt{a-y}}\right]\\&+k^{-1/2}\int\limits_a^\infty(e^{-ikt}\psi(t))'\left[\frac{e^{-iky}}{\sqrt{t+y}}-\frac{e^{iky}}{\sqrt{t-y}}\right]dt\Bigg\},\quad 0<y<a.\end{aligned} \tag{16}$$

Setting

$$\eta=y/a,\quad j_z(y)=j(\eta) \tag{17}$$

and using (14) we obtain the asymptotic formula

$$\begin{aligned}j(\eta)={}&\frac{cE_0}{\pi}\left(i\cos\gamma\left[\sin\varkappa a\eta-0.5e^{-ka(1-\eta)+i\varkappa a\eta}\right]+j_+(\eta)+j_-(\eta)\right);\\ j_\pm(\eta)={}&v_\pm\Bigg\{e^{ka(1-\eta)\pm i\varkappa a}\sqrt{\pi i(\varphi_\mp-i)}\left[1-\Phi\left(\sqrt{ika(\varphi_\mp-i)(1-\eta)}\right)\right]\\&+\frac{e^{-ika(\eta+\varphi_\mp)+i\pi/4}}{2(ika)^{1/2}(1+\eta)^{3/2}(i-\varphi_\mp)}\left[1-\Phi\left(\sqrt{2ika(1-\eta)}\right)\right]\\&-\frac{e^{-ika(1+\eta)\pm i\varkappa a+i\pi/4}}{2(ika)^{3/2}(1+\eta)^{3/2}(i-\varphi_\mp)}\\&-\frac{e^{-ika(1-\eta)\pm i\varkappa a+i\pi/4}}{(ika)^{1/2}(1-\eta)^{1/2}}+\ldots\Bigg\},\end{aligned} \tag{18}$$

where $\Phi(z)$ is the probability integral.

Equation (18) is valid for all η, $0<\eta<1$, and is simplified if η lies in the range $0<\eta\le\eta_0<1$.

4. We find the coefficient of scattering from the projection. The average power scattered per unit length is related to the current density $j_z(y)$ by the equation

$$P=2E_0\operatorname{Im}\int\limits_0^a j_z(y)\sin\varkappa y\,dy, \tag{19}$$

which gives P in terms of $\bar{\psi}(\tau)$:

$$\begin{aligned}P=\frac{E_0^2ac}{\pi}\operatorname{Im}\Bigg\{&2k^{-1}\int\limits_0^1 g(a\eta)\sin\varkappa a\eta\,d\eta-\sqrt{\frac{\pi}{i}}\\&\times\int\limits_1^\infty\bar{\psi}(\tau)\Big(\sqrt{\varphi_-}e^{-i\varkappa a\tau}\left[\Phi\left(\sqrt{ika\varphi_-(\tau+1)}\right)-\Phi\left(\sqrt{ika\varphi_-(\tau-1)}\right)\right]\\&-\sqrt{\varphi_+}e^{i\varkappa a\tau}\left[\Phi\left(\sqrt{ika\varphi_+(\tau+1)}\right)-\Phi\left(\sqrt{ika\varphi_+(\tau-1)}\right)\right]\Big)\,d\tau\\&-\frac{2\sin\varkappa a}{\sqrt{ka}}\int\limits_1^\infty\bar{\psi}(\tau)\left[\frac{e^{-ika(\tau+1)}}{\sqrt{\tau+1}}+\frac{e^{-ika(\tau-1)}}{\sqrt{\tau-1}}\right]d\tau\Bigg\}.\end{aligned} \tag{20}$$

Defining the scattering coefficient by the expression

$$R=\frac{P}{P_0};\qquad P_0=\frac{E_0^2ac}{\pi}, \tag{21}$$

we obtain the asymptotic expansion

$$\begin{aligned}\frac{R}{2}={}&\cos\gamma+\frac{R^{(1)}}{ka}+\frac{R^{(2)}}{(ka)^{3/2}}+\ldots;\\ R^{(1)}={}&-0.5\,(\cos\gamma-\operatorname{ctg}\gamma\,(1+4\sin^2\gamma)^{-1}[2\sin\gamma\cos2\varkappa a\\&-(1+2\sin^2\gamma)\sin2\varkappa a])\\&+\operatorname{Im}(2i)^{-1}\Big(\sqrt{(1-i\varphi_+)(1+i\varphi_-)}\left[1-e^{2i\varkappa a}(1-2i\sin\gamma)^{-1}\right]\\&-\sqrt{(1-i\varphi_-)(1+i\varphi_+)}\left[1-e^{-2i\varkappa a}(1+2i\sin\gamma)^{-1}\right]\\&+\sqrt{i\varphi_+}\,\Phi\left(\sqrt{2ika\varphi_+}\right)\left[\sqrt{1-i\varphi_-}+\sqrt{1-i\varphi_+}e^{2i\varkappa a}(1-2i\sin\gamma)^{-1}\right]\\&+\sqrt{i\varphi_-}\,\Phi\left(\sqrt{2ika\varphi_-}\right)\left[\sqrt{1-i\varphi_+}+\sqrt{1-i\varphi_-}e^{-2i\varkappa a}(1+2i\sin\gamma)^{-1}\right]\Big).\end{aligned} \tag{22}$$

The expansion (22) is applicable for all angles of incidence, $0<\gamma\le\pi/2$; for $\pi/2-\gamma_0\le\gamma\le\pi/2$, and for $0<\gamma\le\eta_0<\pi/2$ the expressions for the coefficients $R^{(n)}$ can simplified. Thus

$$\left.\begin{aligned}R^{(1)}\left(\gamma=\frac{\pi}{2}\right)=-0.5\left[1-(20)^{-1/4}\sin\left(2ka+\frac{a}{2}-\frac{\pi}{4}\right)\right],\\ a=\operatorname{arc\,tg}2,\end{aligned}\right\} \tag{23}$$

and for $0<\gamma\le\gamma_0<\pi/2$ we have

$$\begin{aligned}R^{(1)}=-0.5\Bigg\{&\cos\gamma-\operatorname{ctg}\gamma\,(1+4\sin^2\gamma)^{-1}[\sin\gamma\cos2\varkappa a\\&-(1+2\sin^2\gamma)\sin2\varkappa a]\\&+\sqrt{\varphi_+\rho_-}\sin\left(\frac{\beta_-}{2}+\frac{\pi}{4}\right)-\sqrt{\varphi_-\rho_+}\sin\left(\frac{\beta_+}{2}+\frac{\pi}{4}\right)\\&-(1+4\sin^2\gamma)^{-1/2}\Bigg[\sqrt{\varphi_+\rho_+}\sin\left(2\varkappa a+\theta-\frac{\beta_+}{2}-\frac{\pi}{4}\right)\\&+\sqrt{\varphi_-\rho_-}\sin\left(2\varkappa a+\theta+\frac{\beta_-}{2}+\frac{\pi}{4}\right)\Bigg]\Bigg\}.\end{aligned} \tag{24}$$

where

$$\left.\begin{aligned}\rho_\pm(\gamma)=[1+(1\pm\sin\gamma)^2]^{1/2};\quad\beta_\pm(\gamma)=\operatorname{arc\,tg}(1\pm\sin\gamma);\\ \theta(\gamma)=\operatorname{arc\,tg}(2\sin\gamma).\end{aligned}\right\} \tag{25}$$

These results may be of interest for the theory of propagation of radio waves around the irregular surface of the earth (cf., e.g., ref. 4 and the bibliography listed there).

Reflection of electromagnetic waves by a moving plasma

V. I. Miroshnichenko

(Submitted June 27, 1973)
Zh. Tekh. Fiz., 44, 844-847 (April 1974)

The kinetic theory of the reflection of electromagnetic waves from a moving plasma in a homogeneous magnetostatic field H_0 perpendicular to the boundary is discussed. It is assumed that the incident wave is slowed down by a plasma which fills all space. The general form of the field penetrating the reflecting plasma is determined under the assumption of a sharp boundary of the reflecting plasma and the diffusion character of the reflection of electrons from the boundary. The coefficient of reflection of the incident electromagnetic wave is calculated.

The reflection of electromagnetic waves by a semibounded moving plasma under the assumption that the incident wave is slowed down by a stationary plasma filling all of space in a steady uniform magnetic field H_0 parallel to the velocity v_0 of the reflecting plasma is treated in ref. 1. The boundary of the reflecting plasma is assumed to be sharp, and the boundary condition for the high-frequency contribution to the equilibrium electron distribution function is taken as[2]

$$f(0,\, v_z) = pf(0,\, -v_z). \tag{1}$$

Then, as shown in ref. 1, the initial system of equations, consisting of Maxwell's equations for the electromagnetic field, the equation of motion of the electrons of the moderating plasma, and the kinetic equation for the high-frequency contribution to the equilibrium distribution function of the electrons in the reflecting plasma, can be reduced to a single integrodifferential equation for the intensity of the electric field

$$\frac{d^2E}{dz^2} + k^2E = -k^2\Bigg\{\int_0^{+\infty} k_1(|z-z'|)E(z')dz' + p\int_0^{+\infty} k_1(z+z')E(z')dz' + \int_0^{z} k_2(z-z')\Big[E(z') + \frac{iV_0}{\omega}\frac{\partial E(z')}{\partial z'}\Big]dz' + F(z)\Bigg\}, \tag{2}$$

where we have introduced the notation

$$k_1(z) = \frac{i\omega_{01}^2}{\sqrt{\pi}\,\omega v_T}\int_0^{+\infty}\frac{dv_z}{v_z}\exp\Big[-\frac{v_z^2}{v_T^2} + \frac{i}{v_z}(\omega + i\nu_1 - \omega_H)z\Big],$$

$$k_2(z) = \frac{i\omega_{02}^2}{\omega V_0}\exp\Big[\frac{i}{V_0}(\omega + i\nu_2 - \omega_H')z\Big],$$

$$F(z) = -\frac{im\gamma_0\omega_{02}^2 u(0)}{e\omega}\exp\Big[\frac{iz}{V_0}(\omega + i\nu_2 - \omega_H')\Big], \quad \omega_H' = \omega_H\sqrt{1-\beta^2} \equiv \omega_H\gamma_0^{-1},$$

$E = E_x - iE_y$, $u = u_x - iu_y$, and u(0) is the value of the transverse high-frequency velocity of the electrons of the retarding plasma at the reflector boundary, and the remaining notation is standard. Equation (2) is solved in ref. 1 for specular reflection of electrons from the boundary (p = 1).

In this note we present the solution of Eq. (2) for diffuse reflection of electrons from the boundary when p = 0.

To solve Eq. (2) in this case we introduce functions $\bar{E}(x)$ and $\bar{F}(z)$, which coincide with E(z) and F(z) for $z \geq 0$, and are zero for $z < 0$,

$$\bar{E}(z) = \begin{cases} E(z) & z \geqslant 0, \\ 0 & z < 0, \end{cases} \quad \bar{F}(z) = \begin{cases} F(z) & z \geqslant 0, \\ 0 & z < 0. \end{cases} \tag{3}$$

It is convenient to continue the kernel $k_1(z)$ of the integral equation (2) onto the left semiaxis by defining it to be even, $k_1(z) = k_1(-z)$, and to take $k_2(z)$ to be zero.

The function $\bar{E}(z)$ introduced in this way is expanded in a Fourier integral:

$$\bar{E}(z) = \frac{1}{2\pi}\int_{-\infty}^{+\infty}\mathcal{E}(t)e^{itz}dt, \quad \mathcal{E}(t) = \int_0^{+\infty}E(z)e^{itz}dz \tag{4}$$

and used with Eq. (2) to obtain the relation

$$\int_{-\infty}^{+\infty}\{[t^2 - k^2\varepsilon(t)]\mathcal{E}(t) + f(t)\}e^{itz}dt = 0 \quad (z \geqslant 0), \tag{5}$$

where

$$\begin{gathered}\varepsilon(t) = 1 + k_1(t) + \frac{\omega - tV_0}{\omega}k_2(t), \\ f(t) = k^2\Big[E'(0) + itE(0) + \frac{iV_0}{\omega}k_2(t)E(0) - F(t)\Big], \\ k_1(t) = \frac{i\sqrt{\pi}\,\omega_{01}^2}{\omega v_T|t|}\exp\Big[-\Big(\frac{\omega-\omega_H}{tv_T}\Big)^2\Big] - \frac{\omega_{01}^2}{\omega(\omega-\omega_H)}\varphi\Big(\frac{\omega-\omega_H}{tv_T}\Big), \\ \varphi(t) = 2te^{-t^2}\int_0^t e^{x^2}dx, \quad k_2(t) = -\frac{\omega_{02}^2}{\omega(\omega + i\nu_2 - \omega_H' - tV_0)}, \\ F(t) = \frac{m\gamma_0 V_0 u(0)}{e}\,\frac{\omega_{02}^2}{\omega(\omega + i\nu_2 - \omega_H' - tV_0)}\end{gathered} \tag{6}$$

E(0) and E'(0) are the values of the electric field and its derivative on the boundary of the reflecting plasma.

It follows from Eq. (5) and the lemma of ref. 3 that the part of the integrand in (5) in the braces is the limiting value along the axis $-\infty < t < \infty$ of the function $\Phi^+(t)$, analytic in the upper half-plane of the complex variable

$$\left.\begin{aligned}\Delta(t)\mathcal{E}(t) + f(t) = \Phi^+(t) \quad (-\infty < t < +\infty), \\ \Delta(t) \equiv t^2 - k^2\varepsilon(t).\end{aligned}\right\} \tag{7}$$

According to (4), $\mathcal{E}(t)$ is the limiting value along the real axis of a function analytic in the lower half-plane, $\mathcal{E}(t) = \Phi^-(t)$; thus, the solution of Eq. (5) can be reduced to the solution of the following inhomogeneous Hilbert problem for two functions:[4,5]

$$\Phi^+(t) = \Delta(t)\Phi^-(t) + f(t) \quad (-\infty < t < +\infty). \tag{8}$$

It can be shown[1] that the index of Δ(t), defined as 1/2π times the increment of the argument of Δ(t) as t varies from −∞ to +∞,

$$n = \frac{1}{2\pi}\arg\Delta(t)\Big|_{-\infty}^{+\infty} \tag{9}$$

is zero in the sub-Cerenkov case, for which the inequality

$$1-\beta^2\left[1-\frac{\omega_{01}^2}{\omega(\omega-\omega_H)}\right]>0, \tag{10}$$

is satisfied.

The solution of the boundary-value problem (8) is standard, and we give the final result:

$$\mathcal{E}(t)=-\frac{f(t)}{2\Delta(t)}+\frac{\Phi_0^+(t)}{2\pi i}\int\limits_{-\infty}^{+\infty}\frac{f(\tau)\,d\tau}{\Phi_0^+(\tau)(\tau-t)}+P(t)\,\Phi_0^-(t), \tag{11}$$

where

$$\left.\begin{aligned}&\Phi_0^+(t)=(t+ia)\sqrt{g(t)}\,H(t),\quad \Phi_0^-(t)=\frac{H(t)}{(t-ia)\sqrt{g(t)}},\\&H(t)=\exp\left[\frac{1}{2\pi i}\int\limits_{-\infty}^{+\infty}\frac{\log g(\tau)\,d\tau}{\tau-t}\right],\quad g(t)=\frac{\Delta(t)}{t^2+a^2},\quad a>0,\end{aligned}\right\} \tag{12}$$

P(t) is a polynomial to be determined.

By comparing the asymptotic forms of the left- and right-hand sides of Eq. (11),

$$\mathcal{E}(t)=\frac{E(0)}{it}+\frac{E'(0)}{(it)^2}+\ldots, \tag{13}$$

we find that in our case the polynomial P(t) is a constant $P(t) = -i\,E(0)$.

Equations (11), (12), and (4) enable us to determine the general form of the field penetrating into the plasma half-space for diffuse reflection of electrons from the boundary.

By comparing the asymptotic forms of the left-and right-hand sides of Eq. (11) to terms of the order t^{-2} we establish the following relation between the field and its derivative at the plasma boundary:

$$E'(0)=CE(0)+D\left[E(0)-\frac{i\omega m\gamma_0}{e}u(0)\right], \tag{14}$$

$$C=-\left[a+\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty}\log g(t)\,dt\right],$$

$$D=\frac{i\omega_{02}^2}{c^2}\frac{1}{\Phi_0^+(t)},\quad t_0=\frac{\omega+i\nu_2-\omega_H'}{V_0},\quad a>0.$$

We note that in the absence of a moderator ($\omega_{02} = 0$) and for an external magnetic field $H_0 = 0$ Eq. (14) reduces to the result obtained earlier.[6]

The coefficient of reflection of an electromagnetic wave from the plasma half-space considered can be determined by adding to Eq. (14) the continuity conditions for the tangential components of the electric field E, the magnetic field H, and the transverse high-frequency velocity u of the electrons of the moderating plasma. Using Maxwell's equations and the equations of motion these can be written in the form

$$\left.\begin{aligned}E_i+E_r&=E(0))\\k_i'E_i+k_r'E_r&=-iE'(0),\\\frac{\omega_H'}{\omega-k_i'V_0-\omega_H'}E_i+\frac{\omega_H'}{\omega-k_r'V_0-\omega_H'}E_r&=-\left[E(0)-\frac{im\gamma_0\omega}{e}u(0)\right].\end{aligned}\right\} \tag{15}$$

Then the reflection coefficient is given by the following general expression:

$$\left.\begin{aligned}R=\frac{E_r}{E_i}=-\left[1-\frac{ik_i'}{C}-\frac{\omega_H'}{\omega-k_i'V_0-\omega_H'}\frac{D}{C}\right],\\\left[1-\frac{ik_r'}{C}-\frac{\omega_H'}{\omega-k_r'V_0-\omega_H'}\frac{D}{C}\right]^{-1}\end{aligned}\right\} \tag{16}$$

C and D are determined by (14). We give the expression for the reflection coefficient R for the case of a "super-anomalous" skin when the relation

$$\frac{\omega_{01}v_T}{\omega c}\gg 1 \tag{17}$$

is satisfied.

In this case the values of C and D are

$$C\simeq\left(-1+\frac{i}{\sqrt{3}}\right)\left(\frac{\sqrt{\pi}\,\omega_{01}^2}{\omega^2\beta_T}\right)^{1/3}\frac{\omega}{c},\quad D\simeq\frac{\omega_{02}^2}{\omega_{01}c}. \tag{18}$$

Substituting the values of C and D from (18) into (16) gives for the reflection coefficient R

$$R=-\left[1+\frac{3}{4}\left(i-\frac{1}{\sqrt{3}}\right)\frac{1}{\beta_0}\left(\frac{\omega^2\beta_T}{\sqrt{\pi}\,\omega_{01}^2}\right)^{1/3}\right.$$
$$\left.+\frac{3}{4}\left(1+\frac{i}{\sqrt{3}}\right)\left(\frac{\omega^2\beta_T}{\sqrt{\pi}\,\omega_{01}^2}\right)^{1/3}\frac{\omega_{02}^2}{\omega\omega_{01}}\frac{\omega_H}{\omega_i-\omega_H}\right]. \tag{19}$$

The second term of Eq. (19) is due to the absorption of part of the energy of the incident electromagnetic wave by electrons of the reflecting plasma having a thermal spread. A comparison of this term with the analogous term of Eq. (50) of ref. 1, where specular reflection of electrons from the boundary is assumed, shows that they differ only by a numerical factor.

The second term in Eq. (19) is related to the part of the part of the electromagnetic wave energy which penetrates the reflecting plasma due to the penetration of the moderating plasma into the reflecting plasma. For diffuse reflection of electrons from the boundary this term is $(\omega_{01}/\omega)\beta_T$ ($\gg 1$) times as large as for specular reflection.

In conclusion the author thanks Ya. B. Fainberg for a discussion of the results of this paper.

A useful function in the thermodynamics of irreversible processes

A. V. Pamfilov, A. I. Lopushanskaya, and L. B. Tsvetkova
Chernovtsy State University
Thernopol' Finance-Economics Institute

(Submitted April 2, 1973)
Zh. Tekh. Fiz., 44, 848-851 (April 1974)

It is shown on the basis of the time axiom and the integrability theorem that the difference of the functions F_2-F_1 gives the part of the entropy production due to the change in thermodynamic forces. The quantity $\sum\limits_{i=1}^{n}\int\limits_{0}^{x_i} I_i\,dX_i$ which is derived contains the thermodynamic forces and coefficients with two and three indices which are functions of the state parameters and which can be written in terms of measurable quantities.

The two most familiar methods of nonequilibrium thermodynamics which go beyond the scope of the linear relations are the approach based on the time axiom and a theorem of integrability[1] and an approach which does not adopt the principle of a local equilibrium.[2] In the first approach, the function F is adopted as the basic function; knowledge of this function for forward and reverse processes is sufficient for describing the time behavior of a system

Using F, we can state a system of n time axioms characterizing the simultaneous occurrence of n processes.

For processes i and k, e.g., the differential form of the time axiom is

$$\frac{dc_i}{dt}=-J_{i1}(r_{11},\ \ldots,\ r_{n1})+J_{i2}(r_{12},\ \ldots,\ r_{n2})=\frac{\partial F_1}{\partial r_{i1}}+\frac{\partial F_2}{\partial r_{i2}}, \qquad (1)$$

where $i = 1, 2, \ldots, n$; c_i is the variable (the state coordinate); t is the time; r_{i1} and r_{i2} are specific variables of component i, related to parameters of the subsystems; and J_{i1}, J_{i2}, F_1, and F_2 are functions of the state parameters. The first index gives the process, and the second shows whether the forward or reverse half-process is meant.

According to this theory, we have

$$J_{i1}=\mu_{i1}\exp\frac{\left(\frac{\partial S}{\partial\lambda_i}\right)^{*}_{01}-\left(\frac{\partial S}{\partial\lambda_i}\right)_{1}}{R};\quad J_{i2}=\mu_{i2}\exp\frac{\left(\frac{\partial S}{\partial\lambda_i}\right)^{*}_{02}-\left(\frac{\partial S}{\partial\lambda_i}\right)_{2}}{R}. \qquad (2)$$

Here, μ_{i1} and μ_{i2} are transition functions, $(\partial S/\partial\lambda_i)_1$ and $(\partial S/\partial\lambda_i)_2$ are the entropy changes of the matter in the initial and final states in the case $\lambda = 1$, λ is the number of reaction runs, $(\partial S/\partial\lambda_i)_0^*$ is the change in the entropy for the intermediate state, and R is the gas constant.

We can also write an integrability theorem in terms of the function F:

$$\frac{\partial^2 F_1}{\partial r_{i1}\partial r_{k1}}=\frac{\partial^2 F_1}{\partial r_{k1}\partial r_{i1}},\quad \frac{\partial^2 F_2}{\partial r_{i2}\partial r_{k2}}=\frac{\partial^2 F_2}{\partial r_{k2}\partial r_{i2}}. \qquad (3)$$

We find an expression for F by using the vector and scalar forms. We introduce the following vectors:

$$\left.\begin{aligned}
\mathbf{r}_0&=(r_{10},\ \ldots,\ r_{i0},\ \ldots,\ r_{n0}),\\
\mathbf{r}_1&=(r_{11},\ \ldots,\ r_{i1},\ \ldots,\ r_{n1}),\\
\mathbf{r}_2&=(r_{12},\ \ldots,\ r_{i2},\ \ldots,\ r_{n2}),\\
\Delta\mathbf{r}_1&=(\Delta r_{11},\ \ldots,\ \Delta r_{i1},\ \ldots,\ \Delta r_{n1}),\\
\Delta\mathbf{r}_2&=(\Delta r_{12},\ \ldots,\ \Delta r_{i2},\ \ldots,\ \Delta r_{n2}),
\end{aligned}\right\} \qquad (4)$$

where the subscript "0" denotes equilibrium.

Expanding the functions J_{i1} and J_{i2} in Taylor series, and using the notation in (4), we find

$$\begin{aligned}
J_{i1}&=J_{i1}(\mathbf{r}_0)+DJ_{i1}\Big|_{\mathbf{r}=\mathbf{r}_0}(\Delta\mathbf{r}_1)^{(1)}+\ldots\\
&+\frac{1}{k!}D^{(k)}J_{i1}\Big|_{\mathbf{r}=\mathbf{r}_0}(\Delta\mathbf{r}_1)^{(k)}+R_{i+1},\\
J_{i2}&=J_{i2}(\mathbf{r}_0)+DJ_{i2}\Big|_{\mathbf{r}=\mathbf{r}_0}(\Delta\mathbf{r}_2)^{(1)}+\ldots\\
&+\frac{1}{k!}D^{(k)}J_{i2}\Big|_{\mathbf{r}=\mathbf{r}_0}(\Delta\mathbf{r}_2)^{(k)}+R'_{i+1},
\end{aligned} \qquad (5)$$

where $D^{(k)}$ is the operator representing k-th order differentiation with respect to the vectors $\mathbf{r}_1$ and $\mathbf{r}_2$; $(\Delta\mathbf{r}_1)^{(k)}$ and $(\Delta\mathbf{r}_2)^{(k)}$ are linear forms of order k, and R_{i+1} and R'_{i+1} are the remaining terms.

In the second approximation these functions are given in scalar form by

$$\begin{aligned}
J_{i1}(r_{11},\ \ldots,\ r_{n1})&=J_{i1}[(r_{10}+\Delta r_{11}),\ \ldots,\ (r_{n0}+\Delta r_{n1})]\\
&=J_{i1}(r_{10},\ \ldots,\ r_{n0})+\sum_{k=1}^{n}\frac{\partial J_{i1}}{\partial r_{k1}}\Big|_{r_{10},\ldots,r_{n0}}\Delta r_{k1}+\frac{1}{2!}\Bigg[\sum_{k=1}^{n}\frac{\partial^2 J_{i1}}{\partial r_{k1}^2}\Big|_{r_{10},\ldots,r_{n0}}\Delta r_{k1}^2\\
&+2\sum_{k=i+1}^{n}\frac{\partial^2 J_{i1}}{\partial r_{i1}\partial r_{k1}}\Big|_{r_{10},\ldots,r_{n0}}\Delta r_{i1}\Delta r_{k1}\Bigg],
\end{aligned} \qquad (6)$$

where $i, k = 1, 2, \ldots, i, \ldots, n$.

In (6) r_{i1} is written in the form $r_{i0} + \Delta r_{i1}$, since $r_{i1} - r_{i0} = \Delta r_{i1}$. The function $J_{i2}(r_{12}, \ldots, r_{n2})$ appears in analogous form.

Using the system of equations

$$\frac{\partial F_1(r_{11},\ \ldots,\ r_{n1})}{\partial r_{i1}}=J_{i1},\quad \frac{\partial F_2(r_{12},\ \ldots,\ r_{n2})}{\partial r_{i2}}=J_{i2},$$

and taking account of the continuity and differentiability of the functions F_1 and F_2, we can write

$$\left.\begin{aligned}
\int_{\mathbf{r}_0}^{\mathbf{r}_1}dF_1&=F_1\Big|_{\mathbf{r}_1}-F_1\Big|_{\mathbf{r}_0}=\int_{\mathbf{r}_0}^{\mathbf{r}_1}\mathbf{J}_1 d\mathbf{r}_1,\quad \mathbf{J}_1=(J_{11},\ \ldots,\ J_{n1}),\\
\int_{\mathbf{r}_0}^{\mathbf{r}_2}dF_2&=F_2\Big|_{\mathbf{r}_2}-F_2\Big|_{\mathbf{r}_0}=\int_{\mathbf{r}_0}^{\mathbf{r}_2}\mathbf{J}_2 d\mathbf{r}_2,\quad \mathbf{J}_2=(J_{12},\ \ldots,\ J_{n2}),
\end{aligned}\right\} \qquad (7)$$

or, in scalar form,

$$\int\limits_{r_{10},\ldots,r_{n0}}^{r_{11},\ldots,r_{n1}} dF_1 = \int\limits_{r_{10},\ldots,r_{n0}}^{r_{11},\ldots,r_{n1}} (J_{11}dr_{11} + \ldots + J_{i1}dr_{i1} + \ldots + J_{n1}dr_{n1}). \quad (7')$$

For the F_2 case we find an equation analogous to (7'), in which the second indices are replaced by "2."

To find the difference of functions $F(X) = F_2(\mathbf{r}_2) - F_1(\mathbf{r}_1)$, where $X = \Delta\mathbf{r}_2 - \Delta\mathbf{r}_1$, we substitute in the corresponding values of J from Eqs. (5) and (6); integrating the left sides of (7) and (7') and collecting terms, we can write F(X) as

$$F(\mathbf{X}) = \sum_{k=1}^{n} \frac{1}{k!} D^{(k)} \mathbf{J}_1 \Big|_{\mathbf{r}=\mathbf{r}_0} \left\{ \int\limits_{\mathbf{r}_0}^{\mathbf{r}_2} (\Delta\mathbf{r}_2)^{(k)}\, d\mathbf{r}_2 - \int\limits_{\mathbf{r}_0}^{\mathbf{r}_1} (\Delta\mathbf{r}_1)^{(k)}\, d\mathbf{r}_1 \right\}. \quad (8)$$

In the second approximation the difference $F_2 - F_1$ is written in scalar form as

$$\begin{aligned} F(X) &= F_2(r_{12}, \ldots, r_{n2}) - F_1(r_{11}, \ldots, r_{n1}) \\ &= \sum_{i,k=1}^{n} \left[\int\limits_{r_{i0}}^{r_{i2}} \frac{\partial J_{i2}}{\partial r_{k2}} \Big|_{r_{10},\ldots,r_{n0}} \Delta r_{k2} dr_{i2} - \int\limits_{r_{i0}}^{r_{i1}} \frac{\partial J_{i1}}{\partial r_{k1}} \Big|_{r_{10},\ldots,r_{n0}} \Delta r_{k1} dr_{i1} \right] \\ &\quad + \frac{1}{2!} \left[\sum_{i=1}^{n} \int\limits_{r_{i0}}^{r_{i2}} \left\{ \sum_{k=1}^{n} \frac{\partial^2 J_{i2}}{\partial r_{k2}^2} \Big|_{r_{10},\ldots,r_{n0}} \Delta r_{k2}^2 \right. \right. \\ &\quad \left. + 2 \sum_{k=i+1}^{n} \frac{\partial^2 J_{i2}}{\partial r_{i2} \partial r_{k2}} \Big|_{r_{10},\ldots,r_{n0}} \Delta r_{i2} \Delta r_{k2} \right\} dr_{i2} \\ &\quad \left. - \sum_{i=1}^{n} \int\limits_{r_{i0}}^{r_{i1}} \left\{ \sum_{k=1}^{n} \frac{\partial^2 J_{1i}}{\partial r_{k1}^2} \Big|_{r_{10},\ldots,r_{n0}} \Delta r_{k1}^2 + 2 \sum_{k=i+1}^{n} \frac{\partial^2 J_{i1}}{\partial r_{i1} \partial r_{k1}} \Big|_{r_{10},\ldots,r_{n0}} \Delta r_{i1} \Delta r_{k1} \right\} dr_{i1} \right]. \end{aligned} \quad (9)$$

We note that in (8) and (9) the difference $F_2(\mathbf{r}_0) - F_1(\mathbf{r}_0)$ vanishes at equilibrium.

Before we use (8) and (9) we note that a quantity of the type

$$\int\limits_{\mathbf{r}_0}^{\mathbf{r}_2} (\Delta\mathbf{r}_2)^{(k)}\, d\mathbf{r}_2 - \int\limits_{\mathbf{r}_0}^{\mathbf{r}_1} (\Delta\mathbf{r}_1)^{(k)}\, d\mathbf{r}_1 \quad (10)$$

can be written

$$\int\limits_{0}^{\mathbf{r}_2 - \mathbf{r}_1} \{(\Delta\mathbf{r}_2)^{(k)} - (\Delta\mathbf{r}_1)^{(k)}\}\, d(\mathbf{r}_2 - \mathbf{r}_1). \quad (11)$$

Introducing the notation $(\Delta\mathbf{r}_2)^{(k)} - (\Delta\mathbf{r}_1)^{(k)} = \mathbf{X}^{(k)}$ we write integral (11) as

$$\int\limits_{0}^{\mathbf{X}} \mathbf{X}^{(k)} d\mathbf{X}. \quad (11')$$

Using (11') we can rewrite (8) as

$$F(\mathbf{X}) = \int\limits_{0}^{\mathbf{X}} \sum_{i=1}^{n} \frac{1}{k!} D^{(k)} \mathbf{J}_1 \Big|_{\mathbf{r}=\mathbf{r}_0} X^{(k)} d\mathbf{X} = \int\limits_{0}^{\mathbf{X}} \sum_{i=1}^{n} \mathbf{I}_k d\mathbf{X}, \quad (12)$$

where $\mathbf{I}_k = f(\mathbf{X}, \ldots, \mathbf{X}^{(k)})$.

In Eq. (12) the quantity $\mathbf{I}_{ki} = \frac{1}{k!} D^{(k)} \mathbf{J}_1 \Big|_{\mathbf{r}=\mathbf{r}_0} \mathbf{X}^{(k)}$ represents a thermodynamic flux, while X represents a thermodynamic force.

Using (10) and (11), we can treat (9) in analogous manner. Collecting like terms in (9), and denoting the coefficients by L_{ik} and L_{ikj}, we find

$$\begin{aligned} F_2 - F_1 = \sum_{i,k=1}^{n} L_{ik} \int\limits_{0}^{X_i} X_k dX_i + \frac{1}{2!} \sum_{i,k=1}^{n} L_{ikk} \int\limits_{0}^{X_i} (\Delta r_{k2}^2 - \Delta r_{k1}^2)\, dX_i \\ + \sum_{i=1,\, k=i+1}^{n} L_{iik} \int\limits_{0}^{X_i} (\Delta r_{i2} \Delta r_{k2} - \Delta r_{i1} \Delta r_{k1})\, dX_i. \end{aligned} \quad (13)$$

Introducing

$$\left.\begin{aligned} X'_k &= \Delta r_{k2}^2 - \Delta r_{k1}^2, \\ X_{ik} &= \Delta r_{i2} \Delta r_{k2} - \Delta r_{i1} \Delta r_{k1}, \end{aligned}\right\} \quad (13')$$

we can write (13) as

$$F_2 - F_1 = \int\limits_{0}^{X_i} \sum_{i=1}^{n} \left\{ \sum_{k=1}^{n} \left(L_{ik} X_k + \frac{1}{2!} L_{ikk} X'_k \right) + \sum_{k=i+1}^{n} L_{iik} X_{ik} \right\} dX_i. \quad (14)$$

The expression in braces in (14) is the thermodynamic flux J_i and (14) becomes

$$F(X) = F_2 - F_1 = \sum_{i=1}^{n} \int\limits_{0}^{X_i} \mathbf{I}_i dX_i. \quad (15)$$

It follows from (12) and (15) that F, which has the dimensionality of entropy per unit time, is the part of the entropy production which is due to the changes in the thermodynamic forces.[3] The function $\sum_{i=1}^{n} \int_0^{X_i} I_i dX_i$ is used in the second approach, whose theory is justified on the basis of the principle of a local equilibrium. Accordingly, we have the inequality $dF \leq 0$, which describes the time evolution of the system with the specified constraints.

We note that the coefficients having three indices are related by equations like the Onsager relations:

$$\left.\begin{aligned} L_{ikk} &= L_{kki} = L_{kik}, \\ L_{ikj} &= L_{kij} = L_{jik}. \end{aligned}\right\} \quad (16)$$

Using (16), we are to select from the set of coefficients having three indices in (14) the coefficients L_{iii}, L_{ikk}, and L_{ikj}.

Then, using (16), we rewrite (14) as

$$\begin{aligned} F_2 - F_1 = \sum_{i,k=1}^{n} \int\limits_{0}^{X_i} L_{ik} X_k dX_i + \frac{1}{2!} \sum_{i,k,j=1}^{n} \int\limits_{0}^{X_i} \{L_{iii} X'_i + \sigma_{ik} L_{ikk} (X'_k + 2X_{ik}) \\ + \sigma_{ikj} L_{ikj} (X_{kj} + X_{ij} + X_{ik})\}\, dX_i, \end{aligned} \quad (17)$$

where σ_{ik} and σ_{ikj} are defined by

$$\begin{aligned} &\sigma_{ik} = 1, \quad i \neq k; \quad \sigma_{ikj} = 1, \quad i \neq k \neq j; \\ &\sigma_{ik} = 0, \quad i = k; \quad \sigma_{ikj} = 0, \quad i = k = j. \end{aligned}$$

Equations (12) and (14) are not convenient for use because they contain the variables X'_k and X_{ik}, whose physical meaning is not clear. If we neglect the reverse process, we can simplify (14) and determine the meaning of X'_k and X_{ik}. In fact it can be shown that in this case we have

$$X'_k \cong X_k^2, \quad X_{ik} \cong X_i X_k. \quad (18)$$

To prove this we write X_k^2 as $X_k^2 = \Delta r_{k2}^2 - 2\Delta r_{k2}\Delta r_{k1} + \Delta r_{k1}^2$. Since we have $\Delta r_{k1} \to 0$, we can neglect the second and third terms; then, using (13'), we find $X_k^2 \cong \Delta r_{k2}^2 \cong x_k'$, i.e., $X_k^1 \cong X_k^2$.

Analogously we can show that, far from equilibrium, $X_{ik} \cong X_i X_k$; since $X_i X_k = (\Delta r_{i2} - \Delta r_{i1})(\Delta r_{k2} - \Delta r_{k1}) = \Delta r_{i2}\Delta r_{k2} - \Delta r_{i1}\Delta r_{k2} - \Delta r_{i2}\Delta r_{k1} + \Delta r_{i1}\Delta r_{k1}$, we can neglect all terms containing Δr_{i1}, $\Delta r_{k1} \to 0$. Then, using (13'), we find $X_i X_k \cong \Delta r_{i2}\Delta r_{k2} = X_{ik}$, i.e., $X_{ik} \cong X_i X_k$.

Using (18), we can rewrite (17) as

$$F(X) = \sum_{i,k,j=1}^{n} \int_0^{X_i} \Big\{ L_{ik} X_k + \frac{1}{2!} [L_{iii} X_i^2 + \sigma_{ik} L_{ikk} (X_k^2 + 2X_i X_k) + \sigma_{ikj} L_{ikj} (X_k X_j + X_i X_j + X_i X_k)] \Big\} dX_i. \qquad (19)$$

Equation (19) contains the ordinary thermodynamic forces and phenomenological coefficients having two and three indices, which are given explicitly by (9) and could be obtained directly from the time axiom.[4]

Effect of ion current on the measurement of the electron energy distribution function by the second-derivative method

V. A. Dovzhenko, A. P. Ershov, and G. S. Solntsev

M. V. Lomonosov Moscow State University

(Submitted August 13, 1973)
Zh. Tekh. Fiz., 44, 851-853 (April 1974)

Conditions are investigated for which it is necessary to take account of the second derivative of the ion current in the second derivative of the total current. The ratio of the second derivative of the electron current to the second derivative of the ion current to a probe is calculated for "thin" and "thick" cylindrical probes on the assumption of a Maxwellian energy distribution for the electrons. It is shown that in helium, the contribution of the second derivative of the ion current is greater than 10% when the ratio of the probe potential to the electron temperature (in electron volts) is higher than 6. The results explain the experimental observation that the second derivative of the total probe current varies slowly at high probe potentials.

Electron energy distribution functions are often measured by the second-derivative method,[1,2] which makes use of the well-known Druyvesteyn equation

$$f_0(V)=\frac{2\sqrt{2}}{Sen}\sqrt{\frac{m}{e}}\sqrt{V_p}\cdot\frac{d^2i_e}{dV_p^2}, \tag{1}$$

where $f_0(V)$ is the distribution function defined by the relation $dn = nf_0(V)dV$, V_p is the potential of the probe relative to the plasma, $V = V_p = (mv^2)/(2e)$ is the potential corresponding to the electron energy in eV, S is the area of the probe, and e, m, and n are the charge, mass, and density of the electron. The quantity $i_e'' = d^2i_e/dV_p^2$ is measured electronically[1,2] and identified with the second derivative of the total probe current $i_p'' = i_e'' + i_p''$. It is assumed that

$$i_p''\ll i_e''. \tag{2}$$

It has in fact been shown experimentally[3] that this inequality holds in the plasma of a mercury vapor positive column at pressures of $\sim 10^{-3}$ torr. On the other hand, it has been noted in ref. 2 that the inequality (2) is not valid at very high probe potentials. This is understandable because i_p'' is small and increases slowly with V_p, whereas i_e'' decreases exponentially to zero. However, the value of V_p at which (2) no longer holds is not estimated in ref. 2.

The aim of the present paper is to investigate the conditions under which the contribution from the second derivative of the ion current must be taken into account.

We assume that the electron distribution is Maxwellian and limit ourselves to low pressures. This case has been considered in detail in a review[4] and the equations for the electron and ion currents per unit length of a cylindrical probe are given there as

$$i_e=-en\sqrt{\frac{kT_e}{2\pi m}}\,2\pi a e^{-\eta}, \tag{3}$$

$$i_p=2\pi r_p en\sqrt{\frac{2kT_e}{M}}\,\alpha', \tag{4}$$

$$i_p=\frac{2\sqrt{2}}{9}\sqrt{\frac{e}{M}}\,\frac{V_p^{3/2}}{a\beta^2\left(\frac{r_p}{a}\right)}, \tag{5}$$

where $\eta = (eV_p)/(kT_e)$, k is the Boltzmann constant, a is the radius of the probe, r_p is the sheath radius, M is the ion mass, $\beta^2(r_p/a)$ is a tabulated function, $\alpha' = 0.37$ for $T_e \gg T_p$, T_e and T_p are the electron and ion temperatures. We use the notation $x = r_p/a$, $\varphi(x) = x\beta^2(x)$ and $\lambda_{De} = (kT_e/4\pi ne^2)^{1/2}$. It can be seen from (4) that i_p'' is proportional to r_p''. In order to find r_p'' and r_p from (4) and (5) we must eliminate i_p. Then the ratio $\chi \equiv i_e''/i_p''$ is

$$\chi=\frac{\dfrac{d^2i_e}{d\eta^2}}{\dfrac{d^2i_p}{d\eta^2}}=\frac{3}{4\sqrt{\pi}}\sqrt{\frac{M}{m}}\left(\frac{a}{\lambda_{De}}\right)^2\Phi(x)\,\eta^{1/2}e^{-\eta}, \tag{6}$$

	η								
	2	3	4	5	6	7	8	9	10
χ	$1.2 \cdot 10^2$	$7.9 \cdot 10^1$	$4.5 \cdot 10^1$	$2.3 \cdot 10^1$	$1.13 \cdot 10^1$	5.2	2.4	1.04	0.45

where

$$\Phi(x) = \frac{\left(\frac{d\varphi}{dx}\right)^3}{\left[-\left(\frac{d\varphi}{dx}\right)^2 + 3\varphi(x)\frac{d^2\varphi}{dx^2}\right]}. \tag{7}$$

The value of x is determined from the expression

$$\varphi(x) = 1.2\left(\frac{\lambda_{De}}{a}\right)^2 \eta^{3/2}. \tag{8}$$

The functions $\varphi(x)$ and $\Phi(x)$ are given in Table 1. In the calculation of $\Phi(x)$, we use the representation of $\beta^2(x)$ in the form of a Langmuir series.[5] It can be seen from (6) that χ depends on the type of gas, the ratio λ_{De}/a, and the probe potential. Since (4) and (5) are derived for high probe potentials, we limit ourselves to $\eta \geq 2$. The variation of χ with η for various λ_{De}/a is shown in Table 2 for helium.

It is evident from Table 2 that when $\lambda_{De}/a \ll 1$ the effect of i_p'' can be neglected. Since $\chi \propto (M)^{1/2}$, it is even more reasonable to neglect the second derivative of the ion current for heavier gases (mercury vapor, for example). At the limits of applicability of (4) and (5), where $\lambda_{De} \simeq 1$, the contribution due to the second derivative of the ion current is greater than 10% for $\eta \geq 6$.

When the theory does not hold, it is possible to use the following equation[6] for the analysis of the ratio i_e''/i_p'' with $\lambda_{De}/a > 1$:

$$i_p = 2ena\sqrt{\frac{2eV_p}{M}}. \tag{9}$$

The ratio of second derivatives is then

$$\chi = \sqrt{4\pi}\sqrt{\frac{M}{m}}\,\eta^{3/2}e^{-\eta}. \tag{10}$$

The results of calculations using this equation are given in Table 3. When $\lambda_{De}/a > 1$ the contribution due to the second derivative of the ion current is 10% or more for $\eta \geq 6$ (in helium), whatever the value of the electron density.

Thus results of measurements of the second derivative of electron current can be trusted at least up to potentials of the order of six electron temperatures.

The results obtained here explain the experimentally observed fact that the second derivative of the total current varies slowly at high probe potentials.

Energy dependence of the focusing of ions by crystals

E. S. Mashkova, V. A. Molchanov, and A. D. Pavlova

(Submitted July 30, 1973)
Zh. Tekh. Fiz., 44, 854-855 (April 1974)

The number of particles scattered at an angle of 25° from the (110) face of a copper crystal has been measured as a function of the azimuthal angle of rotation of the target for 5-30 keV incident argon ions. The sharp oscillations of the number of scattered particles diminish appreciably when the energy of the incident ions lies below 10 keV.

It is known[1] that under certain conditions a focusing effect obtains when ions are scattered by the crystal surfaces. Under these conditions a beam of ions scattered by a crystal is appreciably narrower than when scattered by surfaces of disordered solids, or for an orientation of the crystal target relative to the beam of primary ions which is arbitrary in the Lindhard sense. In particular, focusing leads to a characteristic shape of the curve for the number of particles scattered in a given direction in the plane of incidence of the beam of primary ions as a function of the azimuthal angle of rotation of this plane, i.e., about an axis perpendicular to the surface of the target. When the plane of incidence of the ions is parallel to certain crystallographic axes on the surface of the target there are sharp maxima in the number of particles reaching the analyzer in spite of the fact that the integrated scattering coefficient is not a maximum.[2]

The present experiment is undertaken to find the effect of the incident ion energy on the character of the dependence of the number of particles scattered on the azimuthal angle of rotation of the target (Fig. 1). The experiment is performed in the following way. A well-collimated beam of singly charged argon ions (5-30 keV) is directed onto the (110) face of a single-crystal copper target at a small angle α with the surface. The scattered particles are recorded by a fast particle detector.[3] The detector current is proportional to the number of fast particles reaching the detector, but depends somewhat on their energy distribution. In the present experiment, however, the scattering angle is constant and the energy distributions of both ions and neutrals are rather narrow[4] and this dependence can be neglected. The angular resolution of the detector is ± 1°.

Figure 2 shows the dependence of the number of scattered particles on the azimuthal angle of rotation of the target β for various energies of the incident ions. In the range of azimuthal angles of rotation of the target investigated ($-110° \leq \beta \leq 110°$) the maximum number of scattered particles is in all cases taken as unity for convenience in comparing the shapes of the angular distributions. The glancing angle α is 12°, and the scattering angle $\theta = 25°$. The dependence of the number of scattered particles on the azimuthal angle of rotation of the target is sharply nonmonotonic, exhibiting maxima and minima, and is symmetric about $\beta = 0°$, which corresponds to the plane of incidence and scattering being parallel to the (110) directions in the target surface. In this case the principal maximum in the number of scattered particles is observed. When the plane of incidence and scattering is parallel to the (100) directions ($\beta = \pm 90°$) there is also an increase in the number of scattered particles, but not so large as at $\beta = 0°$. Thus for 30 keV incident ions the corresponding maxima in the number of scattered particles differ by about a factor of 2, as do their half-widths. It should also be noted that the maximum at $\beta = 0°$ is split into two components. If the ratio of the maximum intensity to the minimum in the angular range under investigation is taken as a measure of the orientation effect, it is a maximum for an ion energy of 25 keV and decreases by about a factor of 5 when the energy is decreased to 5 keV. The decrease in energy leads to a decrease in the intensity relative to the principal maximum, and to an increase in the half-width of all maxima. The depth of the intensity dip at $\beta = 0°$ (the depth of splitting of the principal peak) is approximately constant for incident ion energies of 30-20 keV, but decreases sharply for lower energies and disappears altogether below 15 keV. Nevertheless, the general qualitative picture of the angular dependences investigated is preserved in the 30-10 keV energy range. When the energy is decreased further the angular dependence of the intensity changes appreciably, as shown by the curve for 5 keV incident ions. The preferential directions of scattering related to the (110) and (100) directions are still preserved, but the sharpness of the directional effect is much decreased and there is a tendency toward a relative increase in the number of particles scattered in other directions.

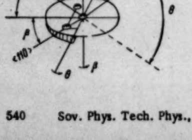

Fig. 1. Scattering scheme.

Steady-state study of the temperature dependence of the mutual-diffusion coefficients of certain gases

N. D. Kosov and B. P. Solonitsyn

S. M. Kirov Kazakh State University, Alma-Ata

(Submitted April 17, 1973)
Zh. Tekh. Fiz., 44, 855-857 (April 1974)

A steady-state, continuous-flow method is used to study the mutual-diffusion coeficients of the hydrogen−nitrogen, helium−nitrogen, and helium−carbon dioxide systems over the temperature range 300-810°K. The data are compared with the experimental data reported elsewhere and with theoretical values calculated on the basis of the Chapman−Enskog and Maxwell−Boltzmann−Jeans theories.

Most methods available for measuring the mutual-diffusion coefficients of gases are nonsteady-state methods. The equations used in these methods are derived from Fick's second law under various assumptions regarding the diffusion. In steady-state methods these equations are derived from Fick's first law. The steady-state method proposed in ref. 1 for measuring the mutual-diffusion coefficients of gases has several advantages (there is no redundant apparatus, and the results are highly reproducible) and has been used to study the mutual-diffusion coefficients of gases at temperatures below room temperature.[2] In this work we report the use of a steady-state continuous-flow method to study the mutual-diffusion coefficients of gases at temperatures above room temperature (up to 814°K).

The apparatus does not differ fundamentally from that described in refs. 1-3. The diffusion cell is a set of 58 identical capillaries 5.000 ± .002 cm long with a total cross-sectional area of 0.1360 ± 0.0002 cm^2. The volume flow rate of the pure gases is 1.116 ± 0.002 cm^3/sec at T = 298.0°K. The experiments are carried out at atmospheric pressure. The results for the three binary systems studied (hydrogen−nitrogen, helium−nitrogen, and helium−carbon dioxide) are shown in Table 1. To the best of our knowledge, this is the first reported measurement of the mutual-diffusion coefficients for the helium−carbon dioxide system above 498°K. The experimental error is less than 2%.

Using the method of least squares, we find the following empirical relations between the experimental mutual-diffusion coefficients and the temperature:

$$H_2—N_2 : \lg D = 1.645 \lg T - 4.1556, \tag{1}$$

$$He—N_2 : \lg D = 1.634 \lg T - 4.1887, \tag{2}$$

TABLE 1. Mutual-Diffusion Coefficients of Three Binary Gaseous Mixtures Measured by the Steady-State Method (the results are referred to normal pressure).

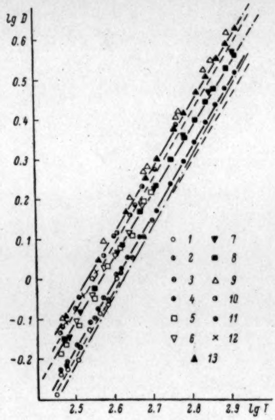

Fig. 1. Mutual-diffusion coefficients measured by the steady-state continous-flow method, experimental data of other workers, and theoretical functional dependences calculated from the Chapman−Enskog theory (dashed lines) and the Maxwell−Boltzmann−Jeans theory (dot−dash lines). The solid lines correspond to Eqs. (1)-(3). He−CO_2: 1) ref. 4; 2) ref. 5; 3) ref. 6; 4) the present work. He−N_2: 5) ref. 6; 6) ref. 5; 7) ref. 7; 8) the present work. H_2−N_2: 9) ref. 8; 10) ref. 5; 11) ref. 9; 12) ref. 10; 13) the present work.

$$He—CO_2 : \lg D = 1.691 \lg T - 4.4005. \tag{3}$$

The average deviation of the experimental coefficients from those calculated from Eqs. (1)-(3) is less than 0.4%.

Our data are compared with the experimental data of other workers[4-10] and with the theoretical functional dependences derived on the basis of the rigorous Chapman−Enskog kinetic theory with the Lennard−Jones (6-12) potential[11] and on the basis of the Maxwell−Boltzmann−Jeans theory, in which the functional dependence of the effective molecular diameter is taken into account,[12] in Fig. 1. For the hydrogen−nitrogen system the Maxwell−Boltzmann−Jeans theory agrees completely with our experimental results, while the Chapman−Enskog theory predicts results which average 6% lower than our experimental results. For the helium−nitrogen system both theories agree with experiment within the experimental error. For the helium−carbon dioxide system both theories predict results which average 6% lower than the experimental results.

The mutual-diffusion coefficients measured by the steady-state continuous-flow method have a small scatter and agree with data reported previously; this method seems to be extremely promising for studying the mutual-diffusion coefficients of gases over broad temperature ranges.

Statistical characteristics of the turbulent wake behind a supersonic sphere

V. G. Ivanov, G. I. Mishin, and S. N. Palkin

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 44, 857-861 (April 1974)

An experimental study has been made of the characteristics of the boundaries of turbulent wakes in a ballistic apparatus using a Schlieren method. The correlation function, roughness dimension, intermittence coefficient, and microscopic scale of the fluctuations in the wake boundaries are found as functions of the downstream distance. The results are compared with those of other workers.

Serious difficulties have been encountered in attempts to find a theoretical explanation for the characteristics of free turbulence.[1] We report here on an experimental study of the statistical characteristics of fluctuations in the boundary of a turbulent wake; these are of considerable importance in connection with the understanding of free turbulence. The experiments are carried out by using a Schlieren method to study the wake behind a sphere 20.7 mm in diameter moving at 675 m/sec ($M_\infty = 2$) in air at a pressure of 760 torr ($Re_\infty = 10^6$). The flow becomes turbulent upon the separation of the boundary layer. The wake in the photographs is 125 mm long.

Data for the statistical analysis are obtained from the part of the wake being studied by measuring the distances y_{bo} from a baseline, which corresponds approximately to the axis of the wake, to the upper and lower boundaries of the wake. In this case the asymmetry of the turbulent wake can be neglected,[2] since the boundary contour of the viscous wake visible on the shadow and Schlieren photographs corresponds primarily to points on the boundary which are near the meridian plane of the wake, parallel to the image plane.

The length of the part of the wake for which the measurements are used to calculate the statistical characteristics is 30 mm (~ 1.5 diameters of the object), and the measurement step is 0.5 mm.

To eliminate the rms value of y_{bo} and its linear change along the wake, we use the method of least squares to find the line corresponding to the average wake boundary. We calculate the deviations of the boundary from this line, Δy_{bo}, and from the results of these calculations we determine the statistical characteristics of the fluctuations in the boundary of the turbulent wake. We then average the results of 10 experiments for each part of the wake.

Figure 1 shows the normalized correlation function of the boundary fluctuations of the turbulent wake calculated for eight parts of the wake. We see that the functional dependence of the normalized correlation function $R(\xi)$ on the delay length ξ weakens with distance along the wake, i.e., the scale of the boundary roughness increases.

A measure of the boundary roughness of the turbulent wake is the rms deviation from the average wake boundary, found by the method of least squares. Figure 2 shows the rms deviation γ divided by the object diameter d as a function of the dimensionless distance downstream from the object, x/d. According to the experimental data shown in Fig. 2, the dimension of the boundary roughness of the

3	6.4	4.7	$7.1 \cdot 10^5$	
4	76.2	6.0	$1.1 \cdot 10^7$	[4]
5	6.4	13.6	$2.6 \cdot 10^5$	[2]

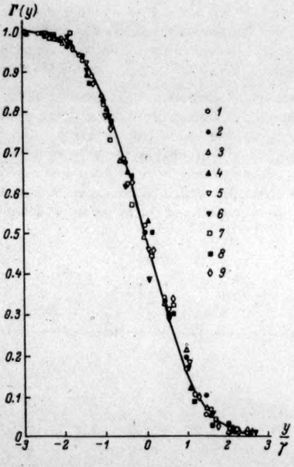

Fig. 5. x/d: 1) 4.1-5.6; 2) 5.6-7.1; 3) 7.1-8.6; 4) 8.9-10.4; 5) 10.4-11.9; 6) 11.9-13.4; 7) 14.4-15.9; 8) 15.9-17.4; 9) 17.4-18.9.

turbulent wake over the range $4 \leq \chi/d \leq 17$ increases approximately according to $\gamma \sim x^{1/2}$.

Figure 3 shows the average wake diameter w, defined as the average distance between the least-squares lines for the upper and lower boundaries of the wake, as a function of the distance from the object.

Since the average wake diameter and the dimension of the boundary roughness increase at the same rate, the rms deviation converted to dimensionless form by dividing by the wake diameter remains constant with distance along the flow (Fig. 4 and Table 1).

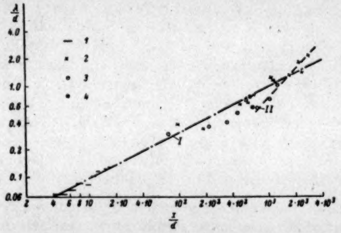

Fig. 6. λ: I) $x^{1/2}$; II) $x^{13/12}$ (ref. 2).

TABLE 2

Curve	Sphere diameter, mm	M_∞	R_∞	Reference
1	20.7	1.97	10^6	The present work
2	3.2	3.2	$2.5 \cdot 10^5$	[2]
3	6.4	4.7	$7.1 \cdot 10^5$	
4	6.4	13.6	$2.6 \cdot 10^5$	

This result agrees well with the experimental data of ref. 2.

Townsend[3] introduced the concept of an "intermittency coefficient," as a statistical characteristic of the intermittence of turbulence; this gives the probability for turbulence to exist at some point in space at a distance y from the average boundary of the turbulent flow.

The intermittency coefficient of the boundary of the turbulent wake, Γ (y), is calculated as the ratio of the time over which a hypothetical probe a distance y from the least-squares line is in the turbulent wake to the total (quite long) measurement time.

Figure 5 shows the calculated intermittency coefficient of the boundary of a turubulent wake. The coordinate y is converted to dimensionless form by dividing it by the rms deviation γ; in this manner we can display the results obtained for different downstream distances. Comparison of the experimental data with the function $\Gamma(y) = (1/2)\,[1 - \Phi(y/\gamma)]$, where Φ is the probability integral, shows that the distribution law for the boundary of the turbulent wake is Gaussian, in agreement with the data of refs. 2 and 4.

One of the important statistical parameters of the fluctuations in the boundary of a turbulent wake is the microscale λ. Since the wake boundary is described by a Gaussian distribution, the microscale λ is, according

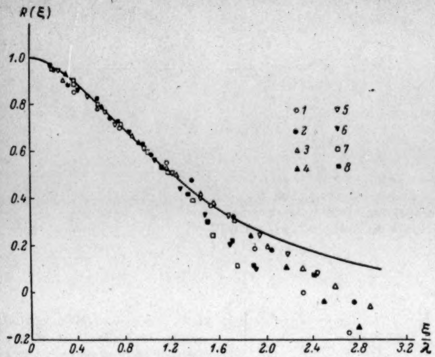

Fig. 7. The solid curve[2] shows $R(\xi) = \sin[(\pi/2)\exp(-2\sqrt{2}\,\xi/\pi\lambda)]$.

to Corrsin and Kistler[3]

$$\lambda=\frac{\sqrt{2}}{\pi}\frac{1}{N_0},$$

where N_0 is the average number of intersections of Δy_{b0} with the zero line per unit length.

It follows from the experimental data in Fig. 6 and Table 2 that the microscale λ converted to dimensionless form by dividing it by the object diameter d increases with increasing dimensionless downstream distance x/d according to $\lambda \sim x^{1/2}$. The functional dependence agrees with the experimental data of Shapker,[2] obtained at large values of x/d. On the other hand, the theoretical function $\lambda \sim x^{13/12}$ proposed by Shapker does not agree with our experimental results. Furthermore, as is pointed out in ref. 5, the values of the displacement lengths obtained on the basis of the theoretical functional dependences of the statistical characteristics of the wake boundaries on the downstream distance proposed by Shapker "are apparently unlikely."

Figure 7 shows the normalized correlation function $R(\xi/\lambda)$, which agrees well with the empirical functional dependence obtained by Corrsin and Kistler[2] on the basis of the results of thermoanemometric measurements:

$$R(\xi)=\sin\left(\frac{\pi}{2}e^{-\frac{2\sqrt{2}}{\pi}\frac{\xi}{\lambda}}\right).$$

Gas focusing of a negative-ion beam

M. D. Gabovich, A. P. Naida, I. M. Protsenko, L. S. Simonenko, and I. A. Soloshenko

Institute of Physics,
Academy of Sciences of the Ukrainian SSR, Kiev

(Submitted July 23, 1973)
Zh. Tekh. Fiz., 44, 861-863 (April 1974)

Gas focusing of a negative beam of H_1^- ions has been studied at beam currents up to 10 mA and at energies up to $eV_0 = 10$ keV. The potential at the beam axis becomes positive, and focusing occurs at a pressure of $p_0 \sim 10^{-4}$ torr in agreement with the calculated value. At $p > p_0$ the radial potential distribution displays two steps. The measured potential drops near the wall and at the beam boundary agrees with the corresponding calculated values.

Focusing of electron beams by the field produced by positive ions formed as the beam passes through a gas was detected a long time ago, but the analogous focusing of negative-ion beams has not previously been reported. The development of accelerator technology and effective plasma-heating methods has stimulated study of the conditions for the transport of such ion beams. Below we report the first observation of gas focusing of intense negative-ion beams and a study of the features of this focusing.

In an effort to observe this effect we produce intense beams of negative hydrogen ions at currents up to 10 mA and energies up to 10 keV converging at an angle ~ 1° toward the crossover point, which is in the entrance aperture of a chamber filled with argon to a pressure of 10^{-5}-10^{-3} torr. Curve 1 in Fig. 1 shows the potential at the axis of the negative-ion beam as a function of the argon pressure in the chamber. This fundamental dependence is obtained by means of a thermal probe; the beam travels a path length of 100 cm in the chamber. We see that as the pressure is raised above a certain value p_0 the negative potential becomes positive. At the same time a thermocouple in this region indicates an increase in the specific power w at the beam axis (curve 2), which is evidence of the desired effect. The value of p_0 agrees with the calculated value of the argon-atom density at which the space charge of the positive ions formed during ionization of the gas by the beam balances the space charge of the beam: $n_{a0} \approx (2/R)(\bar{v}_{\pm}/v_-)(1/\sigma_i)$, where R is the beam radius, $\bar{v}_+$ is the average velocity of the ions produced, v_- is the velocity of the beam ions, and σ_i-is the ionization cross section.

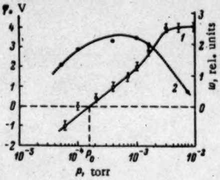

Fig. 1. Space potential (curve 1) and specific power (curve 2) at the beam axis as functions of the argon pressure in the chamber. The current of the beam of H_1^- ions is $I_- = 5$ mA; the energy is $eU_0 = 10$ keV.

To clarify the mechanism and features of this effect consider Fig. 2, which shows the radial profile of the potential over the entire chamber cross section at a pressure $p \gg p_0$, along with the corresponding radial distribution of the current density in the beam. Since the potential profile has two steps, we conclude that the field at the boundary of the beam, which contracts the beam, is due not to the total potential drop $\varphi_1 + \varphi_2$, but only to the small potential drop in the beam zone, φ_2. This circumstance is partially responsible for the relative weakness of the contraction. Another factor is the loss of electrons by negative ions, which is appreciable at $p > p_0$, and which also explains the peak on curve 2 in Fig. 1. Even at the pressure $p = p_0$ the mean free path for this detachment of electrons,

$$\lambda_{-10} = \frac{1}{n_{a0}\sigma_{-10}} = \frac{Rv_-\sigma_i}{2v_+\sigma_{-10}},$$

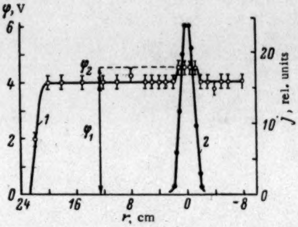

Fig. 2. Radial profiles of the potential (curve 1) and the negative-ion current density (curve 2). The current of the H_1^- beam is $I_- = 5$ mA, and the energy is $eU_0 = 10$ keV.

turns out to be comparable to the distance covered by the beam in the gas. The important role of electron detachment governs our choice of a thermocouple as a probe to detect this effect. This thermocouple detects both fast charged particles and fast atoms, which move toward the axis before they undergo charge exchange. This latter circumstance explains why a probe which detects charged particles only is less sensitive to the beam contraction.

It is important to note that the two-stepped potential profile found experimentally also follows from the Poisson equation, which is solved numerically in refs. 1 and 2 for the case of the passage of an electron beam (although a distribution of this type has not been detected for the case of an electron beam). Considering the condition for the quasineutrality of the plasma formed in a two-stepped well, the capture of the slowest electrons in this well, and the loss of electrons from this well due to Coulomb collisions with ions, we can estimate the order of magnitude of the potential drops without resorting to this solution. The potential drop in the beam is of order

$$\varphi_2 \approx a^{1/3} e \left(\frac{U_i}{U_0}\right)^{1/3} \left(\frac{M}{m}\right)^{1/3} \frac{1}{n_{a0}^{1/3} (\sigma_i + \sigma_{-10})^{1/3}} \left(1 - \frac{n_{a0}}{n_a}\right)^{1/3} n_-^{1/3},$$

where n_- is the ion density in the beam, eU_0 is the ion energy, M is the mass, and U_i is the ionization potential of the atoms. Estimates reveal a correspondence between the calculated and measured values of φ_1 and φ_2.

We note in conclusion that a more or less well-defined two-stepped potential profile should also be observed when an intense beam of any type of fast particles passes through a gas with a sufficiently high density. In the passage of electrons or negative ions the field at the beam boundary is a focusing field under these conditions; in the case of the free propagation of a positive-ion beam it is always a defocusing field.

Time characteristics of the near radiation field of the injection laser

Zh. I. Alferov, V. N. Deryagin, L. E. Marasin, Yu. V. Popov, and E. L. Portnoi

(Submitted July 18, 1973)
Zh. Tekh. Fiz., 44, 863-864 (April 1974)

Semiconductor lasers are finding increasing use in optical location systems,[1] in which the operating accuracy is governed largely by the time structure of the laser radiation. It has been pointed out[2] that there is a significant temporal inhomogeneity over the emitting surface of an injection laser with a diffuse p−n junction in GaAs.

We report here a study of the temporal characteristics of the near radiation field of injection heterolasers. The active region of the samples is made from lightly doped n-type GaAs ($n \simeq 5 \cdot 10^{16}$ cm^{-3}), and is enclosed between wide-band p-type and n-type $Al_xGa_{1-x}As$ emitters with $x \simeq 0.2$ (refs. 3, 4). Some of the samples have a thin active layer ($d \leq 1\ \mu$), which corresponds to the generation of the fundamental transverse mode, while others have thicker active layers, corresponding to the generation of higher-order transverse modes.[5]

The temporal characteristics of the near field are studied by a pulsed phase method involving the measurement of short time intervals[6] as an iris is moved over a magnified image of the emitting surface. The time resolution is about 0.05 nsec, and the spatial resolution is $\simeq 0.05\ \mu$.

Figure 1 shows typical distributions of the radiation intensity and the delay times in the direction perpendicular to the plane of the active layer. Comparison of these data with those of ref. 2 shows that heterolayers display a near-field structure which is much more homogeneous than that of p−n junction lasers. This circumstance could be due to the absence from the heterolaser structure of traps of the double-acceptor type,[7] which are responsible for the delay times in lasers having a diffuse p−n junction.

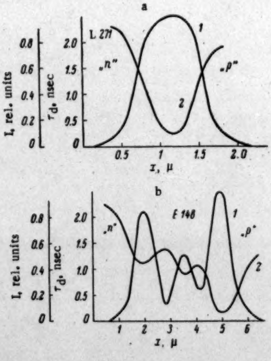

Fig. 1. Distributions of the intensity (1) and delay time of the radiation (2) for a heterolaser with a thin active layer (a) and a thick active layer (b).

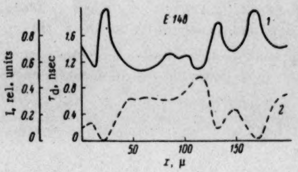

Fig. 2. Distributions of the intensity (1) and radiation delay time (2) in the direction along the active layer for a laser with a thin active layer.

It is extremely interesting to consider the correlation observed between the intensity of the near-field radiation and the temporal distribution; this correlation is found both for heterolasers with the fundamental transverse mode (Fig. 1a) and in those having higher-order transverse modes (Fig. 1b). Here the delay time is evidently decreasing as the amplitude of the radiation field is increasing, leading to an increase in the rate of stimulated radiative transitions. On the basis of this result we can conclude that there is a direct connection between the time intervals measured by the pulsed-phase method and the lifetime of the minority carriers in the active layer of a heterolaser.

Measurements of the temporal distribution along the active layer of the heterolasers (Fig. 2) also reveal a structure which is much more homogeneous than that of diffuse lasers.[2] The explanation apparently lies in the much more homogeneous generation pattern in this direction, which is characteristic of heterolasers.[8]

These results show that heterolasers are promising for use as radiation sources in highly accurate optical range finders.

The authors thank V. M. Tuchkevich for his continued interest in this work.

Frequency-doubling single-mode laser for picosecond pulses

A. M. Bonch-Bruevich, A. M. Tkachuk, and A. A. Fedorov

(Submitted July 10, 1973)
Zh. Tekh. Fiz., 44, 864-867 (April 1974)

A frequency-doubling single-mode neodymium-glass laser that provides picosecond pulses has been designed using a KDP crystal. The energy distribution, lifetime, and spectral distribution of the generated pulses have been investigated. It is shown that the laser output consists of a train of 10-15 nanosecond or subnanosecond pulses with a period of 16 nsec. With self-mode-locking the divergence is 15″ for the first harmonic and 21″ for the second harmonic. Each subnanosecond pulse consists of two ~ 5 · 10^{-12} sec spikes separated by a 200 nsec interval. The maximum radiated power in one picosecond pulse is ~ 3 · 10^{11} and ~ 10^{11} W in the first and second harmonics respectively.

A neodymium-glass self-mode-locked laser with a telescopic resonator is described which uses a KDP crystal for frequency doubling. The low radiation divergence of such a laser and the high power density due to self-mode-locking make it possible to obtain frequency doubling with a KDP crystal with a conversion efficiency of about 30% without the aid of special optical devices. Figure 1 shows the experimental arrangement used to obtain the radiation

characteristics of the single-mode subnanosecond pulse laser. We have investigated the short- and long-range energy distribution and the spectral distribution of the first- and second-harmonic pulses. The active element is a neodymium-glass cylinder 45 mm in diameter and 710 mm long with end faces cut at an angle of 87° to the resonator axis. Pumping is provided by four linear IFP-20000 lamps with cylindrical reflectors. The telescopic resonator[1] is formed by two mirrors with radii of curvature $r_1 = -500$ cm and $r_2 = +125$ cm with a reflection coefficient $R_1 = R_2 = 99.5 \pm 0.5\%$ at $\lambda = 1.06\ \mu$ and a prism. A test cell with an initial transmission of 0.7 is used as a passive shutter for Q modulation. The cell filled with a solution of polymethine dye in nitrobenzene is placed close to the opaque mirror so that its surface makes an angle of 85-82° with the resonator axis. The radiation exits from the resonator asymmetrically at the prism side. Figure 1b shows a photograph of the radiation in the near region (at a distance 40 cm from the active element end face). An analysis of the angular distribution of radiation intensity in the far region indicates that the intensity distribution of the free lasing radiation at the focus of an optical system with an equivalent focal length of 50 m is of a diffraction nature and that the half-width of the central distribution spot corresponds to an angular divergence of about 11" (Fig. 1c, curve 1). This is almost twice the diffraction limit. The self-mode-locking half-width of the central spot in the radiation intensity distribution increases to 15" (Fig. 1c, curve II), which is apparently associated with wave-front distortion caused by insertion of the cell into the resonator. After conversion to second harmonic the half-width of the central spot of the radiation intensity distribution at $\lambda = 530$ nm is about 21", the distribution of intensity between the central spot and the side peaks being somewhat less uniform, as indicated by curve III in Fig. 1c. However, it can be assumed that transmission through a KDP crystal placed outside the resonator does not change the radiation mode composition and that the observed waveform distortion is associated with optical imperfections of the crystal.

An oscilloscope study of 1.06 μ and 530 nm output signals with the aid of F-21 photocells and a 6LOR-2M high-speed oscilloscope indicates that as the transmission of the nonlinear filter is varied between 0.5 and 0.7 the radiation consists either of a single pulse or of a train of 10-15 nanosecond or subnanosecond pulses following each other at an interval $2L/c = 16$ nsec, where L is the optical length of the resonator. The time resolution of the photoelectric system is about 0.5 nsec. As seen in Fig. 2, a-d, the first- and second-harmonic pulse trains, as well as the individual pulses in the trains, are of the same form. The actual structure of the nanosecond pulses and the length of the subnanosecond pulses have been determined by the two-photon luminescence method.[2] It has been found that the nanosecond pulses in the trains have no fine structure. Their lengths have been determined from oscillograms and found to depend on the nonlinear-shutter transmission, varying from one to several nanoseconds (Fig. 2a, b). Subnanosecond pulses (Fig. 2c, d) consist of two (sometimes one) spikes of $T = (2-5) \cdot 10^{-12}$ sec at an interval of about 200 psec. A photograph of rhodamine 6G fluorescence produced by the transmission of two opposing pulses is shown in Fig. 3a, b. Simultaneous measurement of first- and second-harmonic oscillation spectra with a spectrum analyzer (second-order dispersion 6.5 A/mm) shows that pulses having a picosecond structure contain a spectral line of width $2\Delta\nu \approx 10$ cm^{-1} at 1.06 μ and $2\Delta\nu \approx 24$ cm^{-1} at 530 nm. The expression[3] $T = 0.88/(c\,2\Delta\nu)$, where $\Delta\nu$ is the line half-width, gives $T_1 = 3 \cdot 10^{-12}$ sec and $T_2 = 1.2 \cdot 10^{-12}$ sec for the first and second harmonics respectively. The oscillations spectrum of structureless nanosecond pulses shows narrow lines whose width is comparable with the instrumental slit width. The values agree with data on two-photon luminescence and with data on the duration of picosecond pulses produced by neodymium-glass lasers described in refs. 2 and 4-6. The obtained pulse length $T = 3 \cdot 10^{-12}$ sec is used to calculate the number of locked modes $\Delta = 5 \cdot 10^3$.

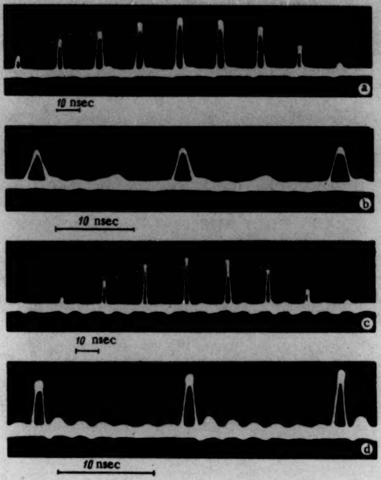

Fig. 2. Oscillograms of nanosecond (a, b) and subnanosecond (c, d) pulses generated in self-mode-locking.

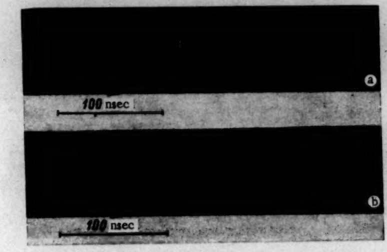

Fig. 3. Two-photon luminescence subnanosecond pulses.

The radiation energy is measured with a calorimeter and calibrated photocells whose output has been observed on an oscilloscope (for checking the number and amplitude of nanosecond pulses in a train as well as the number of relative giant-pulse amplitudes per flash). The average energy of one giant pulse is 14-15 J at the first harmonic and 4-5 J at the second harmonic. It should be noted that the conversion factor is significantly affected by the presence of internal structure in a nanosecond spike. Maximum first-to-second harmonic conversion efficiency is about 30% for a beam cross section of 12 cm^2. Maximum power in one picosecond pulse is $3 \cdot 10^{11}$ W at the first harmonic and about 10^{11} W at the second harmonic.

Unidirectional cw oscillation in a solid state ring laser with a return mirror

A. A. Mak, V. I. Ustyugov, V. A. Fromzel', and M. M. Khaleev

(Submitted September 3, 1973)
Zh. Tekh. Fiz., 44, 868-870 (April 1974)

Single-frequency cw operation is analyzed in a ring laser with an additional return mirror. Strong spectral broadening of axial modes is observed in a YAG:Nd^{3+} cw laser; insertion of the mirror also causes the laser to operate in the pulsed mode rather than the cw mode. The intensity ratio of the opposing modes is $3 \cdot 10^3$; however, a single-frequency operation is achieved only with an additional frequency selector in the form of a plane-parallel glass plate 8 mm thick. The output power of the single TEM$_{00}$ mode is 0.43 W for a mode ratio of 600.

In refs. 1 and 2 it is proposed to use a ring resonator with an additional return mirror as a simple means of achieving a traveling wave regime and removing the spatial inhomogeneity of the field in the active medium, thus obtaining single-frequency operation,[1] in refs. 1 and 2. Limiting ourselves to solid-state lasers we note that experiments have shown the difficulty of achieving single-frequency operation by this method. In the published papers, which all are devoted to the study of pulsed excitation (a survey of these papers is contained, for example, in ref. 3), a single-frequency spectrum is not achieved over the entire pulse length; however, single-frequency operation over a portion of the pulses is reported in refs. 4 and 5.

In this note we analyze the conditions necessary for stationary single-frequency lasing in a ring resonator with a return mirror; the results of an experimental study of cw operation of a YAG:Nd^{3+} laser are also described. Considering the case of low transmission through the output mirror 3 (Fig. 1), we assume that two opposing modes are supported in the resonator with the intensities I_1 and I_2, which are constant along the resonator axis; the fields at the surface of the output mirror at the point x = 0 have the form $E_1 = |E_1| \exp[i(\omega t + \varphi_1)]$, $E_2 = |E_2| \exp[i(\omega t + \varphi_2)]$, respectively. Since the wave directed into the resonator by the return mirror is formed from the wave E_2, its field at the point x = 0 has the form $E_3 = |E_3| \exp \cdot [i(\omega t + \varphi_2 - 2kd - \pi)]$, where $(2kd + \pi)$ is the phase shift due to reflection and the two-way passage through the optical path length d. For constructive interference of the waves E_1 and E_3 it is necessary that $\varphi_2 - 2kd - \pi = \varphi_1$. This condition phases the opposing waves with respect to each other (it is assumed that scattering of wave I_1 into the wave I_2 does not disturb it), producing localized maxima and minima of the field along the resonator axis; in particular, it is easy to verify that a minimum of the fields of all axial modes, independent of their index, exists at the point $x_1 = -d$, and also at the point x_2 separated from x_1 by the optical length L/2, where L is the optical length of the resonator. The optimum configuration for flat-mirror resonator for unidirectional operation and frequency selection is obtained when the center of the active medium coincides with the point x_2 (as in Fig. 1). This location of the active element ensures that in the presence of a thermal lens in the medium the wave E_3 coincides with the field in the resonator (in terms of curvature of the phase front) regardless of the pump power. This configuration is best for frequency selection because the spatial difference of the fields of different axial modes near the point x_2 (and the point x_1 also) is a minimum. The presence of spatial localization of the field minima and maxima in the stationary regime makes this case to some extent analogous to a linear resonator, and amenable to a calculation whose starting point is formulated in ref. 6. In the plane wave approximation the energy density of the field of an axial mode of index $m = j + \xi$ in the active medium can be represented in the form $u_\xi(z) = u_\xi \varphi_\xi(z)$, where $\varphi_\xi(z) = 1 - \mu \cos[4\pi\varkappa \times (j + \xi) z/L]$, $\mu = 2(\chi)^{1/2}/(1 + \chi)$, $\chi = I_1/I_2$ is the ratio of opposing modes in the resonator in the stationary regime, and $\varkappa$ is the refractive index of the active medium. For stationary oscillation in a single axial mode with $\xi = 0$, whose energy density is proportional to A_0 (see the notation in ref. 6) and whose frequency coincides with the center of the homogeneously broadened luminescence line, we require

$$\frac{g_\xi n \gamma_0}{l \gamma_\xi} \int\limits_{-l/2}^{l/2} \frac{\varphi_\xi(z)}{1 + A_0 \varphi_0(z)} dz < 1 \tag{1}$$

for all $\xi \neq 0$. Here, n is the excess pumping above threshold, and g_ξ and γ_ξ are the shape factor of the emission line and the resonator losses at the frequency of the mode, respectively (at the line center $g_0 = 1$). Evaluation of the integral (without constraint on the pumping for $\xi \ll j$, $\chi \gg 4$, $g_\xi^{-1} - 1 \ll 1$, and $(\gamma_\xi - \gamma_0)/\gamma_0 \ll 1$ gives

$$n < \left\{1 - \frac{\chi\,[g_\xi^{-1} + (\gamma_\xi - \gamma_0)/\gamma_0 - 1]}{2\,(1 - \sin 2\pi\zeta\xi/2\pi\zeta\xi)}\right\}^{-1}, \tag{2}$$

where $\zeta = l\varkappa/L$. Setting $\zeta = 1/2, 1$, we find that the inequality (2) is satisfied for any pumping level if

$$\chi > \chi_1 = \frac{2}{[g_\xi^{-1} + (\gamma_\xi - \gamma_0)/\gamma_0 - 1]}. \tag{3}$$

In the absence of a frequency selector in the resonator $(\gamma_\xi - \gamma_0 = 0)$ we obtain $\chi_1 = 6 \cdot 10^4$, as applied to a YAG:Nd^{3+} laser with an emission linewidth of 7 Å and L = 55 cm. The introduction of even a very weak selector into the resonator lowers this value. Thus, in the case of a plane-parallel glass plate with refractive index of 1.5 and 8 mm thick, $\chi_1 = 150$ according to Eq. (3).

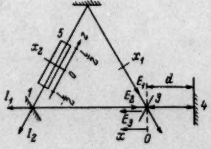

Fig. 1. Resonator diagram. 1, 3) Ring resonator mirrors; 4) return mirror; 5) active medium.

The basic experiments are performed with a three-mirror ring resonator with optical length of 55 cm, which operates in the TEM_{00} mode; the YAG : Nd^{3+} active element (5 × 50 mm) is located along the resonator axis as shown in Fig. 1. A four-mirror resonator scheme has also been investigated. The shape of the mirror backings and the tilt of the active element with plane-parallel coated faces at an angle which precludes interference of the beams reflected from the faces ensures the absence of parasitic frequency selection. The spectrum is studied with a Fabry–Perot interferometer with 5 and 16 mm spacings with image-converter tube or photographic recording. An important result is the sharp broadening of the spectrum with the introduction of the return mirror; the output also goes from cw to spiked (Fig. 3a and Fig. 2). With the results of ref. 7 in mind relative to the exceptionally high sensitivity of the radiation kinetics to the fluctuations in the resonator Q value, we note, as is evident from Fig. 3a, that in our case the mechanical stability of the resonator elements is good enough for the laser to operate without the return mirror in the stationary single-frequency regime with a low level of amplitude noise. The mode ratio at the lasing threshold $\chi_{th} = 200$, and increases with increasing pumping (Fig. 2). In some cases (with the smallest scattering at the optical surfaces) we achieve $\chi = 3 \cdot 10^3$, but the spectrum is multifrequency and nonstationary; the same result relative to the spectral width is obtained by photographing the spectrum at exposures up to 1/500 sec. A comparison of the experimental data with the considerations developed above shows that the multifrequency spectrum corresponds to the condition[2] according to which for $\chi = 200$ and $\zeta = 0.17$ and stationary single-frequency lasing is not possible even with $n-1 > 0.02$. The persistence of the multifrequency regime despite the increase of χ with increasing pumping is evidently related to the peculiarities of the nonstationary processes occurring at the time. It is clear that the observed high sensitivity of the laser to the misalignment of the return mirror, noted also in all previous publications, should play a dominant role in the generation kinetics. As noted earlier, single-frequency lasing is observed in portions of the radiation spikes in some experiments on pulsed excitation, when the wave ratio is below that required by condition (2). This result does not contradict the foregoing if we consider that the treatment of the spike regime within the framework of the stationary model has meaning only as applied to the integrated spectrum over a sufficiently large period of time, the width of which, as we noted, is always large.

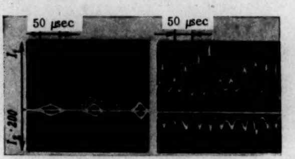

Fig. 2. Kinetics of multifrequency lasing with return mirror. 1) Pumping near threshold; 2) excess above threshold 1.13.

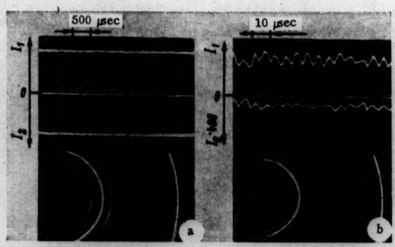

Fig. 3. Kinetics and spectrum of axial modes. a) Without frequency selector and return mirror; b) with frequency selector and return mirror; excess above pumping 1.25. The Fabry–Perot interferometer spacing is 16 mm.

The relatively high value of χ_{th} obtained in our experiments permits (2) to be satisfied for any pumping level by introducing the selective glass plate considered above. In fact, the use of this plate 8 mm thick results in single-frequency lasing and also in a reduction of the fluctuations of the radiation (Fig. 3b). It is interesting to note that at the same time the modulation of the opposing wave intensities became of opposite phase as compared to the spike lasing.

The output power of the single-frequency radiation obtained with the selective plate is limited primarily by the appearance of higher transverse modes. In the TEM_{00} mode it is 0.43 W with $\chi = 600$, and can be increased with the onset of higher transverse modes of 0.65 W.

---

1) Here and below single-frequency lasing is understood to mean the excitation of one axial mode when the laser operates in a single transverse mode.

Measurement of plasma ion temperature by a thin probe with $T_i \gtrsim T_e$

B. I. Kanaev and E. E. Yushmanov

(Submitted August 15, 1973)
Zh. Tekh. Fiz., 44, 870-873 (April 1974)

A method is described for measuring ion temperatures using the ion branch of the volt–ampere characteristic of a cylindrical Langmuir probe operating in the "orbit-limited" regime. The method is applicable for $n \in (10^{12}\text{-}10^{13})\ \text{cm}^{-3}$ and $T \in 200$ eV (in hydrogen); under the proper conditions the absolute error is less than 20%.

INTRODUCTION

Plasmas with ion temperatures higher than electron temperatures are the object of investigation in a number of areas of modern physics, e.g., thermonuclear fusion. The measurement of the ion temperature presents a complicated problem in diagnostics; at energies of several hundreds of electron volts and higher (hydrogen plasma) it is appropriate to use energy analysis of charge-exchange neutrals; on the other hand, reliable methods are not available below 100 eV. In this work we describe a probe method which is especially suitable for the above purpose.

The method is based on the properties of the volt–ampere characteristic of the ion saturation current of a cylindrical Langmuir probe operating in the "orbit-limited" regime. Let us briefly recall the main features of the problem (see, e.g., ref. 1). If the thickness of the probe sheath d is much smaller than r_0, the probe radius, the current of particles collected by the probe (for an attractive potential) is determined by the random flux at the outer surface of the sheath essentially independent of the probe potential, due to the fact that the effective collection radius remains almost constant, i.e., $r_0 + d \approx r_0$. If, on the other hand, the radius of the probe is much smaller than the thickness of the sheath, the current to the probe is determined by the orbital motion of the particles in the field of the probe, and the effective radius is given by $r_0(1 + e\varphi/\varepsilon_\perp)^{1/2}$, where φ is the potential difference (attractive) between the probe and the plasma, and $\varepsilon_\perp$ is the energy of the particles at infinity in the direction perpendicular to the probe axis.

This relationship, given by Langmuir, has been confirmed using the electron saturation current. For the ion current the situation is much more complicated, because of the sheath (for $T_i \ll T_e$, a condition which usually holds for gas discharges), and the ion current does not satisfy the above relationship. This question has been studied in detail in ref. 2; however, experiment shows[3] that it is not completely correct.

In a hot-ion plasma ($T_i \gg T_e$) the theory of orbital collection can be applied to the ion saturation current in simple form, offering the possibility of determining T_i as follows: The plot of the square of the probe current $I_i^2(\varphi) = \text{const}\,(1 + e\varphi/\varepsilon_\perp)$ is linear, and its intersection with the horizontal axis gives $\varepsilon_\perp$, which is related to T_i.

SOURCES OF ERROR

1. Spectral broadening. The effective radius of the probe is different for particles with different energies and one must integrate over all energies of the collected particles. Because it depends on the form of the spectrum, the volt–ampere characteristic is not linear when plotted on a quadratic scale. The results of the integration are given in ref. 1 for the case of a Maxwellian distribution. The plot shows that an appreciable deviation from linearity occurs only in the region of small attractive potentials, i.e., $0 < e\varphi < 0.5T$ (here and in what follows the temperature will be expressed in energy units). As far as ion collection is concerned this region is not useful anyway, because of incomplete blocking of the electron current. In the region of attractive potentials from 0.5T to 5T the quadratic characteristic is linear; however, the value of $\varepsilon_\perp$ which is determined by it is not equal to the true average value of perpendicular energy T, but rather to a somewhat smaller value, namely 0.85T. The complete form of the expression which describes the ion current in this range is

$$I_i \simeq \frac{env}{4} S \left(1 + \frac{e\varphi}{0.85T_i}\right)^{1/2}. \tag{1}$$

Here, n is the plasma density, $v = [8T_i(\pi M_i)^{1/2}]$ is the average speed of the ions, $S = 2\pi r_0 L$ is the area of the probe, and φ is the absolute value of the negative potential of the probe relative to the plasma.

2. Effect of the finite thickness of the sheath. As noted earlier, orbital collection occurs when the condition $r_0 \ll d$ is satisfied. If the sheath thickness d is finite, the difference between the true value of current and that given by Eq. (1) is of order $(r_0/d)^2$, according to the calculation cited above. An estimate for d is obtained from the Debye distance: $d \simeq (T_i/4\pi m e^2)^{1/2}$. For $n \simeq 10^{12}$ cm^{-3} and $T_i \simeq 100$ eV, d is of the order of 0.1 mm, and in order to make the error small the probe should be 10 to 20 μ thick, which causes no technical complications.

3. Magnetization. If the plasma is located in a magnetic field, then the obvious condition for the applicability of orbital considerations is the smallness of r_0 compared with the Larmor ion radius ρ. This condition is more easily satisfied than the previous one, since even in a field of 10 kG, $\rho = 1.4$ mm for a hundred-volt proton.

4. Secondary emission. The ions which strike the probe knock out secondary electrons which leave the probe and thereby give rise to a fictitious ion current. For incident ion energies of about 500 eV (for protons), the coefficient of secondary emission is clearly larger than unity, and the form of the volt–ampere characteristic deviates from Eq. (1). This puts an upper limit on the value of the temperature measured by this method.

5. Plasma potential. A realistically measurable volt–ampere characteristic has for its argument the value of potential with respect to a certain reference value (for example, zero), not with respect to the plasma potential. Therefore, the horizontal intercept of the straight line $I_i^2(\varphi)$ is not the quantity $0.85T_i$ itself, but in-

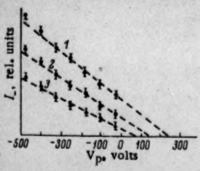

Fig. 1. Quadratic volt–ampere characteristics of the ion current of a thin probe operating at various values of the ion temperature. $U_1 > U_2 > U_3$; T_i, eV. 1) 220; 2) 130; 3) 65.

stead is a correction equal to the potential of the plasma taken with respect to the reference value. The magnitude of this correction can usually be estimated to an accuracy of ± T_e, and if $T_e \ll T_i$, the error in the estimate is not large. If T_e and T_i and comparable a special measurement must be made.

6. Excess heating and disintegration of the probe. Apart from the other considerations, the applicability of the present method in a dense and hot plasma is limited by the need to avoid excess heating of the probe (resulting in thermal emission noise), not to mention disintegration. This requirement imposes a limit on the duration of the process under study. It is not difficult to make a quantitative estimate of this limitation.

EXPERIMENTAL APPLICATION

Our method for measuring T_i has been used in experimental studies of the confinement of a plasma in a minimum-B mirror device[4]. A hot-ion plasma is established by a radio-frequency ion magnetron, using the following as initial parameters: $n \geq 10^{12}$ cm^{-3}, $T_i \simeq 50$-250 eV, and $T_e \simeq 3$-15 eV. The probe for the measurement of T_i is located in a region of reduced density ($n \simeq 10^{11}$ cm^{-3}) at the periphery so that the loss of ions to the probe does not result in a significant reduction of the confinement time. The active portion of the probe is a tungsten wire 20 μ thick and 1 cm long. Data for the volt–ampere characteristics are obtained by making a number of measurements for various values of the negative probe potential.

Figure 1 shows the volt–ampere characteristics (on a quadratic current scale) for various values of the rf voltage U which causes the heating of the plasma introduced into the collector. The curves are nearly linear, and show the various ion temperatures. Some distortion seen at high potentials is probably caused by secondary emission. The errors shown in Fig. 1 refer to the deviation in the values of current from one shot to another. The values of the plasma potentials which are measured approximately for the given regimes, amount to about 20% of the intercepts of the linear sections on the horizontal axis; the error caused by inaccurate knowledge of the potential (± 5-10 V) is therefore small, as noted earlier.

In addition to using the probe method to measure T_i, it was estimated in these experiments by using the spectra of the electrostatic trapping of ions escaping along the magnetic field and by extrapolating the charge-exchange spectrum to the low energy region. Although the results obtained by both of these methods show a greater spread, they are in satisfactory qualitative and quantitative agreement with the probe results given above.

CONCLUSION

In principle, it is possible to use the method described above to measure the local ion temperature in a plasma with $T_i \gg T_e$ in the temperature region (for a hydrogen plasma) from about 200 eV on down and for densities up to 10^{12}-10^{13} cm^{-3}. Although the method is of relatively low accuracy (10-20%), it is useful because of the lack of other methods of comparable simplicity.

The authors thank M. S. Ioffe for a number of useful comments.

Effect of instrumental noise on a system with two spin oscillators using Cs^{133} and He^3

R. A. Zhitnikov, V. V. Semenov, and P. A. Klyushkin

M. I. Kalinin Polytechnic Institute, Leningrad

(Submitted September 28, 1973)
Zh. Tekh. Fiz., 44, 873-875 (April 1974)

We describe the effect of instrumental noise on the operation of a system with two spin oscillators, He^3 and Cs^{133}, one of which (Cs^{133}) is used to stabilize the magnetic field by means of a phase-locked loop. The experimental instrumental noise power spectrum in the frequency range 0.03-1 Hz is given. The frequency drift of the He^3 and Cs^{133} spin oscillators is calculated and compared with the experimental data.

Instrumental noise, which is generated by nearly all electronic equipment, has a significant effect on the operation of an optically pumped spin oscillator.[1] Manifesting itself primarily at low frequencies, line noise modulates the frequency and phase of the oscillations.[2]

In an optically pumped spin oscillator the sources of low-frequency instrumental noise are the intensity fluctuations of the spectral pump lamp, flicker noise current in the photodetector circuit and in the first amplifier stage of the feedback loop, and instability of the power supply. Assuming the sources to be uncorrelated, we can combine them into one equivalent noise generator acting on the input of the feedback amplifier in the form of photodetector flicker noise currents, whose variance is the sum of variances of all noise components in the oscillator circuit. This total noise has a spectral density S_Σ given by the well-known expression[2]

$$\frac{4}{A} > t > \left(\frac{\omega^2\tau_3^4}{A}\right)^{1/n}. \qquad (1)$$

where A is a constant characterizing the noise intensity, and n is a number between 0.6 and 3. Values $n < 1$ correspond to stationary instrumental noise, which leads to a line broadening that is independent of time. For $n > 1$ the noise is nonstationary, and manifests itself in spectral line broadening $\Delta\omega(t)$, which increases with time. The value of $\Delta\omega(t)$ for optically pumped spin oscillators can be determined from the expressions in ref. 1, if the coefficients A and n are known.

In this paper we study the effect of instrumental noise on the operation of a system containing two spin oscillators with optical orientation of Cs^{133} and He^3 in the same cell; the cesium spin oscillator is used in a phase-lock loop to stabilize the magnetic field.[3] The system operates in a magnetic field of about 10 mOe; the Q factor of the Cs^{133} resonance line ~ 4, and that of the He^3 line ~ 500. The mean-square frequency fluctuation of the cesium spin oscillator is less than $5 \cdot 10^{-3}$ Hz over several hours, and is determined mainly by the instability of the reference quartz oscillator in the phase-locked loop. The magnitude and stability of the magnetic field are controlled with the He^3 signal, whose fluctuations are less than $5 \cdot 10^{-5}$ Hz over 30 sec at a signal-to-noise ratio ~ 20 in the 200 kHz bandwidth of the feedback amplifier. The mean value of the fluctuation amplitude of the He^3 spin oscillator frequency increases to $5 \cdot 10^{-4}$ Hz after one hour of operation. We assume that this effect is due to magnetic field variations due to instrumental noise in the Cs^{133} spin oscillator circuit, which cause fluctuations of the oscillator frequency affecting the phase-locked loop. This assumption is verified experimentally by measuring the spectral power density of the instrumental noise in the He^3 and Cs^{133} circuits. The measurements are made with an ultralow-frequency spectrum analyzer, which operates in the 0.01-1 Hz range and has a noise level of ~ $5 \cdot 10^{-6}$ W^2/Hz at 1 Hz. Two photodiodes are connected to the analyzer through a differential input, which either subtracts or adds the signals. In the subtraction mode the analyzer measures the spectral density of the photodetector noise S_p; in the addition mode we measure S_Σ, i.e., the total noise spectral density due to the instability of the pump lamp power supply and the photodetectors (these are the principal noise sources in a spin oscillator).[1)] The experimental values of S_Σ and S_p are plotted versus frequency in Fig. 1 for the He^3 (curves 1 and 3) and Cs^{133} (curves 2 and 4) spin oscillators. The dashed line shows the internal noise level of the analyzer. The He^3 and Cs^{133} spin oscillators employ an FD-7K silicon photodetector connected to a 20 kΩ load and operating as a photodiode with a bias voltage ~ 5 V, and ~ 100 μA (Cs^{133}) and ~ 150 μA (He^3) at constant illumination flux. As follows from Fig. 1, the noise level in the He^3 spin oscillator is about twice as high as in the Cs^{133} oscillator, due to the different values of the dc current flowing through the diodes. At the same time the same slope of the S_Σ and S_p curves indicates that the instrumental noise in both spin oscillators has the same character. The coincidence of the values of S_Σ and S_p at $f = 1$ Hz shows that at this frequency the photodetector flicker current is the main contribution to the instrumen-

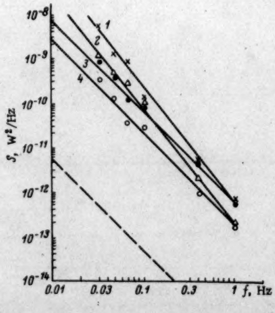

Fig. 1. Curves of the spectral power density of the flicker noise in the Cs^{133} and He^3 spin oscillators as a function of frequency. 1 and 2 represent S_Σ for the He^3 and Cs^{133} spin oscillators, respectively; 3 and 4 show S_p for the same He^3 and Cs^{133} spin oscillators. The dashed curve is the internal noise level of the spectrum analyzer.

tal noise of the spin oscillators. With decreasing frequency other souces of instrumental noise related mainly to the instability of the supply voltages begin to play the predominant role (the curves S_p and S_Σ have different slopes). The pump lamp noise of the He^3 and Cs^{133} spin oscillators turns out to be much smaller than the FD-7K photodetector noise, and is therefore not determined.

The measurements of S_Σ and S_p show that instrumental noise in a system with two spin oscillators, He^3 and Cs^{133}, is of nonstationary character ($n > 1$), and causes broadening of the line with time. Let us evaluate the linewidth $\Delta\omega(t)$ at time t. We use the expression for the instrumental linewidth of a spin oscillator given in ref. 1. It is evident from Fig. 1 that $n \geq 2$. For this case we have

$$\Delta\omega(t) = \frac{1}{2Q}\left\{2A\left[\frac{\pi t^{n-1}}{\tau_2^2\Gamma(n)\sin\frac{\pi(n-1)}{2}} - 2\Gamma(3-n)\,t^{n-3}\sin\frac{\pi(n-2)}{2}\right]\right\}^{1/2}, \qquad (2)$$

where $Q = \omega\tau_2/2$ is the Q of the magnetic resonance line; ω is the Larmor frequency, τ_2 is the transverse relaxation time, including the effect of the pumping light, Γ is the gamma function, which depends on n, and t is the observation time, which satisfies

$$\frac{4}{A} > t > \left(\frac{\omega^2\tau_2^4}{A}\right)^{1/n}.$$

The coefficient A, determined by the value of the spectral density S_Σ at 1 Hz, is $2.5 \cdot 10^{n-14}$ sec^{n-1} for the He^3 and Cs^{133} spin oscillators as determined for $n = 2.5$ from the slope of the curves 1 and 3 in Fig. 1. Substituting these values of A and n into Eq. (2) and using the experimental data, we obtain the following values for the linewidths of the spin oscillators in a magnetic field of 10 mOe: $3 \cdot 10^{-2}$ Hz after one hour for Cs^{133}, and $\sim 10^{-5}$ Hz after 10^7 sec for He^3. It is assumed in the calculation that the character of the curves in Fig. 1 is preserved at lower frequencies. A comparison of these values with the experimental data shows that the magnetic field variations corresponding to the calculated broadening of the cesium spin oscillator linewidth ($\sim 9 \cdot 10^{-3}$ gamma/h) are about of the same order of magnitude as the increased mean fluctuation of the magnetic field obtained in the experiment from the He^3 spin oscillator signal ($16 \cdot 10^{-3}$ gamma/h). The measurements are made with thermostatic control of the cell and of the cesium spectral pump lamp operation. This makes it possible to lower the measurement errors due to thermal frequency shifts of the Cs^{133} spin oscillator.[4,5]

---

1) The spectrum analyzer and the method of measurement of the quantities S_Σ and S_p will be described in a separate paper.

Method for determining the absolute characteristics of CF_3I laser emission

V. S. Komarov, V. G. Seleznev, and G. A. Skorobogatov

A. A. Zhdanov Leningrad University

(Submitted April 26, 1973)
Zh. Tekh. Fiz., 44, 875-878 (April 1974)

A method is proposed for calculating the absolute pump radiative flux from the absolute energy and the shape of the stimulated emission pulse of a CF_3I laser. This method is used to measure the absolute characteristics of the stimulated emission and pump radiation for a CF_3I laser with initial CF_3I pressures ranging from 20 to 370 torr for pump fluxes (10^{22}-10^{23} photon/cm^2 · sec in the CF_3I absorption band) that exceed by one order of magnitude the values attained by previous researchers. Our data and those of other authors for four values of the initial CF_3I pressure (20, 74, 185, and 370 torr) are used to plot the absolute quantum yield of the CF_3I laser emission as a function of the absolute pump rate.

1. Since the discovery by Kasper and Pimentel[1] of the iodine CF_3I laser, there have been about 10 published papers[2-9] which studied the dependence of stimulated emission on the initial concentration $[CF_3I]_0$ of the active medium, the pump energy, and other parameters. It was established in these papers that for a sufficiently long pump pulse CF_3I lasing always cuts off due to some internal mechanism, so that only 2-5% of all CF_3I molecules in the working volume contribute even one photon of stimulated emission. The possible chemical processes leading to quenching of CF_3I laser action have been widely discussed in the literature.[4-6,8-13] These discussions, which are based on a comparison between the stimulated emission characteristics derived from some model and the experimental data suffer from the fact that, there is nothing to compare the calculations with. Almost all of the experimental papers measure only the relative stimulated emission energy; the pump fluxes are not determined. The absolute stimulated emission energies are measured in only four papers[3,6-8] for several isolated $[CF_3I]_0$ values, and only in refs. 6 and 8 are the pump fluxes estimated.

Considering the experimental difficulties of direct measurements of the absolute light fluxes, on the one hand, and the decisive role of these data in choosing a model for CF_3I laser action, on the other, we have devised a method for determining these parameters. The method has been employed to measure the absolute characteristics of stimulated emission of the CF_3I laser and the pump radiation over a broad range of $[CF_3I]_0$ values with pump fluxes (in the CF_3I absorption band) that exceed those attained previously by more than one order of magnitude.

2. The quartz laser cell (inner diameter 5.4 mm, l = 250 mm, and working volume V = 5.7 cm^3) with end windows tilted at 90° to the cell axis, is surrounded by four IFP-5000 lamps wrapped in aluminum foil. The pump pulse, which passes through a coaxial air discharge gap, is obtained by delivering voltage of 10 to 30 kV to the lamp from two KMK-40-4 capacitors (C_{tot} = 7.6 μF, L = 15 nH). For a discharge energy of 500 J the pump pulse length in the uv region at half-height is 10 μsec; for 3600 J it is 20 μsec.

The cavity is formed by an opaque mirror and a mirror with a dielectric coating with 10% reflection at 1300 nm. The radius of curvature of the mirrors is 1 m and they are 750 mm apart. A portion (20%) of the stimulated emission is reflected by a quartz plate and, after attenuation by approximately a factor of 100 passes through the waveguide to the sensor (a FD9E111B photodiode) of an S1-29 recording oscilloscope. The remaining 80% falls on the input to an IKT-1M calorimeter. The use of cells with Brewster windows does not increase the yield of stimulated emission energy per 1 cm^3 of working volume.

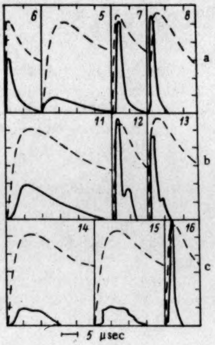

Fig. 1. Pump (dashed lines) and stimulated emission (solid lines) pulses of a CF_3I laser for $[CF_3I]_0$ = 74, 185, and 370 torr (a, b, and c, respectively). The numbers in the figure correspond to the numbers in the table.

Trifluoridemethane (99.8% of the basic product) is purified by 10 vacuum distillations with sampling in each case of 4/5 of the volume of the substance during the middle of the distillation. The purity of the product is monitored by using a gas chromatograph and the IR spectra.

3. The measured pump and stimulated emission pulses are shown in Fig. 1. It can be seen from Fig. 1 that in all cases lasing cuts off due to true chemical quenching before the pumping radiation drops 20-40% below its peak. For each initial pressure $(CF_3I)_0$ given in Table 1, we also give the pump energy (E_{pump}), the measured yield of stimulated emission energy per 1 cm^3 of working volume (E_{las}), the time at which maximum lasing is reached (t_{max}), and the lasing cutoff time (t_{quen}). The table also gives values, calculated from

$$\Gamma_\Sigma (\%) = \frac{0.988 \cdot 10^{19} E_{las}\ (\mathrm{J/cm^3})}{[CF_3I]_0\ (\mathrm{mole/cm^3})} \cdot 100 \qquad (1)$$

for the integrated stimulated emission yield (Γ_Σ) in per-

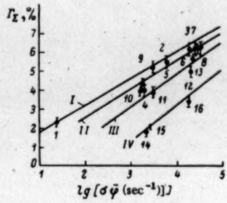

Fig. 2. Integrated quantum yield Γ_Σ (%) of stimulated emission of the CF_3I laser as a function of the logarithm (base 10) of the absolute pump rate $\sigma\tilde{\varphi}$ (sec^{-1}) averaged over the lasing time. The numbers next to the points correspond to the numbers in the table. torr: I) 20; II) 74; III) 185; IV) 370.

cent of the maximum possible value $2/3[CF_3I]_0$. Also, the measured values of E_{las} and the shapes of the lasing pulses are used to calculate the maximum stimulated emission power E_{max}(J/cm^3 · sec) per unit working volume. These values are given in the table in units of photon/cm^3 · sec (G_{max}). The table also contains the values obtained from

$$\sigma\varphi\,(t_{max})\,\frac{1}{\sec.} = \frac{1.5G_{max}\,(\text{photon/cm}^3 \cdot \sec)}{[CF_3I]_0} \tag{2}$$

for the flux (φ) of pump radiation in the CF_3I absorption band at maximum lasing (t_{max}) multiplied by the cross section (σ), averaged over the band, of the absorption of photons by the CF_3I molecules[12] ($\sigma \simeq 4 \cdot 10^{-19}$ cm^2/mole). The justification for using Eq. (2) [the basic equation of this paper] is based on the following four considerations.

First, in contrast to earlier ideas about the operation of photodissociation lasers,[15,9,11] recent experimental work[6,12,16-18] has established that no chemical process can raise the output of a CF_3I laser by more than 10-13% in comparison to the peak output [see Eq. (20) ref. 13]

$$G(t) = \frac{2}{3}\,\sigma\varphi\,(t)\,[CF_3I]. \tag{3}$$

Second, quantitative estimates indicate that for sufficiently high Q of the cavity and sufficiently high pumping energies, the output energy density increases to values in accordance with Eq. (3) even for a short time ε after onset of lasing (t_{las}).

Third, investigations[9,10,13,19] undertaken by us indicate that for a time $t \leq \min\{t_{las} + 1\ 3(t_{quen} - t_{las}), t_{max}\}$ and for any possible quenching mechanism, CF_3I laser action is not reduced by more than 2-5% in comparison with (3).

Fourth, in the CF_3I laser at t_{max} not more than 2-4% of the initial amount of the active medium has been consumed, so that one can set $[CF_3I] = [CF_3I]_0$ in Eq. (3):

$$G(t) = \frac{2}{3}\,\sigma\varphi\,(t)\,[CF_3I]_0 \Big\{ t_{las} + \varepsilon < t \leq \min\Big[t_{las} + \frac{1}{3}(t_{quen} - t_{las}),\ t_{max}\Big]\Big\}. \tag{4}$$

Equation (2) is obtained from Eq. (4) for $t = t_{max}$.

The table also contains values of σ multiplied by the fluxes $\tilde{\varphi}$, averaged over the lasing time, of the pump radiation in the CF_3I absorption band

$$\sigma\tilde{\varphi} = \frac{1}{t_{quen} - t_{las}} \int\limits_{t_{las}}^{t_{quen}} \sigma\varphi\,(t)\,dt, \tag{5}$$

which are calculated for fixed shapes of the pump pulses and values of $\varphi(t_{max})$. Allowing for experimental error and the assumptions made in deriving Eq. (4), we can assume that the values of $\sigma\tilde{\varphi}$ have a relative error of 20-25%. The relative amount of active CF_3I at maximum lasing is

$$n\,(t_{max}) = \frac{[CF_3I]_{t_{max}}}{[CF_3I]_0} = \exp(-\sigma\tilde{\varphi} t_{max}). \tag{6}$$

It is evident from these values that the assumption $[CF_3I] = [CF_3I]_0$ made in the derivation of Eq. (4) is valid in all cases.

In addition to our data, Table 1 gives the experimental results of other authors after processing by our method. On the basis of the values obtained for Γ_Σ and $\sigma\tilde{\varphi}$ the dependence of Γ_Σ(%) on the product of σ and the average absolute fluxes of $\tilde{\varphi}$ of pumping radiation in the CF_3I absorption band is given in Fig. 2 for different values of $[CF_3I]_0$.

In conclusion, the authors thank A. G. Morachevskii, whose support made the present work possible.

Electrostatic analyzer for wide beams

V. G. Kovalenko and B. V. Polenov

(Submitted July 21, 1972; resubmitted January 12, 1973)
Zh. Tekh. Fiz., 44, 878-880 (April 1974)

The design of a novel electrostatic analyzer is proposed in which the electrodes are shaped like logarithmic spirals to increase sensitivity and to reduce size and weight.

Cylindrical electrostatic analyzers in which the electrode gap and curvature are independent of the deflection angle of the particle beam are currently used widely for energy selection of widely charged particles.[1] However, the sensitivity of the corresponding measurements in terms of the flux density turns out to be inadequate for several problems because of the small area of the entrance of the analyzer. The analyzer dimension or the gap between the electrodes can be increased only at the cost of a significant increase in the overall dimensions of the apparatus. Furthermore, an increase in the gap alone leads to a degradation of the resolution and the selectivity of the analyzer in terms of the type of radiation being detected, and higher working voltages are required.

We report here on the design and characteristics of a cylindrical electrostatic analyzer[2] in which the sensitivity of the measurements in terms of the flux density is increased and the dimensions of the apparatus are reduced through the use of electrodes whose directrices are described by the logarithmic spiral

$$r(\varphi) = ae^{-k\varphi},$$

where a = const, r and φ are polar coordinates, $k = \cot\psi$, and ψ is the angle between radius vector r and the tangent at an arbitrary point of the line $r(\varphi)$ (Fig. 1).

Neglecting the fringing fields, we can determine the potential distribution between the analyzer electrodes, $V(r, \varphi)$, in the r, φ coordinate plane through a conformal mapping:

$$W(z) = U(z) + iV(z) = ie^{i\beta}(A \ln z + B),$$

where A and B are constants governed by the potentials on the analyzer electrodes, $\tan\beta = k = \cot\psi$, and z is the complex variable.

In the case of in-phase voltage on the analyzer electrodes ($V = \pm V_0/2$), the potential distribution between the electrodes is given by

$$V(r, \varphi) = V_0 \frac{\ln \frac{r}{\sqrt{a_1 a_2}} + k\varphi}{\ln \frac{a_2}{a_1}}.$$

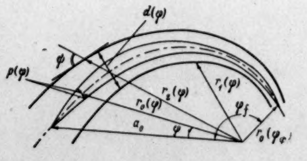

Fig. 1. Electrostatic analyzer with electrodes shaped like logarithmic spirals.

It follows from this equation that the equipotentials are also logarithmic spirals. The radius vector $\mathbf{r}_0 = (\varphi) = \sqrt{\mathbf{r}_1(\varphi)\mathbf{r}_2(\varphi)}$ specifies the equilibrium trajectory, at which the potential is zero.

In an analyzer whose electrodes are shaped like logarithmic spirals the ratio of the gap between the electrodes $\mathbf{d}(\varphi)$ to the radius of curvature of the equilibrium trajectory, $\rho_0(\varphi)$, is a constant:

$$\frac{\mathbf{d}(\varphi)}{\rho_0(\varphi)} \approx \frac{(a_2 - a_1)\sin\psi}{\sqrt{a_1 a_2 (1 + \mathbf{k}^2)}} = \text{const.}$$

Because of the constancy of the ratio $[\mathbf{d}(\varphi)]/[\rho_0(\varphi)]$, particles having energies of approximately $\mathbf{E}_0 = \mathbf{q}[(\mathbf{V}_0\rho_0)/2\mathbf{d}]$, where **q** is the particle charge, can pass through the analyzer.

Since the lines of force intersect the equilibrium trajectory at right angles, the electrodes should be cut off at the entrance and exit of the analyzer along the normal to the equilibrium trajectory, rather than along the radius vector, even though the second approach is in principle possible.

To determine the focusing angle φ_f we use the equation for the displacement $\rho(l)$ (Fig. 1) with respect to a trajectory coinciding with an equipotential. The displacement $\mathbf{p}(l)$ is a function of the path length along this trajectory, l, and is found from[3]

$$\frac{d^2\mathbf{p}(l)}{dl^2} + \frac{2}{\rho(l)^2}\mathbf{p}(l) = 0$$

and the boundary condition $\mathbf{p}(0) = 0$.

Taking into account the relations among l, ρ, and $\mathbf{r}$ [$l = (\sqrt{1 + \mathbf{k}^2})/\mathbf{k}(a - \mathbf{r})$ and $\rho = \sqrt{1 + \mathbf{k}^2}\mathbf{r}$], we can rewrite this equation

$$\frac{d^2\mathbf{p}(r)}{dr^2} + \frac{2}{r^2\mathbf{k}^2}\mathbf{p}(r) = 0$$

with the boundary condition $\mathbf{p}(a) = 0$. Particle focusing is achieved if the solution of this equation is a periodic function, as it is in the case[4] $k < 2\sqrt{2}$. In this case, using $\mathbf{r} = ae^{-\mathbf{k}\varphi}$, we find $\mathbf{p}(\varphi) = \mathbf{C}e^{-\mathbf{k}\varphi/2}\sin\sqrt{(8 - \mathbf{k}^2)}/2\varphi$, where C is a constant. Hence we have $\varphi_f = (2\pi/\sqrt{8 - \mathbf{k}^2})\mathbf{n}$, where **n** is an integer.

With $\mathbf{k} \geq 2\sqrt{2}$, the analyzer has no focusing properties, so when the experimental conditions require no focusing the analyzer can have a large value of k, so that the analyzer dimensions can be reduced further.

To study the analyzer characteristics, we have calculated the electrode shapes and constructed an electron spectrometer with cylindrical electrodes and entrance and exit cuts along the normal to the equilibrium trajectory. This analyzer has the following dimensions: a_1 = 85 mm,

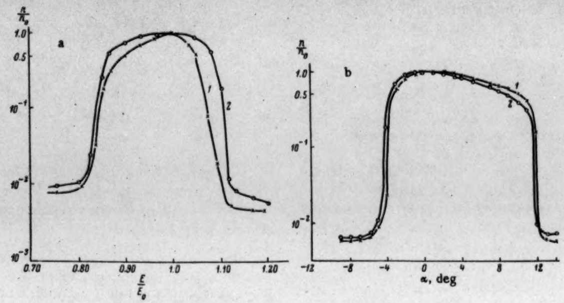

Fig. 2. Energy (a) and angular (b) characteristics of the analyzer E, keV: 1) 1; 2) 3.6.

$a_2 = 118$ mm, an electrode height of $h = 110$ mm, $d/\rho_0 = 0.24$, $\varphi_p = \varphi_f = 130°$, $\psi = 60°$, $S_{en}/S_{exi} = 3.6$, and $k = 1/\sqrt{3}$. The effects of the fringing fields at the entrance and exit are suppressed by means of limiters with rectangular apertures having a height of 55 mm and a width equal to the entrance or exit gap (the centers of these apertures coincide with the centers of the entrance and exit windows). For the case of a broad, unidirectional electron flux at an energy of $E_0 = 1.0$ or 3.6 keV, incident normal to the entrance window of the analyzer, the ratio of the particle flux density at the exit of the analyzer to that at its entrance is 1.6 or 1.7, respectively, about 3.5 times higher than in the case of an ordinary cylindrical electrostatic analyzer. Typical energy and angular characteristics of the analyzer are shown in Fig. 2.

In conclusion we should note that analyzers which collimate broad particle beams can be used with discrete detectors with a relatively small entrance window and a restricted field of view (e.g., with secondary-electron multipliers with discrete and continuous dynodes). The shapes of the analyzer electrodes can correspond to parts of a sphere or torus.

Vacuum-UV and soft x-ray emission in a magnetoplasma compressor

P. E. Kovrov and L. G. Tokarev

(Submitted April 13, 1973)
Zh. Tekh. Fiz., 44, 881-883 (April 1974)

The emission in the range 150-200 Å and below 20 Å of magnetoplasma compressors of the rod and radial types is studied by means of absorbing filters. It is found that UV emission continues for a time comparable to the discharge time, while the x-ray emission (energy of 2.5-4 keV) is irregular. The emission intensity is given as a function of the discharge parameters.

There is general agreement in the importance of studying the short-wavelength emission in high-current discharges; such studies not only furnish the necessary complement to spectral studies in the visible region, but are also of decisive importance for the understanding of certain physical processes and can reveal several of the most important plasma characteristics.

On several occasions measurements of this type have been carried out in connection with a study of coaxial plasma guns.[1-4] Both soft and hard x-ray emission have been demonstrated, both at an energy several times higher than that corresponding to the applied voltage. In coaxial guns, however, and in z pinches[5] and in the plasma focus,[6] the hard x-ray emission lasts for only a fraction of a microsecond, a time much shorter than the length of the discharge.

On the other hand, the theory of ref. 7 predicts that high plasma parameters can be attained in steady-state operation of a magnetoplasma compressor. Experimental work on these compressors[8] has demonstrated the presence of ions with a high degree of ionization in the compression zone; these ions have a long lifetime.

In this note we report on a study of the vacuum-UV and soft-x-ray emission. We use two types of magnetoplasma compressors: a conical type and a radial type (Fig. 1). In the conical version the compressor consists of a cylindrical central electrode (d = 12 cm), one end of which is tapered into a cone, and an external electrode, consisting of 12 rods spaced uniformly at a distance D = 21 cm. In the radial version both electrodes are a system of rods arranged along the radii of two coaxial circles, at a distance z = 4 cm apart. The current is supplied by a coaxial cable.

The working gas is hydrogen, which is injected into the vacuum chamber before the experiment, at a pressure of 0.1-5 torr; in the conical version, there is also a pulsed injection of gas.

The discharge current is 250-500 kA, the bank voltage is 5 kV, and the current pulse is 75-150 μsec long. The polarities of the electrodes can be reversed. A detailed experimental study of the magnetoplasma compressor is reported in ref. 8.

The emission is analyzed by a method involving absorbing filters and detection by a plastic scintillator with a photomultiplier. The filters are made from aluminum foil ranging from 6 to 70 μ in thickness from beryllium foil, 100, 150, and 500 μ thick, and various combinations of these foils. The resolving time of the apparatus is 0.1 μsec.

We are interested primarily in the zone of maximum density – the plasma focus; in the conical version this is the axial zone beyond the end of the central electrode; in the radial version this is the axial zone between the electrodes.

EXPERIMENTAL RESULTS

Figure 2 shows characteristic oscillograms of the emission recorded with various filters. We see that the nature of the oscillogram is strongly influenced by the filter used, because the emission detected in these cases falls in different spectral regions.

The oscillogram in Fig. 2b corresponds to the case in which the total radiation in the visible and UV regions is detected. The first large peak on this oscillogram results from the appearance of a dense plasma piston, which precedes the formation of the plasma focus in the region being observed. This peak lasts about 5 μsec and is always observed before the feature in the discharge current. The

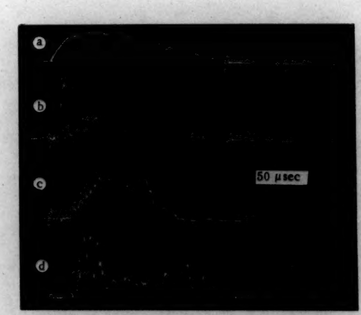

Fig. 2. Oscillograms of the discharge current (a) and of the emission detected through various filters (b-d). a) Discharge current, I_m = 350 kA; b) Al (thickness of 800 Å); c) Al (5.85 μ); d) Al (3 × 5.85 μ).

intensity of the visible emission at this time is much higher than that at later times.

The far-UV region poses serious experimental difficulties. We only study the emission in a narrow spectral region, $\lambda = 150\text{–}200$ Å, corresponding to a transmission "window" of the aluminum foils. The spectral interval studied is determined by the combination of aluminum, beryllium, and hydrogen filters. The oscillogram in Fig. 2c is typical of the emission intensity in this spectral range.

The UV emission always begins with the appearance of the feature in the discharge current and lasts for a long time (for a time of the order of the lifetime of the discharge current). The oscillograms display a deep, irregular modulation. The modulation depth in the conical version is influenced only slightly by the collimation of the measuring system, while that in the radial version increases as the collimation is improved. In both cases the modulation intensifies when the hydrogen pressure in the discharge cap is reduced or when the inner electrode is made the anode (this arrangement has the positive polarity).

The emission intensity in this spectral range is approximately the same for the radial and conical versions, changes slightly as a function of the gas pressure, and is essentially independent of the polarity. The emission intensity is a very strong function of the bank voltage:

$$\frac{I_2}{I_1} = \left(\frac{U_2}{U_1}\right)^n, \quad 3 < n < 4,$$

where I is the emission intensity at a bank voltage of U.

Experiments carried out with a pinhole camera and a scintillation method with various degrees of collimation show the source of the UV emission to be the zone in which the plasma density is a maximum.

According to our experiments, the energy emitted in the range 150-200 Å by these magnetoplasma compressors is about 1 J per discharge when the input energy is ≈ 20 kJ. This is the sum of the energies corresponding to the line, recombination, and bremsstrahlung emission; we do not know the relative contributions. Measurements with thicker filters allow us to study the emission in the soft x-ray region; Fig. 2d shows a characteristic oscillogram of the emission in this region. As in the UV region, the emission begins when the feature appears in the discharge current and lasts for 10-90 μsec. The oscillograms of the emission intensity are less regular and are dominated by bursts lasting an average of ≈ 1 μsec. The intensity also varies markedly from discharge to discharge, in both length and amplitude. In the positive-polarity case, the intensity of this emission increases by nearly an order of magnitude, other conditions being the same. The increase in the x-ray intensity as a function of the bank voltage is analogous to that of the UV intensity.

The energy of the x-ray emission is determined in a two-channel setup by means of a combination of aluminum and beryllium filters. The spectral range of this emission turned out to have a narrow band corresponding to an energy of 2.5-4 keV and to be essentially independent of the compressor design and the discharge parameters, including the bank voltage.

This behavior distinguishes this emission in a magnetoplasma compressor from the emission described in refs. 1-6, where the x-ray emission is observed at an energy lower than that corresponding to the applied voltage by a factor of 10, and the emission lasts for a fraction of a microsecond.

The x-ray emission is most probably due to an instability of the plasma formation.

In conclusion the authors thank A. I. Morozov for his interest in this work, they thank A. I. Yaroslavskii, A. K. Vinogradova, V. I. Berkov, and E. N. Gavrilovskaya for useful discussions, and they thank M. A. Tsibizov and V. P. Trofimov for assistance in the experiments.

Multiple recording and erasure of optical information in certain glassy chalcogenides

V. V. Korsakov, V. I. Nalivaiko, V. G. Remesnik, and V. G. Tsukerman

(Submitted July 24, 1973)
Zh. Tekh. Fiz., 44, 883-885 (April 1974)

Glassy chalcogenide semiconductors are completely new recording media, used in holography.[1-5] In addition, they are extremely promising materials because of their capability of recording holograms with a high diffraction efficiency and with essentially unlimited resolution. Workers describing the properties of these materials have also pointed out the possibility of a reversible recording of holograms; the optical information is erased by heating part of the semiconducting layer. No information has been reported on the changes in the properties of the material over repeated cycles of recording and erasure. These properties are extremely important in an evaluation of the operation of chalogenide semiconductors as operational storage media. In this note we report the preliminary results obtained in a study of the multiple recording and erasure of optical information in certain glassy chalcogenides.

We have studied compounds of the systems As–S, As–Se, As–S–Se, As–S–I, As–Se–I, and As–S–Se–I. The samples, ranging in thickness from a few microns to 20μ, are prepared by a vacuum deposition of the stock material on a substrate by pulsed thermal evaporation or by the electron-beam method. The substrates are polished plates of BaF_2 and CaF_2 crystals, whose linear expansion coefficients are approximately equal to those of the material being deposited. This matching avoids cracks and other types of damage which occur in the material when films on glass substrates are heated and cooled; it permits a repeated study of cycles of optical recording and thermal erasure of information. The information is recorded by means of a helium–neon laser in films based on antimony selenide and by an argon laser in films based on antimony sulfide. The film composition is chosen on the basis of the position of the fundamental absorption edge, which lies in the range of wavelengths generated by the lasers ($\lambda_{He-Ne} = 6328$ Å and $\lambda_{Ar} = 5145$ Å). Under the influence of the radiation or the heating the fundamental absorption edge shifts toward longer wavelengths; there is a concomitant change in both the transmission coefficient and the refractive index of the material. These quantities are found to be interrelated (Fig. 1). The abscissa in Fig. 1 shows the change in the relative film transmission ($\Delta T = T_0 - T_1$, where T_0 is the transmission of the part of the film at the given wavelength, assigned the value of 100%, and T_1 is the relative transmission of the exposed or heated region). The ordinate shows the change in the refractive index, determined from the shift of the fringes observed in a dual-beam interferometer. The exposed sample is placed in one arm of the interferometer, and the light source is a helium–neon laser.

We see from this figure that the shift in the edge of the absorption band is accompanied by a significant change in the refractive index, due to the high diffractive efficiency of the recorded diffraction grating. In our experiments the diffraction efficiency reaches 30% in the case of recording by a helium–neon laser and 80% with an argon laser. However, the first thermal erasure causes significant changes in the properties of the material. Figure 2 shows the decrease in the changes of the optical properties of the material during exposure after the first erasure of the information in the film through a heating of the film to a temperature of 200°C and subsequent cooling to room temperature. We see from this figure that the change in the transmission (Fig. 2a) and that in the refractive index (Fig. 2b) during the irradiation reach saturation, but the limiting changes in these parameters decrease rapidly after the first erasure cycle. After more of these cycles, the values of these quantities do not change, and the properties of the material remain essentially constant (Fig. 3). The extent of the changes in the optical properties of the recording film depends on the film composition and the deposition technique. As a rule, films having a relatively high sensitivity to radiation (i.e., films displaying relatively large changes in Δn and ΔT) suffer a more pronounced loss in sensitivity after the first erasure cycle.

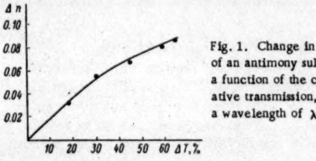

Fig. 1. Change in the refractive index of an antimony sulfide film, Δn, as a function of the change in the relative transmission, ΔT, measured at a wavelength of $\lambda = 5200$ Å.

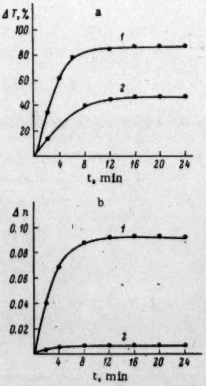

Fig. 2. Changes in the relative transmission (a) and in the refractive index (b) of an $As_2S_3 \cdot As_2Se_3$ film during its irradiation by a helium–neon laser (intensity of $p = 6.5$ mW/mm^2). 1) After film deposition; 2) after the first erasure cycle.

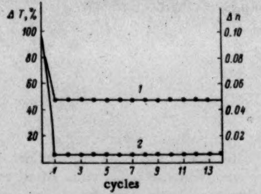

Fig. 3. Change in the relative transmission ΔT (1) and change in the refractive index Δn (2) of an As_2S_3. As_2Se_3 film as a function of the number of recording–erasure cycles N. The film was irradiated by a helium–neon laser at an intensity of p = 6.5 mW/mm² for 10 μsec.

It could be suggested that the loss of optical sensitivity is due to oxidation of the surface with heating in air; however, the materials do not retain their properties when they are heated in high vacuum (a residual gas pressure lower than 10^{-6} torr) or when special brightening or protective coatings are applied.

Since the deposition technique strongly affects the sensitivity of a film, it could be argued that the film structure after the deposition is extremely disordered. Photochemical processes in the film caused by the illumination[4] improve the structure, thereby significantly changing the optical properties of the material. Erasure of the stored information requires heating the material to its softening point. The film structure becomes more ordered in this process, so the changes displayed in the optical properties upon a repeated illumination are not as pronounced.

Figure 4 shows that the film must be heated to its softening point (180–200°C) for erasure of the stored information. We see that the diffractive efficiency of the grating recorded by an argon laser in an antimony sulfide film does not change at temperatures up to 180°C. At higher temperatures the diffractive efficiency falls off sharply, implying erasure. When the grating is rerecorded, the diffractive efficiency is below 5–7%.

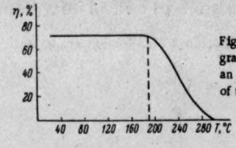

Fig. 4. Diffractive efficiency η of a grating recorded by an argon laser in an antimony sulfide film as a function of the erasure temperature.

Accordingly, the second and subsequent erasures of the information stored in thin glassy chalcogenide films cause the diffractive efficiency of the recorded grating to fall off by an order of magnitude. If we assume that the responsible mechanism involves an improvement in the structure of the material upon slow heating and cooling, we can assume that a more rapid process, e.g., local heating by a powerful laser or pulsed illumination, would help stabilize the properties of the material. We have observed this effect during pulsed recording and erasure of information bits in such materials.[6] Obviously, the question of the optimum program of multiple erasure of the optical information in glassy chalcogenide films requires further study.

The authors thank V. M. Lyubin and M. N. Korotkevich for synthesizing the stock materials and for support.

Temperature dependence of the dielectric permittivity of single-crystal TiO_2 in the submillimeter range

A. A. Volkov, N. A. Irisova, and G. V. Kozlov

P. N. Lebedev Physics Institute,
Academy of Sciences of the USSR, Moscow

(Submitted April 27, 1973; resubmitted August 31, 1973)
Zh. Tekh. Fiz., 44, 886-888 (April 1974)

A procedure is described for obtaining the dielectric characteristics of transparent dielectrics as functions of the temperature in the submillimeter range of wavelengths. Measurements of ε' and tan δ are reported for single-crystal TiO_2 for λ = 0.8-3.5 mm at temperatures from 4.2 to 1000°K.

The dielectric properties of single-crystal TiO_2 are of interest because the structural formation of TiO_2 represents a basic structural element of ferroelectric titanates, whose properties have been the subject of extensive research. In addition, crystalline rutile has wide technical applications in optics, microwave technology, and radio engineering. Its dielectric properties in these ranges have been thoroughly studied.[1]

Recent rapid developments in physics and engineering require broadening our knowledge of the properties of rutile in the submillimeter range.

We have measured the permittivity and loss tangent of single-crystal TiO_2 at wavelengths from 0.8 to 3.5 mm at temperatures from 4.2 to 1000°K. The measurements are performed on a quasioptical setup using monochromatic backward-wave oscillators and wire mesh optical elements. Measurements are made of the transmission of a plane slab of TiO_2 15 mm square and 1.32 mm thick, with the optic axis in the plane of the sample, placed in a thermostat in a nitrogen[3] or helium cryostat.

Figure 1 shows a block diagram of the experimental arrangement.

Monochromatic radiation from a backward-wave tube is shaped by a horn and a Teflon lens into a parallel beam, polarized by a mesh element, passed through the sample in the cryostat (thermostat), and recorded by an OAP-5 optical–acoustic receiver. A grid polarizer can polarize the incident radiation with the **E** vector parallel to or perpendicular to the optic axis of the crystal under study.

The fixed-frequency signal to the receiver, recorded on a two-coordinate recording instrument while the sample in the cryostat is cooled from room temperature to the temperature of liquid nitrogen, is shown in Fig. 2. The oscillatory character of the curve is a result of the interference of radiation inside the sample. The distance between interference maxima is determined by the change of the index or refraction with temperature, and the widths of the curves depend on the index of refraction n and tan δ, which characterize the absorption in the sample.

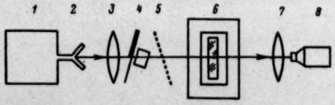

Fig. 1. Schematic diagram of experimental arrangement. 1, 2) Monochromatic oscillator with horn; 3, 7) Teflon lenses; 4) modulator; 5) polarizer; 6) thermostat (cryostat) with sample; 8) optical–acoustic receiver.

Considering the slab of TiO_2 as a Fabry–Perot interferometer, its transmission τ as a function of the wavelength λ and the index of refraction n for a sample thickness d can be described by the well-known Airy equation,[4] which is valid when the index of refraction of the sample n is independent of λ:

$$\tau=\left(1-\frac{A}{1-R}\right)^2\frac{1}{1+[4R/(1-R)^2]\sin^2\frac{2\pi nd}{\lambda}},$$

where R is the reflection from the sample and A is the absorption in it.

The interference maxima in the transmission of a slab appear when

$$nd=\frac{m\lambda}{2},$$

where m = 1, 2, 3, ... is the number of the maximum.

If the index of refraction of the sample depends on the temperature, this condition is satisfied periodically for a certain fixed wavelength λ_1 and for slow cooling or heating of the sample, and at certain temperatures the sample becomes transparent. By changing the wavelength we obtain the same maxima but at different temperatures (Fig. 2, curve 2). Thus, having experimental curves of the temperature dependence of the transmission of the sample $\tau(T)$ taken at various wavelengths it is possible to trace the displacement of any maximum with temperature and to determine its number, m. When the position of the m-th maximum for λ_1 coincides with the (m + k)-th maximum (where k is an integer) obtained with another wavelength λ_2, the condition

$$m\lambda_1=(m+k)\lambda_2$$

is satisfied and the number corresponding to maximum m is determined. Many measurements made with various

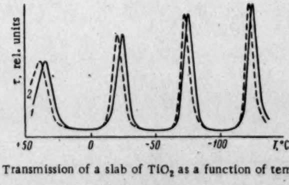

Fig. 2. Transmission of a slab of TiO_2 as a function of temperature.

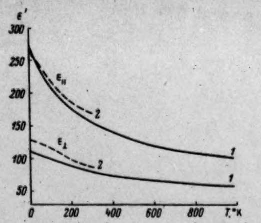

Fig. 3. Temperature dependence of permittivity of rutile. λ, mm: 1) 0.8-3.5; 2) 10 (ref. 5).

wavelengths for various values of k always give accurately integral values of the numbers m of the maxima. This indicates there is not much dispersion and one can assume that the numbers of the maxima m are determined with absolute accuracy. By varying the wavelength we obtain the m-th maximum at a different temperature each time, and in each case we determine the index of refraction n from the condition on the behavior of the interference maximum.

A sample of rutile is studied in this way in a thermostat up to a temperature of 1000°K. In all the temperature measurements the temperature gradient in the sample does not exceed 0.03 deg/mm. However, in the measurements in the helium cryostat, where the temperature can be varied smoothly from 4.2°K to the liquid-nitrogen temperature, the pronounced nonlinearity of the temperature gages prevents us from obtaining interference maxima suitable for processing by the procedure we have described. Therefore in this case we measure the transmission of the sample, not as a function of temperature, but of the wavelength of the transmitted radiation at fixed temperatures, and observe the displacement of the maxima. The number of a maximum can be obtained by using measurements made in the nitrogen cryostat. To do this it is sufficient to know the number of the maximum of the $\tau(T)$ relation at the liquid-nitrogen temperature and the wavelength at which it is obtained, and then to find this maximum on the $\tau(\lambda)$ relation obtained at the liquid-nitrogen temperature in the helium cryostat.

We note that it is difficult to determine $\tau(\lambda)$ since retuning the backward-wave tube changes its power output and prevents a direct determination of $\tau(\lambda)$ by using the scheme shown in Fig. 1. Another receiver is required to measure the power incident on the sample. The final determination of $\tau(\lambda)$ is made by dividing the reading of the receiver beyond the sample under study by the reading of the receiver before it.

Measurements made at wavelengths from 3.5 to 0.8 mm show that within the experimental error n is independent of the wavelength at all temperatures.

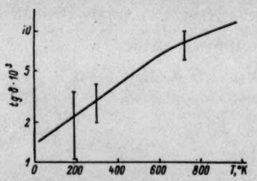

Fig. 4. Temperature dependence of tan δ for rutile at a wavelength λ = 1.9 mm.

Figure 3 shows the permittivity of a single crystal of rutile along two axes using 1 mm waves at temperatures from 4.2 to 1000°K. For comparison the figure also shows the values of the permittivity of rutile obtained[5] for λ = 10 mm.

The accuracy of the measurement of n is determined by the quality of the interference maxima on the transmission curve. For the frequency and temperature ranges studied the interference maxima have Q values from 50 to 300, ensuring an error of no more than 1% in n.

The loss in the sample is calculated from the half-widths of the maxima of the $\tau(T)$ and $\tau(\lambda)$ curves discussed above. The error in measuring tan δ for rutile increases to 100% as the temperature is lowered, since the TiO_2 sample becomes highly transparent and the maxima are noticeably narrowed. The quality of the equivalent resonator is now determined mainly by the reflection from the faces of the sample and becomes very large in comparison with the small changes due to the decrease of absorption in the sample at lower temperatures.

Figure 4 shows the temperature dependence of tan δ obtained for a single crystal of rutile at a wavelength of 1.9 mm. This variation of tan δ with temperature agrees with the results of temperature measurement using microwaves.[5] It is clear that in the submillimeter range rutile is highly transparent and becomes even more so as the temperature is lowered.

Taking account of this fact, the high permittivity, the good mechanical propoerties, and the well-developed technology of obtaining large single crystals makes rutile a promising material for cryogenic technology in the submillimeter region.

Low-voltage gun with a resonator for formation of electron bunches in a linear accelerator

V. A. Boiko, R. M. Voronkov, and V. A. Danilichev

(Submitted May 3, 1973; resubmitted October 10, 1973)
Zh. Tekh. Fiz., 44, 888-891 (April 1974)

Results are given for an investigation of the beam parameters at the exit of an experimental 10-MeV electron linear accelerator in which a device consisting of a low-voltage gun and an accelerating resonator is used as an injector. For operation of the accelerator with a pulse length of 6 μsec and a current of 1.6 A, an energy-spectrum width based on a half-drop in current of 4% is obtained.

For effective operation of an electron linear accelerator it is necessary that even in its initial part the electron stream should consist of bunches which follow the frequency of the accelerating microwave field and are phased properly with respect to the crest of the traveling wave. Usually such bunches are formed from the continuous beam from an electron gun using a waveguide buncher; in the latter the phase velocity of the wave increases along the length from the velocity corresponding to the gun voltage to the velocity of light according to a specially calculated relation. It is preferable to use an accelerating structure which initially has a phase velocity of the wave equal to the velocity of light. With a sufficiently high accelerating microwave field (100 kV/cm) in such a structure, compact bunches located near the wave crest form very rapidly (over a length of several tens of centimeters) from a continuous electron beam. However, it is necessary that the energy of the injected electrons be more than 100 keV. In acceleration fewer than 50% of the injected electrons are captured, and those that remain fall on the wall of the waveguide. This has motivated us to carry out a preliminary processing of the electron beam so that a bunch with phase length of at least 120° is formed before it is introduced into the accelerating structure; thus we can eliminate the "superfluous" electrons. One of the methods for processing the beam is to pass it through a resonator with a transverse deflecting electric (or magnetic) microwave field and collimator which enables us to eliminate the improperly phased part of the electron beam. Another method uses a klystron-type buncher, i.e., a resonator in which the continuous electron beam from the gun is modulated according to the velocity of the microwave voltage, which is small in comparison with the gun voltage.

A very attractive idea for forming electron bunches is the use of a combination that is similar to a klystron-type buncher, but differs in the fact that the electron gun operates at a very low voltage (10-20 kV) and the microwave voltage on the resonator is many times greater (300-500 kV). In this case, approximately 30% of the electrons that enter the resonator form a bunch with length of about 90° and energy up to 500 keV, which is highly suitable for introduction into the accelerating structure with constant phase velocity equal to the velocity of light. The remaining approximately 70% of the electrons enter at unfavorable phases and fall on the resonator walls, but these are low-energy electrons, so that the effect is not harmful.

The aim of the present work is to investigate the operation conditions of an experimental electron linear accelerator at an energy of about 10 MeV, using as an injector a low-voltage gun and resonator with high microwave voltage.

The dynamics of electrons in such resonators for high fields has been thoroughly investigated in a number of papers, e.g., refs. 1 and 2. Therefore within the framework of the present work we do not discuss the electron dynamics, but consider briefly the application of such a resonator in an injector for an electron linear accelerator. The principal advantage of an injector with an accelerating resonator is that it allows us to use a comparatively low-voltage gun and to obtain a beam consisting of separate bunches with high energy. The reduction of the voltage on the electron gun to 10-20 kV makes it possible to simplify the power supply scheme and the gun. If we require several pulse lengths of beam current, including nanosecond pulses, then for a voltage of 10-20 kV such pulses can form directly on the cathode, without using any additional devices, such as a grid or an inflector.

A schematic diagram of the injector with accelerating resonator is shown in Fig. 1. The electron gun consists of a cathode node 1 and an anode 2. In the present structure we select a system of plane electrodes. The cathode of the gun is a disk of lanthanum hexaboride about 1.4 cm in diameter. To obtain large currents from the cathode (tens of amperes for nanosecond pulses) the anode−cathode distance, calculated from the equation for a plane diode, is made several times smaller than the anode aperture. Therefore, to improve the current extraction from the cathode, the anode is made from a high-transmission tungsten grid with grid size several times smaller than the anode−cathode distance.

The cylindrical resonator of the injector 3 is made from oxygen-free copper. To prevent penetration of the

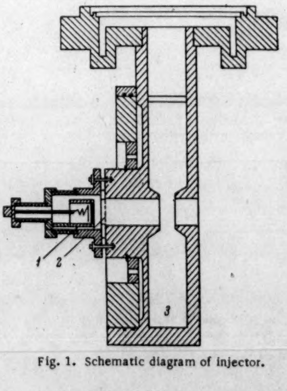

Fig. 1. Schematic diagram of injector.

microwave field into the anode–cathode region, the beam is introduced into the resonator through a small drift tube, which is a section of a waveguide beyond cutoff. The beam is extracted from the resonator through the same tube. The power to the resonator is supplied by the waveguide through a rectangular aperture in the cylindrical wall.

The injector is investigated for operation of the accelerator both in the quasistationary regime (i.e., for pulse length of the beam current considerably greater than the time of filling of the waveguide by microwave energy), and also in the stored-energy regime (when the pulse length of the beam current is less than the filling time). In the first case the power engineering of the injector resonator is very simple and a resonator efficiency of about 30% is obtained. In the second case the engineering of the resonator has a number of distinctive features, and we discuss these in detail.

We carry out a preliminary estimate of the quality factor of the resonator Q and the power P_0 needed to supply the resonator, using the following example. The mean electron energy at the injector exit E = 500 keV, the current of accelerated electrons I = 10 A, the current pulse length t = 10 nsec, the admissible energy drop per current pulse $\delta E = 0.1$ (10%), the microwave-generator pulse length $\tau = 1.5$ μsec, and the generator frequency $f_0 = 1820$ MHz. In this case we can assume that the electrons are accelerated in the resonator and the sections because of the stored energy, and the injection of energy during the current pulse can be neglected. Electrons should be injected into the accelerator when the energy storage is completed. In order for this to occur the quality factor of the resonator Q must be such that a stationary regime is established in the resonator during the pulse. We can assume that this condition is satisfied if

$$Q \leqslant \frac{2\pi f_0 \tau}{5}.$$

For our example Q ≤ 3000. The energy removed by the beam per pulse $W_b = I \cdot E \cdot t$; in our case $W_b = 0.05$ J.

For small decreases in electron energy during a current pulse we can assume that the allowable drop in energy stored in the resonator is $\delta W_r \approx 2\delta E$; hence, the energy stored in the resonator is

$$W_r = \frac{W_b}{2\delta E}.$$

In our case $W_r = 0.25$ J. Acceleration of electrons by the stored energy requires that $P_0 \approx P_{loss}$, where P_{loss} is the power loss in the resonator.

Using the definition of the quality factor of the resonator and taking account of the fact that $P_0 = P_{loss}$, we obtain

$$P_0 \approx \frac{2\pi f_0 W_r}{Q}.$$

For this example, $P_0 = 1$ MW. The coefficient of coupling between the waveguide and the resonator for large beam-current pulse lengths is chosen taking account of the shunting action of the electron beam.

The height of the accelerating gap in the resonator is chosen on the basis of the calculation of electron dynamics, carried out according to the method discussed in ref. 1. A gap height of about 3 cm is chosen. The coupling between the resonator and the waveguide is selected so that a current of 1.5 A can be accelerated for large pulse lengths.

The injector is investigated for the following operational regime. The power fed to the resonator is up to 2 MW, the microwave pulse length is 6 μsec, the voltage on the gun cathode is 15 kV, the operating frequency is 1818 MHz. The current at the resonator exit is measured with a Faraday cup, and the energy is measured with an electrostatic spectrometer.

Figure 2 shows the electron energy spectrum obtained at the resonator exit for a pulsed accelerated-electron current of 1.5 A. The mean energy of accelerated electrons is about 500 keV and the energy-spectrum width based on the half-drop in current is 120 keV.

After the injector is investigated above, its operation is checked together with the accelerating sections having phase velocity equal to the velocity of light. The length of the section is 1.65 m; the mean field for an input microwave power of 18 MW for an unloaded regime is about 10 kV/cm. The power is introduced into the resonator through an iris with about 10 dB loss and a remotely controlled phase shifter. Focusing of the beam is accomplished by short coils in the injector and by a solenoid in the accelerating section. The current at the exit is measured with a Faraday cup, and the energy is measured with a magnetic spectrometer with a resolution better than 1%.

Curve 1 of Fig. 3 shows the energy spectrum of the electron beam at the exit of the section for a pulse length of 5.5 μsec. The energy at the maximum is 10.3 MeV. The width of the energy spectrum based on the half-drop

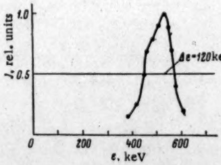

Fig. 2. Energy spectrum of electron beam at injector exit.

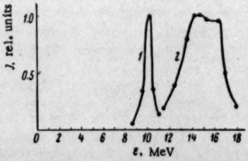

Fig. 3. Energy spectra of electron beam at accelerator exit. 1) For current pulse length 5.5 μsec; 2) for pulse length 150 nsec.

in the current is about 4%. The current in a pulse at the exit of the section is 1.5 A. The coefficient for conversion of energy of the microwave field into energy of the electrons is about 80%. The beam parameters obtained at the exit of the section with the described injector are considerably better than the parameters obtained with other types of injectors under the same conditions.

Curve 2 of Fig. 3 shows the energy spectrum of the beam at the exit of the section for a beam-current pulse length of 150 nsec and an exit current of about 1 A. This spectrum has a rather clearly expressed flat peak, characteristic of accelerators operating in a stored-energy regime. The flat part of the peak of the spectrum is due to the fact that the electron energy decreases from bunch to bunch essentially linearly as the energy stored in the section is expended in accelerating the beam.

The experiments that have been carried out show that a low-voltage gun with an accelerating resonator can, with some further developments, be used as an injector for an electron linear accelerator. Such an injector can be used both in an accelerator operating in a stored-energy regime, and also in an accelerator operating in a quasistationary regime. The use of this injector enables us to simplify the power supply scheme and to eliminate the bunching waveguide section from the accelerator.

Parametric excitation of surface waves in a spatially modulated electron beam

A. I. Pasynok and N. S. Repalov

Physicotechnical Institute,
Academy of Sciences of the Ukrainian SSR, Khar'kov

(Submitted September 10, 1973; resubmitted December 7, 1973)
Zh. Tekh. Fiz., 44, 891-894 (April 1974)

The parametric stability of surface waves in an electron beam modulated by a spatially periodic electrostatic field is investigated. It is shown that the instability develops at frequencies above a critical value. In this case the excitation of surface waves is comparable in efficiency to the excitation of volume waves. The effect of an external magnetic field on the excitation of such waves is discussed, and the growth rate is given as a function of the angle between the direction of propagation of the surface wave and the wave vector of the modulating wave.

The parametric excitation of slow waves ($u_p \ll c$) in an electron beam subject to an external spatially periodic electrostatic field has been investigated[1] on the assumption that the beam completely fills the transverse cross-section of the waveguide. This formulation of the problem obviously does not treat effects connected with a free surface of the beam and phenomena in which surface waves are important. In this paper we show that in an electron beam whose boundary is far from the walls of the waveguide, parametric excitation of surface waves is comparable in efficiency with the excitation of volume waves (in a moderate external magnetic field $\omega_0 \gtrsim \omega_H$).

We use the equations obtained in ref. 1. In order to avoid unwieldy equations, we confine ourselves to wavelengths much smaller than the radius of the beam and the thickness of the gap between the boundaries of the beam and the wall. With these assumptions the equations that describe the perturbation of the potential in the beam are

$$\left.\begin{aligned} \frac{d^2\varphi(k,x)}{dx^2} - p^2\varphi(k,x) &= \alpha\varphi(k-k_0,x) \\ \frac{d^2\varphi(k-k_0,x)}{dx^2} - p_-^2\varphi(k-k_0,x) &= \beta\varphi(k,x) \end{aligned}\right\} x>0, \tag{1}$$

where k_0 is the wave number of the modulated wave,

$$p^2 = k_z^2 + \frac{\varepsilon_3(k)}{\varepsilon_1(k)}k_y^2,\quad p_-^2 = k_z^2 + \frac{\varepsilon_3(k-k_0)}{\varepsilon_1(k-k_0)}(k-k_0)_y^2,$$

$$\alpha = \frac{\xi}{2\varepsilon_1(k)}[a_{-1} + b_{-1}(p_-^2 - k_z^2)],$$

$$\beta = \frac{\xi}{2\varepsilon_1(k-k_0)}[a_{+1}(k-k_0) + b_{+1}(k-k_0)(p^2 - k_z^2)].$$

Expressions for the coefficients $a_{\pm 1}$, $b_{\pm 1}$, and ξ are given in ref. 1. Equation (1) can be written in a Cartesian system of coordinates in which the ZOY plane is the surface of separation, the Y axis coincides with the direction of the external magnetic field, H_0, and the X axis is directed into the plasma. In the region free from plasma ($x < 0$) the potential perturbations satisfy Eqs. (1), in which

$$\alpha = \beta = 0,\quad p_0^2 = k_y^2 + k_z^2,\quad (p_-^0)^2 = (k-k_0)_y^2 + k_z^2.$$

To solve (1) we proceed as follows: We differentiate the first equation twice, and eliminate from it the function $\varphi(k-k_0, x)$ using the second equation. We then obtain

$$\frac{d^4\varphi(k,x)}{dx^4} - (p^2 + p_-^2)\frac{d^2\varphi(k,x)}{dx^2} + (p^2p_-^2 - \alpha\beta)\varphi(k,x) = 0. \tag{2}$$

The function $\varphi(k-k_0, x)$ also satisfies this equation. The solution of Eq. (2) will be sought in the form

$$\varphi(k,x) = e^{\lambda x}. \tag{3}$$

Substituting Eq. (3) in Eq. (2) and solving the characteristic equation we obtain

$$\lambda_{1,2}^2 = \frac{p^2 + p_-^2}{2} \pm \frac{1}{2}\sqrt{(p^2 - p_-^2)^2 + 4\alpha\beta}. \tag{4}$$

We will not consider the case $p \to p_-$ ($k_0 \to 0$). Assuming that $\alpha\beta \sim \xi^2 \ll 1$, we obtain

$$\lambda_1^2 = p^2 + \frac{\alpha\beta}{p^2 - p_-^2},\quad \lambda_2^2 = p_-^2 - \frac{\alpha\beta}{p^2 - p_-^2}. \tag{5}$$

Hence, the solution of (1) which vanishes as one goes away from the boundary when $\lambda_{1,2} > 0$, has the following form:

$$\left.\begin{aligned} \varphi(k,x) &= A_1e^{-\lambda_1 x} + A_2e^{-\lambda_2 x}; & x>0, \\ \varphi(k,x) &= Be^{p_0 x}; & x<0. \end{aligned}\right\} \tag{6}$$

The function $\varphi(k-k_0, x)$ is

$$\left.\begin{aligned} \varphi(k-k_0,x) &= a_1e^{-\lambda_1 x} + a_2e^{-\lambda_2 x}; & x>0, \\ \varphi(k-k_0,x) &= be^{(p_-^0)x}; & x<0. \end{aligned}\right\} \tag{7}$$

The coefficients A_i and a_i in (6) and (7) are not independent. Substituting Eqs. (6) and (7) in the first equation of Eqs. (1) we obtain the following relation:

$$A_1 = \frac{p^2 - p_-^2}{\beta}a_1,\quad A_2 = \frac{-\alpha}{p^2 - p_-^2}a_2. \tag{8}$$

A similar procedure using the second of Eqs. (1) leads to the same result.

In order to obtain a dispersion equation for the surface waves in the modulated beam it is necessary to match the solutions (6) and (7) using the appropriate boundary conditions. The boundary conditions are as follows:[2]

$$x = 0:\ \{\varphi\} = 0,\quad \left\{\varepsilon_1\frac{d\varphi}{dx}\right\} = 0. \tag{9}$$

Substituting (6) and (7) in (9) and expanding the coefficients which form the determinant, we obtain

$$(p_0 + \lambda_1\varepsilon_1)(p_-^0 + \lambda_2\varepsilon_1^-) = -\frac{\alpha\beta}{(p^2 - p_-^2)^2}(p_0 + \lambda_2\varepsilon_1)(p_-^0 + \lambda_1\varepsilon_1^-), \tag{10}$$

where

$$\lambda_1 = p + \frac{1}{2}\frac{\alpha\beta}{p(p^2 - p_-^2)},\quad \lambda_2 = p_- - \frac{1}{2}\frac{\alpha\beta}{p_-(p^2 - p_-^2)},\quad \varepsilon_1^- \equiv \varepsilon_1(k-k_0).$$

Introducing the quantities Θ and Θ_1, the angles between the vectors **k**, and **k** − $\mathbf{k}_0$ and the direction of the external magnetic field, and taking account of the fact that $k_z = k\cos\Theta$, $k_y = k\sin\Theta$, in the zeroth approximation with respect to ξ, for the frequencies of the surface waves we have from (10)

$$\left.\begin{aligned}\omega_{1,2} &= kv_0 + \frac{1}{2}\left[\omega_H\cos\Theta \pm \sqrt{2\omega_0^2 + \omega_H^2(1+\sin^2\Theta)}\right],\\ \omega_{3,4} &= (k-k_0)U_0 + \frac{1}{2}\left[\omega_H\cos\Theta_1 \pm \sqrt{2\omega_0^2 + \omega_H^2(1+\sin^2\Theta_1)}\right],\end{aligned}\right\} \quad (11)$$

where $\omega_H = eH_0/(mc)$ is the cyclotron frequency.

We confine our investigation of the parametric interaction of surface waves in a spatially-modulated electron beam to a few special cases.

1. The waves propagate parallel to the boundary in the absence of an external magnetic field ($\Theta = \Theta_1 = \pi/2$, $H_0 = 0$). In this case the dispersion equation (10), taking into account the fact that we have substituted in its right-hand side the frequencies of the surface waves in the zeroth approximation with respect to ξ given by Eqs. (11), takes the form

$$(1+\varepsilon_3)(1+\varepsilon_3^-) = \xi^2\frac{(k+3k^-)(k^-+3k)}{(k+k^-)^2},\quad k^- \equiv k-k_0. \quad (12)$$

Assuming further that the modulation of the beam leads to a deviation of the surface-wave frequencies from the resonance value given by Eq. (11) by an amount $\Delta\omega \ll \omega$, and expanding the left-hand side of Eq. (12) in powers of $\Delta\omega$, we obtain

$$(\Delta\omega)^2 = \xi^2\frac{(k+3k^-)(k^-+3k)}{(k+k^-)^2}\,\frac{1}{\varepsilon_3'(\varepsilon_3^-)'}.$$

The imaginary part of this equation defines the growth rate of the parametric instability:

$$\gamma = \frac{\xi}{2\sqrt{2}}\,\frac{\omega_0}{\omega}\left(\omega^2 - \frac{\omega_0^2}{8}\right)^{1/2};\quad \omega > \frac{\omega_0}{\sqrt{2}}. \quad (13)$$

It follows from (13) that in the frequency range $\omega > \omega_{gr} = \omega_0/\sqrt{2}$ the growth rate is identical with that obtained in ref. 1, apart from a numerical factor.

2. In the presence of a finite external magnetic field for waves which propagate along the boundary of the beam, Eq. (10) takes the form

$$k(k^-)\left[1+(\varepsilon_1\varepsilon_3)^{1/2}\right]\left[1+(\varepsilon_1^-\varepsilon_3^-)^{1/2}\right]$$
$$= -\frac{\alpha\beta}{\left[k^2\frac{\varepsilon_3}{\varepsilon_1} - (k^-)^2\frac{\varepsilon_3^-}{\varepsilon_1^-}\right]^2}\left[k + (k^-)\varepsilon_1\left(\frac{\varepsilon_3^-}{\varepsilon_1^-}\right)^{1/2}\right]\left[k^- + k\varepsilon_3^-\left(\frac{\varepsilon_3}{\varepsilon_1}\right)^{1/2}\right], \quad (14)$$

while the growth rate is given by

$$\gamma = \frac{\xi}{4\sqrt{2}}\,\frac{\left[\omega^2(2\omega_0^2+\omega_H^2)^2 - \frac{\omega_0^2+\omega_H^2}{2}(\omega_0^2+2\omega_H^2)\right]^{1/2}}{\omega(\omega_0^2+\omega_H^2)^{1/2}};\quad \omega > \frac{(\omega_0^2+\omega_H^2)^{1/2}}{\sqrt{2}}. \quad (15)$$

Comparing Eqs. (13) and (15) it is easy to show that the magnetic field increases the lower limiting frequency of the instability region, while the growth rate is reduced.

3. In conclusion we consider the propagation of surface waves in a beam when the wave vectors **k** and **k** − $\mathbf{k}_0$ are directed at angles Θ and Θ_1 respectively to the wave vector of the modulating wave $\mathbf{k}_0$ in the absence of a focusing magnetic field. Bearing in mind that in this case $k_z = k_z^-$, i.e., $k_y^2 - (k_y^-) = k^2 - (k^-)^2$, Eq. (10) takes the form

$$(1+\varepsilon_3)(1+\varepsilon_3^-) = \xi^2\frac{1}{(k+k^-)^2}\,\frac{k_yk_y^-}{kk^-}\left[k_y+3k_y^-\right]\left[k_y^-+3k_y\right]. \quad (16)$$

The expression for the growth rate then takes the form

$$\gamma = \frac{\xi}{2\sqrt{2}}\,\frac{\omega_0}{\omega}\left(\omega^2 - \frac{\omega_0^2}{8}\right)^{1/2}\sqrt{\sin\Theta\sin\Theta_1};\quad \omega > \frac{\omega_0}{\sqrt{2}}. \quad (17)$$

The angles Θ and Θ_1 are related by the following expression:

$$\operatorname{tg}\Theta_1 = \operatorname{tg}\Theta - \frac{k_0}{k}\sqrt{1+\operatorname{tg}^2\Theta}. \quad (18)$$

The analysis shows that parametric excitation of surface waves in a spatially modulated electron beam in the frequency range $\omega > \omega_0/\sqrt{2}$ is comparable in efficiency with the excitation of volume waves. The solutions (11) correspond to surface waves only when k and k − k_0 are positive. At frequencies $\omega < \omega_0/\sqrt{2}$ the quantity k − k_0 becomes negative, which is easily shown using the resonance condition. Calculations similar to those given above show that the surface-wave parametric instability is not excited in this range.

250 years of the Academy of Sciences of the USSR

Zh. Tekh. Fiz., 44, 897-905 (May 1974)

In May 1974, The Academy of Sciences of the USSR – acknowledged leader of Soviet Science – celebrates its 250th anniversary. In a resolution on October 17, 1973 concerning this anniversary, the Central Committee of the Communist Party of the Soviet Union noted, in particular, the outstanding role played by the Academy, its institutes, and numerous groups of collaborators in the development of the basic and applied research which is being carried on at an ever increasing tempo and which is now leading to an era of scientific and technical revolution in our country.

Little more than a fifth of the lifetime of the Academy of Sciences falls within the Soviet period of the history of our country. But those years are marked by the greatest of achievements which gained international prestige for our Academy and all Soviet science. Science in the Soviet Union enjoys exceptional consideration and support from the Party and the government. The expenditures on science grow every year, as does the number of scientists.

The national regard for the Academy is especially marked when one considers the position the Academy occupied, particularly with regard to physical research, in the prerevolutionary period, especially at the end of the 18th and the greater part of the 19th centuries. In those far-off years, the Academy, of course, might invite outstanding physicists to work within its walls; however, one can say that any definite successes they managed to achieve were not due to help from the Tsarist government and to some extent even despite its indifference to the needs of native science.

Conditions were different in the years of immediate preparation for the establishment of an Academy and in the first decades of its existence.

The founder of our Academy was Peter I, a man of vast and powerful intellect who understood that consolidation of the victories of Russian arms, future strengthening of the government, and the development of its industries were unthinkable without education and science in the land. Acquaintance with the economics and industry of European governments – England, Germany, France, and Holland, which he visited many times and for extended periods – convinced Peter of this. At the very beginning of the 18th century he took energetic steps directed toward organization of an Academy. He carried on negotiations involving the invitation of European scientists – physicists, chemists, mathematicians, naturalists, and humanists – to the Academy created in St. Petersburg. There were almost no such specialists in Russia at the time; despite the relatively high level of literacy and the development of printing, there were no universities in the country.

Preparation for the opening of the Academy was in full swing. L. L. Blyumentrost, physician to Peter, author of the rules and regulations for the St. Petersburg Academy, and its future first president, asked Tatishchev (one of the most illustrious people of that time, a historian and geographer, who left St. Petersburg for Sweden in 1724) to find out if there were Swedish scientists who might wish to work in the Russian Academy. Tatishchev replied, "It is useless to plant seed when the earth in which it is sown is not prepared." Peter, who was present at this conversation, answered Tatishchev for Blyumentrost with the following parable: "A certain nobleman wished to build a mill in his village but had no water. Seeing lakes and marshes near his neighbors, who had an abundance of water, he quickly conceived a plan to build a canal, with their consent, and to lay up stores at the mill; although he was not able to bring the project to completion by himself, his children, pitying the enforced dependence of their parents, accepted the need for the project and completed it."

In the draft of the decree establishing an Academy of Sciences and Arts, which was approved by Peter on January 22, 1724 an organizational basis of the Academy was laid out which in his idea would assure in Russia for many years in the future the development of three classes of sciences: mathematical sciences (pure mathematics, astronomy, geography, navigation, mechanics), physical sciences (theoretical and experimental physics, anatomy, chemistry, botany), and the humanities (oratory, history, politics, and law).

The initial momentum the Academy received (which was the result of the efforts put forth by Peter during the last 10-15 years of his life) was so powerful that the Academy of Sciences in St. Petersburg based on his plans proved to be viable, even after his death, in the first year of the reign of Catherine I, got through the very difficult years under Biron, and acquired a European reputation in the years 1740-1760. The crop planted by Peter yielded a remarkable harvest; the very existence of the great Lomonosov, pupil of the Academy and the first Russian physicist-academician, was sufficient to justify everything that was done to establish the Academy![1)]

In the draft of Peter's decree concerning the Academy (still preseving traces of corrections in his own hand), he speaks of an Academy of Sciences and Arts. At that time, the "arts" were understood to be the application of "pure science" in practical matters (and also in the professions). In other words, the arts were applied sciences. The problem of the interrelation between the basic and applied sciences concerned the organizers of the St. Petersburg Academy even at that time and the necessity for this sort of application, which was provided for from the very beginning, was one of the features of the Academy. One should note here that from the dictionary definition (particularly the dictionary of Brockhouse and Efron), academies are scientific societies which "are concerned with science not for practical purposes, but for science itself".[2)]

Many of the first academicians arriving in St. Petersburg in 1725 displayed a devotion to "pure science". In view of this, it is interesting to follow the activities of Daniel Bernoulli, who began his work in Russia in 1725 and who maintained his connection with the Academy to the end of his life. Shortly before his arrival in St. Petersburg, Bernouilli wrote the mathematician Goldbach,[3)] who furthered Bernouilli's invitation, that he hoped "nothing would be required from him other than that which relates to pure theory". At the same time, he repeatedly reported at St. Petersburg, without urging by anyone, on his work of an applied nature. Thus, Vol. I of the "Proceedings of the Sessions of the Conference of the Imperial Academy of Sciences" indicates that on November 2, 1731, Bernouilli read a paper on the circulation of air in the stoves usually used in Russia. In 1732, he told a Conference (meeting of academicians) of his "Views on raising the great Moscow bell into a bell tower"; he also expounded repeatedly on the principles for the construction or improvement of physical instruments (barometers, hydrometers, etc.).

This understanding of the unity of science and its applications, their mutually enriching effect, is outstandingly characteristic of Lomonosov – the pride of our country. He performed exceptionally great service for Russian science. From studies of creative works and biography, Lomonosov is second only to Pushkin. There is therefore no need to speak of his scientific discoveries in physics and chemistry, of his role in the development of Russian literary language and also of scientific language (including here both physical and chemical terminology; a number of the terms which we use today were introduced by Lomonosov) as well as the language in government documents – decrees, messages, etc. Although Lomonosov wrote numerous works not only in Russian but also in Latin, which he mastered completely in the opinion of specialists, and these works were well known to his contemporaries (in particular, Euler had an extremely high opinion of them),[4] he was rediscovered at the beginning of this century primarily because of the studies of his work by Prof. B. N. Menshutkin of the Leningrad Polytechnic Institue published both here and abroad (in the well-known publication "Science Classics" by W. Ostwald). In the preface to the "Biography of Mikhail Vasil'evich Lomonosov" by B. N. Menshutkin, S. I. Vavilov cited the remarkable statement of A. Smith, president of the American Chemical Soviety, "the rediscovery of Lomonosov straight away added a chemist of first magnitude and an individual of astonishing vigor to be exclusive circle of the greatest people in the world". B. N. Menshutkin himself wrote, "It was with amazement that I became acquainted with the physical chemistry of Lomonosov, which completely corresponds to modern chemistry with its atomistic hypothesis and a number of theories based on that hypothesis having to do with the principle of energy conservation, the theory of heat, the kinetic theory of gases, etc. All these theories were formulated 100-120 years after his death."

Lomonosov is deserving of even greater credit because he had to pursue physics and chemistry at irregular intervals; even people of importance kindly disposed toward him, in particular I. I. Shuvalov, considered the creation of poetry and work on the Russian language and its grammar to be his principal activities. Lomonosov pointed out in the preface to this "Grammar" (1755), "Versifying is my delight, physics is my exercise." Two years earlier, he wrote Shuvalov, "As far as my other activities in physics and chemistry are concerned, there is no need or possibility at all that they be abandoned. Every man needs relaxation from work; for that purpose, putting aside the business at hand, he, together with guest or family, turns to pastimes such as cards, checkers, or other amusements, and even to smoking tobacco, all of which I have long ago renounced because I find in them nothing but boredom. So I hope that as relaxation from the work which I report on and present at conferences on Russian history and the work on ornamentation of the Russian word, several hours a day will be allowed me to use not for billiards but for physical and chemical experiments, which are to me not only excellent matters to replace amusement but also serve as exercise in place of medicine, and more than that, may of course lead to a usefulness and honor for the Motherland hardly less than my principal activity."

Leonard Euler was another scientist of the 18th century of whom we can rightfully be proud and who worked at the Academy in St. Petersburg for more than 20 years before his death. Daniel Bernouilli, Euler, Lomonosov – their names are inseparably linked with the establishment of science in Russia and with the general recognition of the Academy of Sciences at St. Petersburg.

The names of the first Russian inventors are also firmly associated with the activities of the Academy in the first years of its existence – A. K. Nartov (his original machine can now be seen at the Hermitage), I. P. Kulibin who worked at the Academy for more than 30 years and who became famous for a number of investigations, and many others.

The 19th century appears in the history of Russian science and of the Academy primarily as a time when the mathematics and chemical schools flourished. It is significant not only that P. L. Chebyshev was one of the most powerful mathematicians of his time but also that his appearance preceded the fruitful work of the mathematicians Ostrogradskii and Bunyakovskii, who were also academicians. It is important that from the middle of the 19th century there was a direct continuity of the mathematical studies carried on in Russia within either the Academy or in the universities which were established at the beginning of the century [in Kazan', Derpt (Tartu), St. Petersburg, Khar'kov, and later other cities as well]. P. L. Chebyshev, A. M. Lyapunov, A. A. Markov, V. A. Steklov – from them, from their students, from the students of their students, one can draw a direct line, a continuous chain which leads directly to the outstanding Soviet mathematicians who are our contemporaries. One cannot trace the line in the opposite direction, say from Ostrogradskii to Euler. The genius Lobachvskii[5] was understood by few of his contemporaties (primarily by Gauss). His activities took place outside the Academy, to which he was not elected a member.

Approximately the same thing can be said about the chemists; there is a direct line leading from the remarkable work and famous names of N. N. Zinin and A. M. Butlerov to the present-day far-flung schools of chemistry in the Soviet Union, but before them (excepting, of course, Lomonosov) we had no great chemist or "chemical traditions". It is worth noting that here also (as in the case of mathematics), one of the most brilliant and splendid representatives of Russian science, D. I. Mendeleev, was not elected to the Academy of Sciences.

As far as physics is concerned, the 19th century had several outstanding academicians: V. V. Petrov (who discovered the electric arc), B. S. Yakobi (electric motor, galvanoplastics), E. Kh. Lenz (Lenz's law, the Joule-Lenz law, remembered by us from school days), but the beginnings of the Russian schools of physics appeared in the last decades of the 19th and the beginning of the 20th century.

In the Academy of Sciences, the start of new work was marked by the activity of B. B. Golitsyn, who because of his brilliant talent in physics (work on radiant energy, molecular and mathematical physics, classical studies in geophysics and seismic waves) and his organizational ability was able to expand the research in the physics laboratories of the Academy and to attract a number of capable young people to the Academy. The physics laboratories were thereby prepared for the role which fell to them in the immediate future, in the first postrevolutionary years. Directed in those years by V. A. Steklov, A. N. Krylov, and S. I. Vavilov, they served as a distinctive seed from which crystallized the V. A. Steklov Mathematics Institute and the P. N. Lebedev Physics Institute (FIAN).

However, as graphically reported in the second volume of "The History of the Academy of Sciences of the USSR" (Moscow, 1964), "The main flow in the development of Russian Physics passed around the walls of the Academy." Indeed, P. N. Lebedev, very likely the first of our own physicists, who obtained in his lifetime recognition of this merit both here and abroad (W. Thompson, for example, in a conversation with K. A. Timiryazev confessed that precisely the work on light pressure[6] convinced him of the validity of Maxwell's electromagnetic theory), was not a member of the Academy; a group of academicians including G. I. Vil'd, F. A. Bredikhin, and P. L. Chebyshev, was unable to achieve election to the Academy of A. N. Stoletov who agreed to the balloting,[7] and neither N. A. Umov nor A. S. Popov were members of the Academy.

The October Revolution opened a new era in the history of the Academy of Sciences. One can say that the Soviet government and Vladimir Il'ich Lenin supporting and stimulating the activities of the Academy from the very beginning strove to direct the main flow in the development of our science into the channels of the Academy.

At an extraordinary general session of the Academy of Sciences on January 24 (February 6), 1918, its permanent secretary, Academician S. F. Ol'denburg, reported that a representative of the People's Commisariat for Education had called on him "in reference to the question of possible scientific work by the Academy in connection with various government problems of the time." Somewhat later, the permanent secretary became acquainted with the "Proposed plan for the mobilization of science for the needs of government construction," opening with the following words which were meaningful for the future of the Academy: "a special commision of the Academy of Sciences staffed by those participating most closely in the work of the organization will be the organizational center for the mobilization of science."

Replying to this proposal, the president of the Academy, A. O. Karpinskii, in a letter of March 5, 1918 to the People's Commissar for Education, A. V. Lunarcharskii, on the problems of the Academy in the study of the national economy of the country spoke of the activity organized in 1915 under the Academy's Commission on the Study of the Productive Forces of Russia (KEPS). In the name of the members of the Academy, he expressed a readiness to collaborate with the Soviet government both in the field of further study of the natural resources of the country and in respect to an analysis of a technical and economic nature in order to facilitate the selection of paths which, when followed, would ensure the most rapid increase in the most important sections of the national economy. In the list of areas of the economic life of the country subject to study and development compiled under the direction of the president of the Academy, there was outlined the creation of scientific bases for commercial methods of producing precious and rare metals, structural materials, salt (in particular, a study of the Kara Bogaz Gol Bay), gaseous fuels, along with planning and development of irrigation and land reclamation work, and the study of waterways as future means of communication. A third group of problems encompassed the needs of agriculture (cultured plants, soil, mineral fertilizers; physicists were brought in later, in the 1930's, to participate in the solution with the Agrophysical Institute organized in Leningrad being the center of their activity).

The next very important step was the compilation by V. I. Lenin of the famous "Draft Plan for Scientific and Technical Operations" (April 1918) addressed to the Academy of Sciences. In this document of paramount importance, it was pointed out that any plan considered "... must include rational distribution of inductry in Russian from the viewpoint of closeness to raw materials and the possibility of least loss of labor in the transition from processing of raw materials through all subsequent stages of processing the semifabricated products to the production of the final product ... special attention to the electrification of industry and transport and the use of electricity in agriculture... the use of low-grade fuels (peat and low-grade coal) for the production of electrical energy with minimum expenditure on extraction and transport of the fuel." The "Draft" of V. I. Lenin was the answer to the suggestions mentioned above which came from the Academy. In that same month, the Council of People's Commissars decided "to meet this proposal, to acknowledge in principle the necessity for financing the appropriate work of the Academy, and to indicate to it as a particularly important and urgent problem the question of the correct distribution of industry in the country and the most rational use of its economic forces."

These proposals began to be realized practically immediately. A whole series of new institutes was created (Institute of Physicochemical Analysis, Institute for the Study of Platinum and Other Precious Metals, State Ceramics Research Institute, Hydrological Institute, State Radium Institute, etc.).

It should be pointed out here that although the physicists were extensively brought into the work (it is sufficient to note among them the direct participation in work on the study of the Kursk magnetic anomaly directed by Academician P. P. Lazarev and active participation in work under the GOÉLRO plan for the creation of a radio industry), the physics institutes formed inmmediately after the October revolution and particularly the State Physicotechnical Roentgen Institute (A. F. Ioffe), the State Optical Institute (D. S. Rozhdestvenskii), and the Institute of Physics and Biophysics (P. P. Lazarev) at first functioned outside the system of the Academy of Sciences.

Besides the encouragement and initiation of every kind of applied work, the Soviet government from the very first years of Soviet power also encouraged the performance of basic research not having a direct and obvious result of consequence for industry but of general scientific interest. The government supported and financed the fruitful activity of the Atomic Commission, in the work of which D. S. Rozhdestvenskii, A. M. Krylov, A. A. Fridman and others participated; large amounts were allotted to studies in quantum theory, atomic physics, crystal physics, and biophysics.

A special resolution of the Central Executive Committe and of the Council of People's Commissars of the USSR on June 25, 1925 referring to the Academy was timed to the 200th aniversary of the Academy, which was to be observed in September 1925. The resolution said in part, "We recognize the Russian Academy of Sciences as the highest all-union scientific institution under the jurisdiction of Council of People's Commissars of the USSR and operating under regulations approved by the latter. We confer on the aforesaid Academy the name Academy of Sciences of the Union of Soviet Socialist Republics'."

This resolution recognized the leading role of the Academy of Sciences in the development of science, which was so brilliantly demonstrated by it during the first postrevolutionary years. To bring into being the sense of this resolution, the Presidium of the Academy of Sciences of the USSR and a number of other academic institutions were moved to Moscow in 1934.

The 1930's appear in the history of Soviet science as years of vigorous growth of the Academy and its institutes. The Physicotechnical Institute was included in the Academy system; a Physical Institute organized by S. I. Vavilov and an Institute of Physical Problems organized by P. L. Kapitsa were opened in Moscow. Where there were 22 institutes in the Academy in 1930, the number had increased to 53 by January 1, 1945 (this does not include the separate laboratories, committees of the Academy of Sciences, its observatories, etc.).

The systematic development of the Academy of Sciences of the USSR and the work being pursued intensively in it were interrupted in June 1941 after the treacherous attack on our country by fascist Germany. The institutes of the Academy adjusted extraordinarily rapidly to the new problems and the new conditions which were especially serious in the first year of the war. Academy scientists joined in the national battle against fascism, working on defense needs and in close collaboration with the defense industries established to serve the cause of victory. The widely known work performed by Soviet physicists included radar, ship degaussing for protection against magnetic mines, participation of Academy scientists in the creation of new types of armament, and in the relocation and speedy startup of war industries in the Urals and in Siberia (in this connection, we mention the committee on mobilization of the resources of the Urals, Western Siberia, and Kazakhstan for defense needs headed by the president of the Academy of Sciences of the USSR, V. L. Komarov, the committee on scientific and technical naval problems under A. F. Ioffe, and the committee on military health under L. A. Orbeli.)

Under difficult wartime conditions, work was started under the leadership of I. V. Kurchatov on the creation of an atomic industry with the consequence by 1949 that the armed forces of the Soviet Union had a powerful new weapon for the defense of the peaceful pursuits of the Soviet people.

The Academy of Sciences of the USSR made its solid contribution to the cause of victory over Hitler's invaders. A resolution of the Council of People's Commissars of the USSR adopted on January 21, 1945, i.e., even before the end of the war, concerning the celebration of the 220th anniversary of the Academy was but an acknowledgement of the services of the Academy and its workers in the efforts directed toward the achievement of victory, the day of which, it was felt, was not far off.

Shortly after this great day, June 10, 1945, a large group of workers at the Academy was decorated with orders and medals by decree of the Presidium of the Supreme Soviet of the USSR for outstanding services in the development of science and technology and in connection with the 220th anniversary of the Academy. On June 16, in greetings from the Council of People's Commissars of the USSR and from the Central Committee of the Communist Party of the Soviet Union (Bolshevik) directed to the Academy of Sciences, they said, " The Academy of Sciences of the USSR marks its anniversary in a period when the Soviet people victoriously concluded the war with the German invaders. In the days of the war, Soviet scientists carried out successful work, helping the military' front and the national economy by their efforts. Soviet scientists made valuable contributions to the job of crushing the enemy. In the institutes of the Academy, Soviet scientists worked frutifully – physicists and chemists, mathematicians and astronomers, biologists and doctors, geologists and geographers, historians and philosophers, lawyers and philologists... the Council of People's Commissars of the USSR and the Central Committee of the CPSU(B) are confident that in its future activities the Academy of Sciences of the USSR will further develop the traditions of our peaceful science, will use its achievements in every way possible for the development of the economy and culture of the peoples of the USSR, and will raise the prestige of Soviet science among the peoples of the world even higher."

Anniversary celebrations of the Academy of Sciences took place in Moscow and Leningrad during June 16–30, 1945; more than 100 scientists from many countries were invited, and this was the first international meeting of scientists on ending world wars.

A new problem faced the Soviet people: restoration of industry and its transfer to peaceful activities; ahead were years of strenuous, and joyful, peaceful labor.

Directed in its activities by the Party and Soviet government, the Academy of Sciences of the USSR in close interaction and collaboration with the Academies of Sciences of the Republics did its sizeable bit toward the construction of a communist society in our country.

sizeable bit toward the construction of a communist society in our country.

Within the confines of a short paper it is not possible to enumerate in any detail the successes achieved by Soviet scientists in the development of physics and its applications; the following review is a rough guide (detailed analysis of the development of physics in Russia over the past halfcentury is given in a number of publications issued on the 50th anniversary of the Soviet government, on the 100th birthday of V. I. Lenin, and on the 50th anniversary of the Great October Socialist Revolution; see the two-volume edition of "Development of Physics in the USSR," Moscow, 1967, the collections "October and Scientific Progress," "Lenin and the Academy of Sciences", and "Academy of Sciences of the USSR—Headquarters of Soviet Science", see also the anniversary issues of Uspekhi Fizicheskikii Nauk and Zhurnal Tekhnicheskoi Fiziki of October 1967).

Theoretical physics achieved fantastic growth in the years of Soviet rule. A large group of Soviet theoreticians work in the institutes of the Academy, students of L. I. Mandel'shtam and I. E. Tamm, students of L. D. Landau, and students of N. N. Bogolyubov.

With the names of A. I. Alikhanov, L. A. Artsimovich, V. I. Veksler, I. V. Kurchatov, D. V. Skobel'tsyn, and G. N. Flerov is associated the research on elementary-particle physics so fruitfully developed in our country as well as work on accelerator physics and technology directly connected with that advanced field of science. The discoveries made at the large accelerators at Serpukhov and Dubna have received worldwide recongnition.

The successes of prewar nuclear physicists (A. K. Val'ter, Ya. B. Zel'dovich, I. V. Kurchatov, L. V. Mysovskii, K. D. Sinel'nikov, D. V. Skobel'tsyn, and Yu. V. Khariton) determined the creation of nuclear power installations in our country; reactors and nuclear power stations (I. V. Kurchatov, A. I. Alikhanov, A. P. Aleksandrov, and A. I. Leipunskii); our country is indebted to L. A. Artsimovich and his numerous associates and students for successful research in plasma physics which, in the final analysis, is called upon to solve the problem of energy sources.

A whole series of important results in the physics of the condensed state belongs to Soviet scientists. Here, one should first mention the work on the physics of crystals and their stability which had its start in the work carried out at the Leningrad school of A. F. Ioffe and by its head, one of the founders of Soviet physics, A. F. Ioffe, first editor-in-chief of Zhurnal Tekhnicheskoi Fiziki. The researches of L. F. Vereshchagin, N. N. Davidenkov, S. N. Zhurkov, G. V. Kurdyumov, I. V. Obreimov, A. V. Stepanov, and Ya. I. Frenkel' provided the basis for a picture of an actual crystal, served as a foundation on which the present physical theory of stability was constructed, and pointed out means for increasing it which have now been realized in a number of institutes.

Among the precious possessions of Soviet science is the research on nonlinear oscillations by L. I. Mandel'shtam, N. D. Papaleksi, N. M. Krylov, and their students. The work of A. A. Chernyshev, S. A. Vekshinskii, G. A. Grinberg, N. D. Devyatkov, Yu. B. Kobzarev, and S. M. Rytov served as a solid foundation for the development of our radio engineering and the physics of electronic instruments. B. A. Vvedenskii, G. A. Grinberg, D. A. Rozhanskii, and V. A. Fok made a great contribution to research in the propagation of radio waves by their work.

It is well known that our times are characterized by exceptional subdivision and differentiation of science. Perhaps this is explained by the ever-increasing complexity of "final products of production" which incorporate achievements reached in many widely separated fields of science and technology. To the greatest extent, such an assertion is valid for the elements of space technology, and the successes of our country in mastering and studying outer space encompasses the progress achieved in mechanics, physical gas dynamics, computer technology, fuel chemistry, electronics, and radio technology. The name of Academician S. P. Korolev is inseparably associated with these remarkable achievements.

The high regard for radiophysical research fostered primarily at the P. N. Lebedev Physics Institute even in the first years of its existence determined its leading position in such new and revolutionary fields of physics as quantum radiophysics and electronics. The work of A. M. Prokhorov and N. G. Basov and of their numerous associates and followers receives worldwide recognition and fame. Another product of this "hot" field of modern science is semiconductor research which was initially performed at the Physicotechnical Institute in Leningrad and is now being successfully developed in the entire country. From the Leningrad school came work of great economic importance on high-power semiconductor instruments which find application in many branches of industry and transport (V. M. Tuchkevich and associates). Work on the physics of doped transistors (Zh. I. Alferov) appears very promising (and is already finding technical application).

The physics of quasiparticles was born in the Soviet Union (I. E. Tamm, Ya. I. Frenkel', I. M. Lifshits, and others) becoming an integral part of the physics and optics of the solid state and a powerful tool in the study of its electronic properties.

The work of D. S. Rozhdestvenskii, S. I. Vavilov, L. I. Mandel' shtam, G . S. Landsberg, E. F. Gross, A. N. Terenin, and S. E. Frish in optics and spectroscopy brought worldwide fame to this field of Soviet physics. The discovery of the phenomenon of combination scattering, the discovery of the Vavilov—Cerenkov effect (which was explained in the theoretical work of I. E. Tamm and I. M. Frank) became valuable assets in the physics of our century.

For many years, a single Academy of Sciences existed in our country. During the years of Soviet rule, local Academies of Sciences were organized in all the Republics. In addition, a number of specialized Academies were created. The specialized and local Academies made sizeable contributions to scientific and technical progress.

One of the main factors ensuring the success of scientific development is scientific information. In our time, numerous journals in all branches of knowledge have become the main means for regular scientific information.

Where in prerevolutionary years in our country, the single physical journal was essentially the Journal of the Russian Physicochemical Society, and Russian physicists preferred to publish their papers in foreign journals, we now publish tens of journals in all fields of scientific research. Yet despite the considerable expansion of international scientific relations Soviet scientists, as a rule, publish the results of their work in our periodicals; the international prestige of Soviet scientific periodicals increases each day.

At the anniversary celebrations connected with the 250th anniversary of the Academy of Sciences of the USSR, the achievements of Russian physics, its traditions, and new paths added to it by the work of Soviet scientists will be demonstrated to the people of the world.

In the resolution of the Central Committee of the CPSU on the 250th anniversary of the Academy, confidence is expressed that "in observing the anniversary of the Academy of Sciences of the USSR, scientists and groups of scientific research institutions of the country will make every effort to solve the problems formulated by the XXIV Congress of the CPSU, will add new successes in future development of the leading scientific fields and in the introduction of scientific achievements into the sphere of material production, and thereby make a worthy contribution to the national battle for communism." The services of the Academy of Sciences of the USSR were noted by the awarding of two Orders of Lenin (1967 and February 1974).

One can assert with confidence that Soviet scientists will be equal to the problems set before them by the Party and the people.

---

[1] The first Russian elected to the Academy (in October 1733) as assistant in higher mathematics was Vasilii Evdokimovich Adadurov who is remembered for his works in Russian and was known as a writer and translator (subsequently, trustee of Moscow University and honorary member of the St. Petersburg Academy of Sciences.)

[2] It is interesting to recall that Academy was the name of a locality near Athens where there were areas for gymnastic exercises developed for the use of wealthy inhabitants of the Greek capitol. Plato often strolled along the picturesque avenues separating these areas in 388 B. C. surrounded by numerous pupils and admirers, conversing with them on philosphic and scientific subjects. Hence there arose the name "Academic School of Plato" which became the prototype for the modern meaning of this word.

[3] Christian Goldbach himself was an academician in Mathematics in St. Petersburg. His name is well-known even now mainly in connection with the "Goldbach problem" formulated by him in a letter to Euler in 1742. This problem was solved by I. M. Vinogradov, member of the Academy of Sciences of the USSR, in 1937, after two centuries.

[4] It was established that the "physics dissertation" of Lomonosov was read by Lavoisier in particular.

[5] M. V. Ostrogradskii, whom it is impossible to suspect of bias or hostility, said, "Everything I understood in the geometry of Lobachevskii was less than mediocre." It is therefore not surprising that in Bulgarin's "Son of the Motherland" in 1834, there appeared a flippant review of the work of Lobachevskii in which, after recalling the author of the work was an ordinary professor of mathematics, it was said, "Considering everything, I conclude with great probability that the true purpose for which Lobachevskii built and published his Geometry is simply a joke, or better a satire, on mathematicians and perhaps on the scientific writers of our time in general."

[6] P. N. Lebedev was awarded the prize of the Russian Academy of Sciences for this research and was elected an honorary member of the London Royal Society.

[7] This agreement signified a readiness (upon favorable outcome of the balloting) to transfer to St. Petersburg; N. E. Zhukovskii, not desiring to break off his connections in Moscow, turned down the balloting when he was put up for membership in the Academy in 1900 (he was a corresponding member).

Two-dimensional diffraction on a system of straight segments (shields)

G. A. Grinberg

A. F. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted November 13, 1973)
Zh. Tekh. Fiz., 44, 906-915 (May 1974)

The diffraction electromagnetic field created by an arbitrary, sinusoidally time-varying external field with components $E_z^0(x, y)$, $H_x^0(x, y)$, and $H_y^0(x, y)$ is analyzed for a system of perfectly conducting, infinitesimally thin plane shields (bands or strips) of finite or semiinfinite width whose edges are parallel to the z axis; these can touch each other and the planes of the shields form arbitrary angles. In the general case the problem is reduced to a system of Fredholm integral equations of the second kind for the current densities induced in the shields by an arbitrarily located line current. A new method for solving the currents induced by an arbitrary external field in a plate of finite width h is given; this solution is a natural one and has an obvious physical meaning and can be used to get the asymptotic expression for kh ≫ 1 in simple form. As an example, the case of a shield in the shape of a right-angled corner piece is considered; it is shown that certain simplifications are possible.

1. We consider the diffraction of electromagnetic waves coming from a line current source I of frequency ω incident on a system of n straight segments (perfectly conducting shelds) of finite or semiinfinite width; the ends of some of the segments can touch each other to form segments of broken lines (Fig. 1). The current filament I and all the plates (strips) A_1A_1', A_2A_3, A_3A_4, etc., are assumed to be unbounded in the direction perpendicular to the plane of the drawing (OZ axis) and the current distribution in the strips is independent of z. The time variation of the fields and currents is given by the factor $e^{i\omega t}$.

We start from the solution for a single plate of arbitrary width h and we put I = 1, i.e., the primary current is of unit strength. We denote by j(r, α, ξ, h) the density of the total induced current at a point in the plate[1)] at a distance ξ from the left side; r is the distance of the edge from the primary current and α is the angle between the direction of r and the plate.[2)] The density j(r, α, ξ, h) satisfies the integral equation[1]

$$\int_0^h j(r,\ \alpha,\ \xi,\ h)\, H_0^{(2)}(k\,|x-\xi|)\, d\xi = -H_0^{(2)}(k\rho),$$
$$\rho = \sqrt{r^2 - 2rx\cos\alpha + x^2},\quad 0 < x < h,\quad r > 0, \tag{1}$$

where k is the wave number and $H_0^{(2)}(t)$ is the zero-order Hankel function of the second kind of argument t. Condition (1) reflects the requirement that the total electric field at the surface of the plate (shield) should be equal to zero. This field is made up of the contributions from the primary line current and from the induced currents in the shield. We use the well-known expression $E = (-I\pi k/c) \cdot H_0^{(2)}(kR)$ for the field created by a line current I of frequency ω at a distance R.

Knowing the function j (r, α, ξ, h) we can easily set up a system of Fredholm integral equations of the second kind for the current densities induced in the plates. Thus denoting by $j_k(\xi_k)$ (k = 1, 2, . . . , n) the total density of the current induced at point M_k of the k-th plate at a distance $A_kM_k = \xi_k$ from its left edge A_k, and by $r_{ik} = M_iA_k$ the distance from A_k to the point M_i of the i-th plate at a distance $A_iM_i = \xi_i$ from its left edge A_i, putting $\alpha_{ik} = \angle M_iA_kM_k$, denoting by h_k the width of the k-th plate and taking the primary current I to be at the point M_0 (with $M_0A_k = r_{0k}$ and $\angle M_0A_kM_k = \alpha_{0k}$), we get the following relations for $j_k(\xi_k)$:

$$j_k(\xi_k) = Ij(r_{0k},\ \alpha_{0k},\ \xi_k,\ h_k) + \sum_{i \neq k} \int_0^{h_i} j_i(\xi_i)\, j(r_{ik},\ \alpha_{ik},\ \xi_k,\ h_k)\, d\xi_i, \tag{2}$$

where the summation is over all plates except the k-th. The first term on the right side gives the magnitude of the current density induced directly at point M_k of the plate by the primary current I. The second term is obtained by summing the current densities induced at this point by all the elementary (line) currents $j_i(\xi_i)d\xi_i$ flowing in the surfaces of all the other plates. Since these equations can be written for all the plates in the system, they give n interrelated linear Fredholm-type integral equations of the second kind for the n currents $j_k(\xi_k)$, k = 1, 2, 3, . . . , n. The problem can be solved if these currents are found because the electromagnetic fields produced by these currents can be determined by standard techniques. The same considerations hold for the solution of the general problem of diffraction on a given system of perfectly conducting shields of two-dimensional electromagnetic waves, in which only the E_z^0, H_x^0, and H_y^0 components are nonzero because the solution of the above problem as formulated by Eqs. (2) for k = 1, 2, . . . , n gives the Green's function for this class of problem.

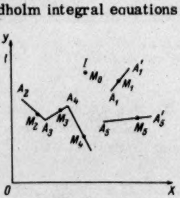

Fig. 1

2. The method requires a knowledge of the function j(r, α, ξ, h). It is well known that it is possible to obtain an exact expression for this in the form of series in Mathieu functions; however, these series are only convenient for numerical calculations when γ = kh is small and we are interested mainly in the question of the asymptotic form of the function j(r, α, ξ, h) when $\gamma \gg 1$. In earlier papers,[2,3] we suggested another approach to the solution of the problem of electromagnetic-wave diffraction on perfectly conducting plane shields and we showed, in particular, that the solution of the most general two-

dimensional problem of diffraction[3] for a strip reduces to an integration if the solution to the prototype problem, formulated by the integral equation

$$\int_0^h j(R,\ \xi,\ h)\, H_0^{(2)}(k|x-\xi|)\, d\xi = -H_0^{(2)}[k(R+x)],$$

$$0<x<h,\ R>0, \tag{3}$$

where $j(R,\ \xi,\ h) = j(R,\ \pi,\ \xi,\ h)$, is known.

In a subsequent paper,[4] the determination of the function $j(R,\ \xi,\ h)$ was reduced to the solution of two independent Fredholm integral equations of the second kind, which could supply the required result for any value of γ and in particular for $\gamma \gg 1$. In this last case, the solution was found in explicit form by iteration to accuracy of $O(\gamma^{-2})$. On the basis of these results, there would be no great difficulty in obtaining a good approximate expression for the function $j(r,\ \alpha,\ \xi,\ h)$ in the case which is of most interest to us, in which γ is not small. This approach, however, leads to rather cumbersome calculations. We have therefore chosen a completely different method of solving the problem, which seems to give quicker results and which provides the solution in the principal approximation in an extremely simple and physically obvious form. We take as our starting point the solution[5] to the problem of electromagnetic-wave diffraction on a perfectly conducting half-plane when the source is a parallel line current I of frequency ω at a distance r from the edge of the half-plane and parallel to it. The direction of r makes an angle α with the half-plane.

The expression for the vector potential $\mathbf{A} = \mathbf{i}_z A_z$ corresponding to the total field is[5]

$$A_z = A(\rho,\ \theta) = \frac{I}{c}\left\{\int_{-b_1}^{\infty} \frac{e^{-ikR_1}}{R_1} d\eta - \int_{-b_2}^{\infty} \frac{e^{-ikR_2}}{R_2} d\eta\right\}, \tag{4}$$

where ρ and θ are the polar coordinates of the point M at which the vector potential is considered (Fig. 2) and

$$\left.\begin{aligned} R_1^2 &= r^2+\rho^2-2r\rho\cos(\theta-\alpha)+\eta^2, \\ R_2^2 &= r^2+\rho^2-2r\rho\cos(\theta+\alpha)+\eta^2, \end{aligned}\right\} \tag{5}$$

$$\left.\begin{aligned} b_1 &= 2\sqrt{r\rho}\cos\frac{\theta-\alpha}{2}, \\ b_2 &= 2\sqrt{r\rho}\cos\frac{\theta+\alpha}{2}. \end{aligned}\right\} \tag{6}$$

We take I = 1.

Remembering that H = curl A, we can easily find the current densities $j_1(\xi)$ and $j_2(\xi)$ induced at the upper (θ = 0) and lower ($\theta = 2\pi$) sides of the half-plane at points distant $\rho = \xi$ from the edge:

$$j_1(\xi) = -\frac{c}{4\pi}(H_r)_{\theta=0} = -\frac{c}{4\pi r}\left(\frac{\partial A}{\partial\theta}\right)_{\theta=0}$$

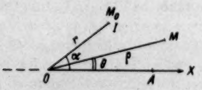

Fig. 2

$$= -\frac{1}{2\pi}\left\{\sqrt{\frac{r}{\xi}}\frac{e^{-ik(r+\xi)}}{r+\xi}\sin\frac{\alpha}{2} + r\sin\alpha\,\psi(-b_0)\right\}, \tag{7}$$

$$j_2(\xi) = \frac{c}{4\pi r}\left(\frac{\partial A}{\partial\theta}\right)_{\theta=2\pi} = -\frac{1}{2\pi}\left\{\sqrt{\frac{r}{\xi}}\frac{e^{-ik(r+\xi)}}{r+\xi}\sin\frac{\alpha}{2} - r\sin\alpha\,\psi(b_0)\right\}$$

$$= -\frac{r\sin\alpha}{2\pi}\int_{r+\xi}^{\infty}\frac{e^{-ikR_0}}{\eta^3}dR_0 = \frac{ir\sin\alpha e^{-ik(r+\xi)}}{2\pi k b_0^3}$$

$$\times\left\{1+\frac{3i}{4\cos^2\frac{\alpha}{2}}\left(\frac{1}{kr}+\frac{1}{k\xi}\right)(1-e^{-ik\mu})\right\}, \tag{8}$$

where μ is some close unknown real number and

$$b_0 = 2\sqrt{r\xi}\cos\frac{\alpha}{2}, \tag{9}$$

$$\psi(b) = \int_b^{\infty}\left(ik+\frac{1}{R_0}\right)\frac{e^{-ikR_0}}{R_0^2}d\eta, \tag{10}$$

$$R_0 = \sqrt{r^2+\xi^2-2r\xi\cos\alpha+\eta^2} \equiv \sqrt{d^2+\eta^2}. \tag{11}$$

Here $d = \sqrt{r^2+\xi^2-2r\xi\cos\alpha}$ is the distance from the current I to the given point of the half-plane.

The total current density induced at a point ξ in the half-plane is[4]

$$j(r,\ \alpha,\ \xi,\ \infty) = j_1(\xi)+j_2(\xi)$$

$$= -\frac{1}{\pi}\left\{\sqrt{\frac{r}{\xi}}\frac{e^{-ik(r+\xi)}}{r+\xi}\sin\frac{\alpha}{2} + \frac{r\sin\alpha}{2}[\psi(-b_0)-\psi(b_0)]\right\}$$

$$= -\frac{1}{\pi}\left\{\sqrt{\frac{r}{\xi}}\frac{e^{-ik(r+\xi)}}{r+\xi}\sin\frac{\alpha}{2} - r\sin\alpha\left[\frac{\pi ki}{2d}H_1^{(2)}(kd)+\psi(b_0)\right]\right\}, \tag{12}$$

where we have used[5]

$$2\psi(0) = \int_{-\infty}^{\infty}\left(ik+\frac{1}{R_0}\right)\frac{e^{-ikR_0}}{R_0^2}d\eta = \psi(b_0)+\psi(-b_0) = -\frac{\pi ki}{d}H_1^{(2)}(kd), \tag{13}$$

so that the difference of the currents is

$$j_1(\xi)-j_2(\xi) = -\frac{r\sin\alpha}{2\pi}[\psi(b_0)+\psi(-b_0)] = -\frac{kir\sin\alpha}{2d}H_1^{(2)}(kd). \tag{14}$$

This last equation can also be obtained directly without use of (7) and (8) because, as is shown in ref. 1, the difference in the current densities $j_1(\xi)$ and $j_2(\xi)$ induced in the two sides of an element of any flat, perfectly conducting shield in the plane y = 0 and placed in an external, time-varying magnetic field $H^0(x,\ y)$ is always subject to the condition

$$j_1(\xi)-j_2(\xi) = -\frac{c}{2\pi}H_x^0(\xi,\ 0); \tag{15}$$

in our case H^0 is the magnetic field of the line current I = 1 passing through the point $M_0(r,\ \alpha)$, so that

$$H_x^0(\xi,\ 0) = -\frac{\pi kir\sin\alpha}{cd}H_1^{(2)}(kd). \tag{16}$$

If we substitute (16) into (15), we obtain (14) and also get the value of the sum $\psi(b_0)+\psi(-b_0)$ in agreement with Eq. (13).

When r > 0 and $\alpha = \pi$, i.e., when I lies on the x axis to the left of the conducting half-plane, the currents $j_1(\xi)$ and $j_2(\xi)$ are equal and are given by

$$j_1(\xi) = j_2(\xi) = -\frac{1}{2\pi}\sqrt{\frac{r}{\xi}}\frac{e^{-ik(r+\xi)}}{r+\xi}. \tag{17}$$

When I is above the half-plane, $j_1(\xi)$ tends with increasing ξ to the value which it would have for the same position of I if the half-plane were replaced by a full plane; the "shadow" current $j_2(\xi)$ decreases rapidly away from the edge.[6] The asymptotic form of this decrease for $kr\cos^2\alpha/2 \gg 1$ and $k\xi\cos^2\alpha/2 \gg 1$ can be obtained from (8) as

$$j_2(\xi) = \frac{i\sin\frac{\alpha}{2}}{8\pi k\sqrt{r}\,\xi^{3/2}\cos^2\frac{\alpha}{2}}\,e^{-ik(r+\xi)}, \tag{18}$$

while for $j_1(\xi)$ under these same conditions we find

$$j_1(\xi) = \frac{\sqrt{k}\,r\sin\alpha}{\sqrt{2\pi}\,d^{3/2}}\,e^{-i\left(kd-\frac{\pi}{4}\right)}. \tag{19}$$

We now find $j(r, \alpha, \xi, h)$. Suppose that the segment OA in Fig. 2 represents a plate of width h on which $0 \le x \le h$. In addition we consider the two including half-planes $0 \le x \le \infty$ and $-\infty \le x \le h$, with edges which correspond respectively with the left and right edges of the given plate and also the full plane $-\infty \le x \le \infty$. We take the plate, the half-planes, and the full plane to be perfectly conducting and we consider the total current densities induced in each of them separately, assuming that the primary field is in all cases produced by the same current $I = 1$ at the point $M_0(r, \alpha)$, $0 < \alpha < \pi$ (Fig. 2). Equation (1) holds for the current density $j(r, \alpha, \xi, h)$ on the plate; the density $j(r, \alpha, \xi, \infty)$ on the first half-plane is

$$\int_0^\infty j(r, \alpha, \xi, \infty)\,H_0^{(2)}(k|x-\xi|)\,d\xi = -H_0^{(2)}(k\rho), \quad 0 < x < \infty, \tag{20}$$

where ρ here and in what follows has the same meaning as in (1); for the second half-plane we obtain[7]

$$\int_{-\infty}^{h} j(r', \alpha', h-\xi, \infty)\,H_0^{(2)}(k|x-\xi|)\,d\xi$$
$$= -H_0^{(2)}(k\rho), \quad -\infty < x < h, \tag{21}$$

where $r' = M_0A$, $\alpha' = \angle M_0AO$; finally, the density $j_0(\xi)$ on the full plane is

$$\int_{-\infty}^{\infty} j_0(\xi)\,H_0^{(2)}(k|x-\xi|)\,d\xi = -H_0^{(2)}(k\rho), \quad -\infty < x < \infty. \tag{22}$$

We now note that it follows directly from (15), which is valid for any plane shield in any electromagnetic field of the type considered in this paper when the shield is a full plane and the sources of external field all lie in the upper half-plane, the total induced current density $\bar{j}_0(\xi)$ is

$$j_0(\xi) = j_1(\xi) = -\frac{c}{2\pi}H_x^0(\xi, 0), \tag{23}$$

since $j_2(\xi) = 0$ (total shielding). Thus (15) can be rewritten as

$$j_1(\xi) - j_2(\xi) = j_0(\xi); \tag{24}$$

this equation relates the difference in the current densities induced on the two sides of any plane shield to the current density induced by the same external field at the same point of the full plane and is of a general nature. In particular, the value of $j_0(\xi)$ for (22) can be obtained from (23) by substituting into this latter equation the value of $H_x^0(\xi, 0)$ given by (16), i.e.,

$$j_0(\xi) = \frac{kir\sin\alpha}{2d}H_1^{(2)}(kd), \quad -\infty \leqslant \xi \leqslant \infty. \tag{25}$$

In what follows we assume that the variable x in (20)-(22) has a value in the interval $0 < x < h$. Subtracting the appropriate terms of (20) from the right and left sides of (1), we get

$$\int_0^h [j(r, \alpha, \xi, h) - j(r, \alpha, \xi, \infty)]\,H_0^{(2)}(k|x-\xi|)\,d\xi$$
$$= \int_h^\infty j(r, \alpha, \xi, \infty)\,H_0^{(2)}(k|x-\xi|)\,d\xi = \int_h^\infty j_0(\xi)\,H_0^{(2)}(k|x-\xi|)\,d\xi$$
$$+ 2\int_h^\infty j_2(\xi)\,H_0^{(2)}(k|x-\xi|)\,d\xi, \quad 0 < x < h, \tag{26}$$

since it follows from (12) and (24) that

$$j(r, \alpha, \xi, \infty) = [j_1(\xi) - j_2(\xi)] + 2j_2(\xi) = j_0(\xi) + 2j_2(\xi).$$

Similarly, subtracting (21) from (1) term by term, we obtain the relationship

$$\int_0^h [j(r, \alpha, \xi, h) - j(r', \alpha', h-\xi, \infty)]\,H_0^{(2)}(k|x-\xi|)\,d\xi$$
$$= \int_{-\infty}^{0} j(r', \alpha', h-\xi, \infty)\,H_0^{(2)}(k|x-\xi|)\,d\xi$$
$$= \int_{-\infty}^{0} j_0(\xi)\,H_0^{(2)}(k|x-\xi|)\,d\xi$$
$$+ 2\int_{-\infty}^{0} j_2'(h-\xi)\,H_0^{(2)}(k|x-\xi|)\,d\xi, \quad 0 < x < h, \tag{27}$$

because

$$j(r', \alpha', h-\xi, \infty) = j_1'(h-\xi) + j_2'(h-\xi), \tag{28}$$

where $j_1'(h-\xi)$ and $j_2'(h-\xi)$ denote the densities of the surface currents induced[8] on the half-plane $(-\infty, h)$.

Finally, subtracting (22) from (1), we get

$$\int_0^h [j(r, \alpha, \xi, h) - j_0(\xi)]\,H_0^{(2)}(k|x-\xi|)\,d\xi$$
$$= \int_h^\infty j_0(\xi)\,H_0^{(2)}(k|x-\xi|)\,d\xi + \int_{-\infty}^{0} j_0(\xi)\,H_0^{(2)}(k|x-\xi|)\,d\xi, \quad 0 < x < h, \tag{29}$$

and adding (26) to (27) and then subtracting (29) we obtain

$$\int_0^h \{j(r, \alpha, \xi, h) - [j(r, \alpha, \xi, \infty) + j(r', \alpha', h-\xi, \infty) - j_0(\xi)]\}$$
$$\times H_0^{(2)}(k|x-\xi|)\,d\xi = 2\int_h^\infty j_2(\xi)\,H_0^{(2)}(k|x-\xi|)\,d\xi$$
$$+ 2\int_{-\infty}^{0} j_2'(h-\xi)\,H_0^{(2)}(k|x-\xi|)\,d\xi$$

$$= 2\left\{\int_0^\infty j_2(h+\eta) H_0^{(2)}(k[\eta + x_1])\,d\eta \right.$$
$$\left. + \int_0^\infty j_2'(h+\eta) H_0^{(2)}(k[\eta + x])\,d\eta]\right\}, \quad 0 < x < h, \tag{30}$$

where $x_1 = h - x$.

If we make use of (3) and the equation which results from it when x is replaced by $x_1 = h - x$ and ξ by $(h - \xi)$

$$\int_0^h j(R, h-\xi, h) H_0^{(2)}(k|x-\xi|)\,d\xi = -H_0^{(2)}[k(R + x_1)], \quad 0 < x < h \tag{31}$$

and introduce the notation

$$w(\xi) = j(r, \alpha, \xi, \infty) + j(r', \alpha', h-\xi, \infty) - j_0(\xi), \quad 0 < \xi < h, \tag{32}$$

for the known quantity which appears in the right side, we find by comparing the right and left sides of (30), (3), and (31) that

$$j(r, \alpha, \xi, h) = w(\xi) - 2\left\{\int_0^\infty j_2(h+\eta)\, j(\eta, h-\xi, h)\,d\eta \right.$$
$$\left. + \int_0^\infty j_2'(h+\eta)\, j(\eta, \xi, h)\,d\eta\right\}, \quad 0 < \xi < h. \tag{33}$$

This is an exact equation, valid for any value of γ. The function $j(\eta, \xi, h)$ has been studied, as noted above, in our earlier paper,[4] where, in particular, the first few terms are calculated for the asymptotic expansion in the case of interest here, $\gamma \gg 1$. It can easily be seen, however, that under this condition Eq. (33) gives the principal asymptotic value directly as

$$j(r, \alpha, \xi, h) = w(\xi) = j(r, \alpha, \xi, \infty) + j(r', \alpha', h-\xi, \infty) - j_0(\xi), \tag{34}$$

since the integrand on the right side of (33) contains only the values of the "shadow" currents $j_2(h + \eta)$ and $j_2'(h + \eta)$ on the corresponding half-planes and there only at distances greater than h from the edges, i.e., where they arise only as a result of diffraction and where for $kh \gg 1$ they are of negligible amplitude.[9] If the integral terms in (33) are taken into account, then the results of ref. 4 must be used; the first approximation to the function $j(\eta, \xi, h)$ can be taken as

$$j(\eta, \xi, h) \cong j(\eta, \xi, \infty) = -\frac{\sqrt{\eta}}{\pi}\frac{e^{-ik(\xi+\eta)}}{(\xi+\eta)\sqrt{\xi}}. \tag{35}$$

We add the following comment. Although (33) has been derived only for the case in which the external field is created by a single line current, it is in fact valid for the case of an arbitrary external field which has only one electric field component $E_z^0(x, y)$ provided that $j(r, \alpha, \xi, h)$ is replaced by the total density $\bar{j}(\xi, h)$ of the currents induced by the external field in a plate lying on the segment $0 \le x \le h$, $j(r, \alpha, \xi, \infty)$ and $j(r', \alpha, h - \xi, \infty)$ are replaced by the current densities induced by the same field in the half-planes $(0, \infty)$ and $(-\infty, h)$ respectively and $j_0(\xi)$ by the density $\bar{j}_0(\xi)$ induced in the plane $(-\infty, \infty)$; $j_2(h + \eta)$ and $j_2'(h + \eta)$ must be taken as the values of the shadow currents in the half-planes.[10] The truth of this statement is obvious, since any external field of this type can be represented as the result of the superposition of fields from current filaments which are discretely or continuously distributed in space around the plate at a finite or infinite distance from it. Formally, it follows from the fact that for any field, all the starting equations (1), (20), (21), and (22) for deriving (33) contain (in their right sides) the function $H_0^{(2)}(k\rho)$, which is equal to $(-c/\pi k)E_z^0$ in the case of a single line current but is replaced by a new function $(-c/\pi k)E_z^0(x, 0)$ for a different field. But since these equations are subtracted from each other in the derivation of (33) and the right sides are generally lost, it is clear that the form of the final equation of the type (33) does not change in the general case.

3. We now apply the method to find the field of a perfectly conducting corner reflector AOB with a cross section (Fig. 3), located in an external field of frequency ω. We show how the solution here and in similar problems can be simplified by using additional considerations. For simplicity we take OA = OB = h and assume that all the external field sources, for which $\mathbf{E} = \mathbf{i}_z E^0(x, y)$, lie in the first quadrant. We denote by $j_x(\xi, h)$ and $j_y(\eta, h)$ the total current densities induced in the sides OA $(0 \le \xi \le h)$ and OB $(0 \le \eta \le h)$ respectively. Writing the condition that the tangential component of the total electric field at the surface of a perfect conductor is zero, we get

$$\int_0^h j_x(\xi, h) H_0^{(2)}(k|x-\xi|)\,d\xi + \int_0^h j_y(\eta, h) H_0^{(2)}(k\sqrt{x^2+\eta^2})\,d\eta$$
$$= E^0(x, 0), \quad 0 < x < h, \tag{36}$$

$$\int_0^h j_x(\xi, h) H_0^{(2)}(k(\sqrt{y^2+\xi^2})\,d\xi + \int_0^h j_y(\eta, h) H_0^{(2)}(k|y-\eta|)\,d\eta$$
$$= E^0(0, y), \quad 0 < y < h. \tag{37}$$

Comparing these equations with those for h = ∞, when the sides OA and OB are two half-planes and when the solution can be obtained directly from the reflection method, we denote the known induced currents by $j_x(\xi, \infty)$ and $j_y(\eta, \infty)$ and find by subtracting (36) and (37) from the corresponding equations with h = ∞, that (say)

$$j_x(\xi, \infty) - j_x(\xi, h) = u(\xi), \quad 0 < \xi < h, \tag{38}$$

$$j_y(\eta, \infty) - j_y(\eta, h) = v(\eta), \quad 0 < \eta < h, \tag{39}$$

and putting $h - x = x_1$, $h - y = y_1$,

$$\int_0^h u(\xi) H_0^{(2)}(k|x-\xi|)\,d\xi = -\int_0^h v(\eta) H_0^{(2)}(k\sqrt{x^2+\eta^2})\,d\eta$$

$$-\int_h^\infty j_x(\xi, \infty) H_0^{(2)}(k|x-\xi|)\,d\xi - \int_h^\infty j_y(\eta, \infty) H_0^{(2)}(k\sqrt{x^2+\eta^2})\,d\eta$$

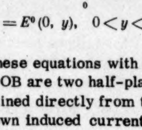

Fig. 3

$$= -\int_0^h v(\eta) H_0^{(2)}(k\sqrt{x^2+\eta^2})\,d\eta - \int_0^\infty j_x(h+\zeta,\ \infty) H_0^{(2)}(k[\zeta+x_1])\,d\zeta$$

$$-\int_h^\infty j_y(\eta,\ \infty) H_0^{(2)}(k\sqrt{x^2+\eta^2})\,d\eta,\quad 0<x<h, \tag{40}$$

$$\int_0^h v(\eta) H_0^{(2)}(k|y-\eta|)\,d\eta = -\int_0^h u(\xi) H_0^{(2)}(k\sqrt{y^2+\xi^2})\,d\xi$$

$$-\int_0^\infty j_y(h+\zeta,\ \infty) H_0^{(2)}(k[\zeta+y_1])\,d\zeta$$

$$-\int_h^\infty j_x(\xi,\ \infty) H_0^{(2)}(k\sqrt{y^2+\xi^2})\,d\xi,\quad 0<y<h. \tag{41}$$

We note that for $\alpha = \pi/2$, Eq. (1) gives

$$\int_0^h j\left(r,\ \frac{\pi}{2},\ \xi,\ h\right) H_0^{(2)}(k|x-\xi|)\,d\xi = -H_0^{(2)}(k\sqrt{x^2+r^2}),\quad 0<x<h, \tag{42}$$

and we use (31) to show that the following relationships follow from (40) and (41) [as in the transition from (30) to (33)]:

$$u(\xi) = \int_0^\infty j_x(h+\zeta,\ \infty)\, j(\zeta,\ h-\xi,\ h)\,d\zeta$$

$$+\int_h^\infty j_y(\eta,\ \infty)\, j\left(\eta,\ \frac{\pi}{2},\ \xi,\ h\right) d\eta$$

$$+\int_0^h j\left(\eta,\ \frac{\pi}{2},\ \xi,\ h\right) v(\eta)\,d\eta,\quad 0<\xi<h, \tag{43}$$

$$v(\xi) = \int_0^\infty j_y(h+\zeta,\ \infty)\, j(\zeta,\ h-\xi,\ h)\,d\zeta$$

$$+\int_h^\infty j_x(\eta,\ \infty)\, j\left(\eta,\ \frac{\pi}{2},\ \xi,\ h\right) d\eta$$

$$+\int_0^h u(\eta)\, j\left(\eta,\ \frac{\pi}{2},\ \xi,\ h\right) d\eta,\quad 0<\xi<h. \tag{44}$$

Introducing the notation

$$f_1(\xi) = \int_0^\infty j_x(h+\zeta,\ \infty)\, j(\zeta,\ h-\xi,\ h)\,d\zeta$$

$$+\int_h^\infty j_y(\eta,\ \infty)\, j\left(\eta,\ \frac{\pi}{2},\ \xi,\ h\right) d\eta, \tag{45}$$

$$f_2(\xi) = \int_0^\infty j_y(h+\zeta,\ \infty)\, j(\zeta,\ h-\xi,\ h)\,d\zeta$$

$$+\int_h^\infty j_x(\eta,\ \infty)\, j\left(\eta,\ \frac{\pi}{2},\ \xi,\ h\right) d\eta, \tag{46}$$

where the given functions may be taken as known,[11] we add and subtract (43) and (44) and put

$$w_\pm(\xi) = u(\xi) \pm v(\xi),\quad 0<\xi<h, \tag{47}$$

to get two independent Fredholm integral equations of the second kind for the functions

$$w_\pm(\xi) = [f_1(\xi) \pm f_2(\xi)] \pm \int_0^h j\left(\eta,\ \frac{\pi}{2},\ \xi,\ h\right) w_\pm(\eta)\,d\eta,\quad 0<\xi<h, \tag{48}$$

where for $\gamma \gg 1$, the function $j(\eta,\ \pi/2,\ \xi,\ h)$ with the plus or minus sign, which plays the role of the kernel and which satisfies the exact equation (33), is given in the main approximation by (34) with $\alpha = \pi/2$. When $\gamma \gg 1$, Eq. (48) can be solved by the method of successive approximations with the functions $\alpha^0_\pm(\xi) = f_1(\xi) \pm f_2(\xi)$ taken as the initial solutions.

We have considered the case of a rectangular corner reflector with equal sides. A similar method can be used for acute angles, corner reflectors with unequal sides, and so on, and the results can be used to solve more complex problems, in which the number of straight-line segments forming the system is greater than 2.

---

[1] That is, the sum of the densities of the currents induced on the two sides of the element of the plate.

[2] We note that when h = ∞ the plate is transformed into a half-plane and the total induced current density at a point is equal to $j(r,\ \alpha,\ \xi,\ \infty)$.

[3] That is, when the external field is independent of the coordinate parallel to the length of the strip.

[4] Compare footnote 2.

[5] The validity of (13) can be tested by putting $\eta = \sinh t$ under the integral sign and using the well-known representation of the Hankel function $H^2_\nu(x) = \left(e^{\frac{i\pi\nu}{2}}/\pi\right)i \int_{-\infty}^{\infty} e^{-ix\,\mathrm{ch}\,\eta-\nu\eta}\,d\eta$, $\mathrm{Im}(x) < 0$. See also the note in the text on Eq. (14).

[6] Providing that the angle α is not too close to zero or π (grazing incidence).

[7] The validity of this equation becomes obvious if we look at Fig. 2 from the plane of the drawing itself; the semiinfinite line $-\infty \le x \le h$ is then directed to the right from point A, where its edge occurs and the line current I = 1 which passes through the point M is at a distance r' from A and is seen from this point to be at an angle α' to AO. But this is exactly the same situation as for the half-plane $(0,\ \infty)$ in Fig. 2 with the sole difference that r is replaced by r', α by α' and that the distance $\xi_1 = h - \xi$ of the given point to A must be taken instead of ξ. The required density is therefore equal to $j(r,\ \alpha',\ \xi_1,\ \infty)$ and this is what is found in Eq. (21).

[8] $j_1'(h-\xi)$ and $j_2'(h-\xi)$ can be obtained from (7) and (8) for $j_1(\xi)$ and $j_2(\xi)$ by replacing r with r', α with α', and ξ with $h-\xi$.

[9] Apart from the cases when the angle α is close to zero or π. Compare the conditions for (18).

[10] It is assumed that the external field sources are all above the plate. If there are also sources below it, the effect of each group can be considered separately as described in the text to give the total effect of a simple arrangement.

[11] At least in the case which interests us when $\gamma \gg 1$.

Conductivity of a medium with inhomogeneous inclusions in a magnetic field

Yu. P. Emets

Institute of Electrodynamics,
Academy of Sciences of the Ukrainian SSR, Kiev

(Submitted July 3, 1973)
Zh. Tekh. Fiz., 44, 916-921 (May 1974)

The two-dimensional electric field in a continuous medium with a low density of inhomogeneous inclusions and an anisotropic conductivity is analyzed. An analytic solution is found for the current distribution near an inhomogeneity; this is used to determine the average macroscopic characteristics of the medium. As the magnetic field is strengthened the current is displaced from the neighborhood of the inhomogeneity, and in a strong magnetic field the effective parameters σ_{eff} and β_{eff} are independent of the magnitude and sign of fluctuations in the system; these become functions of the volume of the inhomogeneous inclusions.

In this work we analyze the electric field in a continuous medium containing inhomogeneous inclusions and which is in a homogeneous magnetic field. We determine the average macroscopic characteristics of such a medium, which has an anisotropic conductivity. We find that for inclusions which are cylinders parallel to the magnetic lines of force or, equivalently, films and plates with inclusions, the current is displaced from the neighborhood of an inhomogeneity as the magnetic field is strengthened. A solution is obtained for the case of a low density of inclusions for an arbitrary difference between the conductivities and Hall parameters of the host (σ_1, β_1) and the disperse phase (σ_2, β_2). In a strong magnetic field the effective parameters σ_{eff} and β_{eff} are independent of the magnitude and sign of the fluctuations in the system and are functions of the volume of inhomogeneous inclusions alone.

In a plasma or a semiconductor in a magnetic field the conductivity is a tensor quantity, and the current distribution is sensitive to inhomogeneities in the medium. At large values of the Hall parameter ($\beta_1 \gg 1$) the appearance of even extremely slight fluctuations in the parameters can lead to a significant perturbation of the electric fields and thus changes in the properties of the medium as a whole.

For the electric fields averaged over a region, the influence of the inhomogeneities can be related to the changes in the electrical properties of the medium; quantitative characteristics of these properties are the effective values σ_{eff} and β_{eff}. It has been shown for stratified media[1-4] and for systems in which regions having different properties are distributed equiprobably[5] that these parameters are quite sensitive to the specific structure of the inhomogeneities. We consider a system consisting of a continuous medium with conductivity σ_1 and a Hall parameter β_1 containing inclusions extended along the lines of force of the external magnetic field and which has parameters σ_2 and β_2. Plates and films can also be described on the basis of this model; in these cases the fluctuation pattern is two-dimensional. We assume the dimensions of the inhomogeneities to be small in comparison with the distances between them, and we assume that the inhomogeneities do not interact with each other. In other words, we assume a low density of inclusions. Under these conditions, as in the papers cited above, the problem of determining σ_{eff} and β_{eff} can be solved analytically for arbitrary differences between the parameters σ_1, β_1, and σ_2, β_2.

1. CURRENT DISTRIBUTION NEAR AN INHOMOGENEITY

Under the conditions of this problem calculation of the field in the medium reduces to calculation of the current distribution near a single inhomogeneous inclusion and averaging of the field over the entire system.

We are to find the current distribution by working from the system of equations

$$\left.\begin{aligned} \mathbf{j}+\frac{\beta}{B}\mathbf{j}\times\mathbf{B}-\sigma\mathbf{E}=0,\\ \nabla\mathbf{j}=0,\quad \nabla\times\mathbf{E}=0. \end{aligned}\right\} \tag{1.1}$$

The Hall effect is taken into account in Ohm's law.

The external magnetic field is assumed to be homogeneous everywhere, and the self magnetic field of the current in the system is assumed to be negligible. At the interface between the two media we have the ordinary electrodynamic conditions: continuity of the current component normal to the boundary and continuity of the tangential component of the electric field. The field is assumed to be homogeneous at infinity and equal to some effective field; this effective field is set up by (in addition to the external sources) all inhomogeneous inclusions other than the one under consideration.

System (1.1) permits the introduction in the complex $\zeta = \rho e^{i\theta}$ plane of the analytic function $j(\zeta) = e^{i\theta}[j_\rho(\rho, \theta) + ij_\theta(\rho, \theta)]$. The theory of the Riemann boundary-value problem[6,7] furnishes a convenient apparatus for determining $j(\zeta)$.

We represent the inhomogeneous inclusion by the area S^+ ($|\zeta| < 1$) enclosed by circle L ($|\zeta| = 1$). We adopt as the positive direction on L that for which the exterior of the circle, S^-, is on the right.

This model is quite general, since any case involving an inhomogeneous inclusion specified by a finite region Σ, bounded by a smooth closed contour l which satisfies the Lyapunov condition can be transformed to the case considered here by means of a conformal mapping $z = \omega(\zeta)$ of Σ into S^+.

We introduce the piecewise-holomorphic function

$$\Psi_1(\zeta)=\begin{cases}\Psi_1^+(\zeta)=j_1(\zeta) & \text{for } |\zeta|<1,\\ \Psi_1^-(\zeta)=\overline{j_1(1/\bar{\zeta})} & \text{for } |\zeta|>1,\end{cases} \tag{1.2}$$

where $\Psi_1^-(\zeta)$ takes on the values which are the conjugates of $\Psi_1^+(\zeta)$ at the points which are the reflections of the points ζ with respect to the circle L. Similarly, we introduce the function $\Psi_2(\zeta)$:

$$\Psi_2(\zeta)=\begin{cases}\Psi_2^+(\zeta)=\overline{j_2(1/\bar\zeta)} & \text{for } |\zeta|<1,\\ \Psi_2^-(\zeta)=j_2(\zeta) & \text{for } |\zeta|>1.\end{cases} \tag{1.3}$$

The components of the functions $\Psi_1^-(\zeta)$ and $\Psi_2^+(\zeta)$ are the unknown values of the complex current outside and inside an inhomogeneity. In all the equations below, subscripts "1" and "2" refer to the host and disperse phases, respectively.

Using one of the two boundary conditions at L,

$$j_{\rho1}(1,\ \theta)=j_{\rho2}(1,\ \theta)=\gamma(\theta), \tag{1.4}$$

and using the functions $\Psi_1(\zeta)$ and $\Psi_2(\zeta)$ introduced here, we can construct two Riemann boundary-value problems:

$$\left.\begin{aligned}\Psi_1^+(t)&=-t^2\Psi_1^-(t)+2t\gamma(\theta),\\ \Psi_2^+(t)&=-\frac{1}{t^2}\Psi_2^-(t)+\frac{2}{t}\gamma(\theta)\end{aligned}\right\} \tag{1.5}$$

($t = e^{i\theta}$, $0 \le \theta \le 2\pi$).

The implicit solution of these problems [in which $\gamma(\theta)$ remains unknown] yields equations which we need below to relate the tangential current components at the interface between the media.

In the first problem in (1.5) the index is positive ($\varkappa = 2$) so that a solution bounded at infinity is given by

$$\Psi_1(\zeta)=\frac{1}{\pi i}\int_L\frac{t\gamma(\theta)\,dt}{t-\zeta}-\bar a\zeta^2-\bar b\zeta-\bar c. \tag{1.6}$$

Here, a, b, and c are complex constants. It can be shown, by exploiting the properties of Cauchy integrals, that these constants are governed by the value of $\Psi_1(\zeta)$ at the origin (the primes denote differentiation with respect to ζ):

$$a=\Psi_1(0),\quad b=\Psi_1'(0),\quad c=\frac{1}{2}\Psi_1''(0). \tag{1.7}$$

In (1.6) we have

$$\left.\begin{aligned}a+\bar c&=\frac{1}{\pi i}\int_L\gamma(\theta)\,dt,\\ b+\bar b&=\frac{1}{\pi i}\int_L\gamma(\theta)\frac{dt}{t}=\frac{1}{\pi i}\int_L\gamma(\theta)\,d\theta.\end{aligned}\right\} \tag{1.8}$$

The solution of the second Riemann boundary-value problem in (1.5) is

$$\Psi_2(\zeta)=\frac{1}{\pi i}\int_L\frac{\gamma(\theta)\,dt}{t(t-\zeta)}. \tag{1.9}$$

Since the index of this problem is negative ($\varkappa = -2$), solution (1.9) exists only if an additional condition is satisfied; in this case, this condition reduces to the vanishing of the quantity in the second equation in (1.8). Accordingly, b can take on only purely imaginary values. The integral on the right-hand side of this equation gives the total current flowing across the interface between the two media. This current vanishes since there are no current sources or sinks in region S^+. We see that the formal condition for the solvability of the inhomogeneous Riemann boundary-value problem with the negative index takes on a completely definite physical meaning.

Using (1.8) we convert the equations for $\Psi_1(\zeta)$ and $\Psi_2(\zeta)$ to

$$\left.\begin{aligned}\Psi_1(\zeta)&=\frac{\zeta}{\pi i}\int_L\frac{\gamma(\theta)\,dt}{t-\zeta}-\bar a\zeta^2+a-\bar b\zeta,\\ \Psi_2(\zeta)&=\frac{\zeta^{-1}}{\pi i}\int_L\frac{\gamma(\theta)\,dt}{t-\zeta}.\end{aligned}\right\} \tag{1.10}$$

Now, comparing the limiting values of $\Psi_1(\zeta)$ and $\Psi_2(\zeta)$ found by means of the Plemelj equations as ζ approaches L, e.g., from within the circle,

$$\frac{1}{t}\Psi_1^+(t)=\gamma(\theta)+\frac{1}{\pi i}\int_L\frac{\gamma(\theta)\,d\tau}{\tau-t}-\bar a t+a\frac{1}{t}-\bar b,$$

$$t\Psi_2^+(t)=\gamma(\theta)+\frac{1}{\pi i}\int_L\frac{\gamma(\theta)\,d\tau}{\tau-t},$$

we find an equation relating the tangential current components $j_{\theta1}$ and $j_{\theta2}$ at the interface:

$$j_{\theta1}(t)+j_{\theta2}(t)=t\left(-a\frac{1}{t}+\bar a t+b\right). \tag{1.11}$$

Turning to the second boundary condition at L,

$$E_{\theta1}(1,\ \theta)=E_{\theta2}(1,\ \theta),$$

we note that we can write it in the following manner by using Ohm's law:

$$-\frac{\beta_1}{\sigma_1}j_{\rho1}+\frac{1}{\sigma_1}j_{\theta1}=-\frac{\beta_2}{\sigma_2}j_{\rho2}+\frac{1}{\sigma_2}j_{\theta2}.$$

Using the limiting values of the current on L and Eqs. (1.2) and (1.3) we find two Riemann boundary-value problems:

$$\left.\begin{aligned}\Psi_1^+(t)&=\frac{\sigma_1+\sigma_2-i(\sigma_2\beta_1-\sigma_1\beta_2)}{\sigma_1+\sigma_2+i(\sigma_2\beta_1-\sigma_1\beta_2)}t^2\Psi_1^-(t)\\ &\quad-\frac{2\sigma_1(\bar a t^2+\bar b t-a)}{\sigma_1+\sigma_2+i(\sigma_2\beta_1-\sigma_1\beta_2)},\\ \Psi_2^+(t)&=\frac{\sigma_1+\sigma_2-i(\sigma_2\beta_1-\sigma_1\beta_2)}{\sigma_1+\sigma_2+i(\sigma_2\beta_1-\sigma_1\beta_2)}\frac{1}{t^2}\Psi_1^-(t)\\ &\quad+\frac{2\sigma_1(\bar a t^2+\bar b t-a)}{\sigma_1+\sigma_2+i(\sigma_2\beta_1-\sigma_1\beta_2)}.\end{aligned}\right\} \tag{1.12}$$

The solution for $\Psi_2(\zeta)$ in region S^+ is

$$\Psi_2(\zeta)=\frac{2\sigma_2}{\sigma_1+\sigma_2+i(\sigma_2\beta_1-\sigma_1\beta_2)}\left(\bar a-\frac{b}{\zeta}\right).$$

All the conditions of the original boundary-value problem are satisfied if we set b = 0. The physical meaning of this condition is that there is no circulation of current around the cylinder. Using this condition we find a solution for the second boundary-value problem in (1.12) for the region S^-:

$$\Psi_1(\zeta)=\frac{\sigma_2-\sigma_1+i(\sigma_2\beta_1-\sigma_1\beta_2)}{\sigma_1+\sigma_2-i(\sigma_2\beta_1-\sigma_1\beta_2)}\frac{a}{\zeta^2}+\bar a.$$

The constant a is determined from the condition of the specified homogeneous current at infinity, $\Psi_1(\infty) = J_0$.

Accordingly, the current distribution in the neighborhood of a circular inhomogeneity of radius R is

$$j(\zeta)=\begin{cases}\dfrac{\sigma_2-\sigma_1+i(\sigma_2\beta_1-\sigma_1\beta_2)}{\sigma_1+\sigma_2-i(\sigma_2\beta_1-\sigma_1\beta_2)}J_0\dfrac{R^2}{\zeta^2}+J_0 & \text{for } |\zeta|>R,\\ \dfrac{2\sigma_2}{\sigma_1+\sigma_2+i(\sigma_2\beta_1-\sigma_1\beta_2)} & \text{for } |\zeta|<R,\end{cases} \tag{1.13}$$

$$j(\zeta)=j_\xi(\xi,\ \eta)-ij_\eta(\xi,\ \eta)=e^{-i\theta}(j_\rho(\rho,\ \theta)-ij_\theta(\rho,\ \theta)).$$

A characteristic property of this solution is that the current distribution within the circle is homogeneous. If the conductivity is isotropic ($\beta_1 = \beta_2 = 0$) or $B=0$ the current within the circle, j_2, flows in the same direction as the current at infinity, J_0, differing from the latter only in magnitude. The current is drawn toward or repelled from the inhomogeneity, depending on the ratio between the conductivities and inclusions, σ_1 and σ_2.

If there is a Hall effect the current j_2, while remaining homogeneous, is rotated around J_0 through an angle (the reduced Hall angle)

$$\pi\varepsilon = \operatorname{arc\,tg}\frac{\sigma_2\beta_1 - \sigma_1\beta_2}{\sigma_1 + \sigma_2}, \quad 0 \leqslant |\varepsilon| < \frac{1}{2}. \tag{1.14}$$

We see from Eq. (1.13) that as the magnetic field is strengthened the current near the inclusion always decreases, regardless of the difference between σ_1 and σ_2. This decrease, by a factor of $(1 + \tan^2 \pi\varepsilon)^{1/2}$, is governed solely by the difference between the Hall constants $R_{Bi} = \beta_i/\sigma_i B_i$ ($i = 1, 2$) and the magnitude of the external magnetic field. For example, when σ_1 is finite but $\sigma_2 \to \infty$, we have $|j_2| \to 2J_0/(1 + \beta_1^2)^{1/2}$, i.e., in a strong magnetic field the current is displaced, even from ideally conducting inclusions, by an amount which is proportional to the Hall parameter of the host (β_1).

2. EFFECTIVITY CONDUCTIVITY OF AN INHOMOGENEOUS MEDIUM WITH AN ANISOTROPIC CONDUCTIVITY

Using the current distribution found here we can determine the effective conductivity σ_{eff} and the effective Hall parameter β_{eff} of a medium using inhomogeneous inclusions.

We must find the complex (because of the anisotropy in the conductivity) proportionality coefficient between the space averages of the field quantities J_{eff} and E_{eff}.

Using the complex form of Ohm's law

$$j_k(\zeta) = \frac{\sigma_k}{1 + i\beta_k} E_k(\zeta) \quad (k = 1, 2),$$

we consider the following integral for averaging over the volume:

$$\frac{1}{S}\int\left(E - \frac{1 + i\beta_1}{\sigma_1} j\right) ds \equiv E_{\text{eff}} - \frac{1 + i\beta_1}{\sigma_1} J_{\text{eff}}.$$

Here we have assumed that a homogeneous current equal to the effective current J_{eff} flows with respect to impurities in the medium. The integrand is nonvanishing only within the inhomogeneities. The contribution of the overall field from the component of the field within the inclusions is proportional to the inclusion volume λ. We therefore have

$$E_{\text{eff}} = \frac{1 + i\beta_1}{\sigma_1} J_{\text{eff}} + \lambda\left(E_2 - \frac{1 + i\beta_1}{\sigma_1} j_2\right),$$

from which we find, using Eq. (1.13) (where we must use J_{eff} instead of J_0), the equation

$$\frac{1 + i\beta_{\text{eff}}}{\sigma_{\text{eff}}} = \frac{1}{\sigma_1}\Big[1 + i\beta_1 + 2\lambda\frac{(\sigma_1 - \sigma_2)(\sigma_1 + \sigma_2) + (\sigma_2\beta_1 - \sigma_1\beta_2)^2 - 2i\sigma_2(\sigma_2\beta_1 - \sigma_1\beta_2)}{(\sigma_1 + \sigma_2)^2 + (\sigma_2\beta_1 - \sigma_1\beta_2)^2}\Big].$$

Hence

$$\left.\begin{aligned} \sigma_{\text{eff}} &= \sigma_1\left(1 + 2\lambda\frac{\Delta + \operatorname{tg}^2\pi\varepsilon}{1 + \operatorname{tg}^2\pi\varepsilon}\right)^{-1}, \\ \beta_{\text{eff}} &= \left(\beta_1 - \frac{4\lambda\sigma_2}{\sigma_1 + \sigma_2}\frac{\operatorname{tg}\pi\varepsilon}{1 + \operatorname{tg}^2\pi\varepsilon}\right)\left(1 + 2\lambda\frac{\Delta + \operatorname{tg}^2\pi\varepsilon}{1 + \operatorname{tg}^2\pi\varepsilon}\right)^{-1}. \end{aligned}\right\} \tag{1.15}$$

Here $\Delta = (\sigma_1 - \sigma_2)/(\sigma_1 + \sigma_2)$ is the relative magnitude of the conductivity fluctuation and $\pi\varepsilon$ is the reduced Hall angle given by Eq. (1.14).

If the conductivity is isotropic ($\beta_1 = \beta_2 = 0$) the quantity σ_{eff} is a function not only of the magnitude, but also the sign of the fluctuation Δ:

$$\sigma_{\text{eff}} = \frac{\sigma_1}{1 + 2\lambda\Delta} \quad (-1 \leqslant \Delta \leqslant 1).$$

These results are valid to first order in λ, so the equation given above can also be written as

$$\sigma_{\text{eff}} = \sigma_1(1 - 2\lambda\Delta).$$

If, on the other hand, there is a Hall effect in the medium, we find that in a strong magnetic field ($\tan^2 \pi\varepsilon \gg 1$), according to (1.15), the effective parameters are altogether independent of the fluctuations in the properties of the medium:

$$\sigma_{\text{eff}} = \frac{\sigma_1}{1 + 2\lambda}, \quad \beta_{\text{eff}} = \frac{\beta_1}{1 + 2\lambda}. \tag{1.16}$$

We see that in the cases of the limiting values of the fields both σ_{eff} and β_{eff} are always smaller than the corresponding parameters of the host phase (σ_1, β_1), regardless of the properties of the inhomogeneous inclusions. The only governing factor is the volume of these inclusions.

Nonlinear polarizability of a gaseous medium in a longitudinal magnetic field

V. A. Sokolov and L. M. Khayutin

A. A. Zhdanov Leningrad State University

(Submitted June 25, 1973)
Zh. Tekh. Fiz., 44, 922-927 (May 1974)

The polarizability of an active (single-isotope) gaseous medium in a fixed magnetic field is calculated in third order in the electric field. The two-mode linear and nonlinear interaction coefficients are calculated for modes with different polarization states. In ring gas lasers with broad Doppler gain spectrum, in a fixed longitudinal magnetic field the nonlinear interaction between modes is due primarily to three effects: 1) the formation of Bennett dips (or peaks), 2) modulation of the population, and 3) excitation of atoms in a coherent superposition of Zeeman sublevels (Hertz coherence).

INTRODUCTION

Several experimental and theoretical papers have appeared recently on the nonlinear interaction of traveling waves with different polarization states in an active gaseous medium in a fixed magnetic field.[1-5] In two-mode ring lasers the electromagnetic field can be represented by eight traveling waves with different polarization states [see Eq. (1) and Fig. 1]. The nonlinear polarizability of a gaseous medium in a magnetic field must be calculated, and the linear and nonlinear coefficients for the traveling-wave interaction must be found, in order to determine the stability regions for various lasing regimes in a ring laser and to determine the frequency characteristics of a ring laser for several problems in laser spectroscopy.[6] The effect of a magnetic field on the operation of a ring laser is of experimental as well as theoretical interest (e.g., in connection with the ring laser in the geomagnetic field and the laser gyroscope). The polarization of the modes in a ring laser is governed by both the properties of the cavity (including those of asymmetric elements inserted in the cavity) and the characteristics of the active medium. The calculated interaction coefficients, given in Eqs. (8) below, can be used to analyze cases of various mode polarizations.[1)]

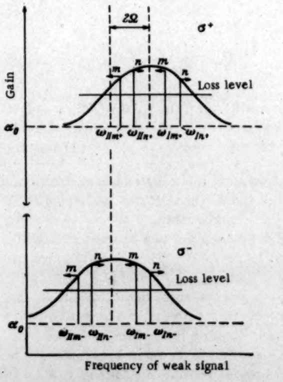

Fig. 1. Splitting of the Doppler gain spectrum in a fixed longitudinal magnetic field (Ω) into two spectra (the Landé g factors are assumed to be identical) corresponding to the σ^+ and σ^- transitions. In a two-mode ring laser (ω_I and ω_{II}) the frequencies of oppositely directed waves of each mode split, because of rotation or because of the insertion of noninteracting element into the cavity, into a total of four waves with right-hand circular polarization (+) and four waves with left-hand circular polarization (−) (here n and m give the propagation directions).

We use the semiclassical approach[8] to analyze the nonlinear polarizability of a single-isotope active gaseous medium. We treat the active medium as a set of atoms in which a dipole transition can occur between two excited states, a and b (with total angular momenta j_a and j_b). The gaseous medium is in a fixed magnetic field along the laser axis, the z axis (z and −z are the propagation directions of the traveling waves). We also choose the z axis as the quantization axis. We find the coefficients for the linear and nonlinear interactions [see Eqs. (8)] for eight traveling waves with various polarization states (Fig. 1) in third-order perturbation theory in the laser field [see (3)].

NONLINEAR POLARIZABILITY OF A GASEOUS MEDIUM

We assume an active gaseous medium in a fixed magnetic field H. We assume the Zeeman splitting $\Omega = g\mu_\beta H$ to be the same for the upper (a) and lower (b) levels (g is the Landé g factor and μ_β is the Bohr magneton).

We write the field in the two-mode ring laser, E(z, t), as eight traveling waves (Fig. 1) in a circular coordinate system:

$$\left.\begin{aligned} E(z,\ t) &= \sum_{p=(I,II)} \sum_{\binom{r=(n,m)}{s=(+1,-1)}} \{(-1)^s \hat{e}_{-s} \mathcal{E}_{prs}(t) \\ &\quad \times \exp[-i(\omega_{prs} t - k_{prs} z)] + \text{c.c.}\}, \\ \mathcal{E}_{prs}(t) &= E_{prs}(t) \exp[-i\varphi_{prs}(t)],\ k_{pns} = -k_{pms} > 0, \\ \hat{e}_s &= -\frac{s}{\sqrt{2}}(\hat{e}_x + is\hat{e}_y),\ s = (\pm 1), \end{aligned}\right\} \tag{1}$$

where $s = \pm 1$ is the index of the circular coordinate; p = I, II is the mode index, r = n, m is the propagation direction of the wave; and $k_{pns} = (2\pi q_n)/L$, where q_n is a large integer, L is the perimeter of the cavity, and ω_{prs} is the circular frequency of wave "prs."

The system of truncated equations for the electric field is

$$\left.\begin{aligned} \frac{d\mathcal{E}_{prs}}{dt} &= i(\omega_{prs} - \nu_{prs})\mathcal{E}_{prs} - \frac{\delta\omega_p}{2}\mathcal{E}_{prs} + \frac{2\pi i\omega_{prs}}{\varepsilon} P_{prs}(t), \\ p &= (I,\ II),\ r = (n,\ m),\ s = (\pm 1), \end{aligned}\right\} \tag{2}$$

where ν_{prs} is the cavity frequency of wave "prs," and ε is the dielectric constant of the medium, neglecting the transition under consideration.

To third order in perturbation theory in the laser field, for which case

$$\frac{|(j_a\|d\|j_b)E|^2}{\hbar^2\gamma_{ab}}\left(\frac{1}{\gamma_a}+\frac{1}{\gamma_b}\right)\ll 1, \tag{3}$$

where $(j_a\|d\|j_b)$ is the reduced matrix element of the dipole transition between working levels *a* and b, we can write the polarizability of the active medium $P_{prs}(t)$ as

$$\left.\begin{aligned}
P_{prs}(t)&=\frac{s\mathcal{E}_{prs}}{2\pi i\omega_{prs}}\Big\{i\chi^{(p)}_{rs}+i\sum_{(p_1,r_1,s_1)}\chi^{(p,p_1)}_{rsr_1s_1}|\mathcal{E}_{p_1r_1s_1}|^2\Big\}\\
&+\frac{s}{2\pi i\omega_{prs}}\{i\mathcal{E}_{pr-s}\mathcal{E}_{pr's}\mathcal{E}^*_{pr'-s}\chi^{(p,p')}_{rsr-sr'sr'-s}\\
&+i\mathcal{E}_{pr-s}\sum_{(r_1)}\chi^{(p,p')}_{rsr-sr_1sr_1-s}\mathcal{E}_{p'r_1s}\mathcal{E}^*_{p'r_1-s}\\
&+i\frac{N_2}{N}\mathcal{E}^*_{p'r'-s}\sum_{(s_1)}\chi^{(p,p')}_{rsr's_1r-s_1r'-s}\mathcal{E}_{pr's}\mathcal{E}_{p'r-s_1}\exp(i\omega_{pp'}t)\\
&+i\frac{N_2}{N}\chi^{(p,p')}_{rsr'srsr's}\mathcal{E}_{pr'r}\mathcal{E}_{p'rs}\mathcal{E}^*_{p'r's}\exp(i\omega_{pp'}t),\\
&p\neq p'=(\mathrm{I},\ \mathrm{II}),\qquad p_1=(p,\ p')\\
&r\neq r'=(n,\ m),\qquad r_1=(r,\ r')\\
&s=(\pm 1),\qquad s_2=(s,\ -s),
\end{aligned}\right\} \tag{4}$$

where $\omega_{pp'}=(\omega_{pr}-\omega_{pr'})-(\omega_{p'r}-\omega_{p'r'})$; $\omega_{pr}=(1/2)\cdot(\omega_{prs}+\omega_{pr-s})$, and N_2/N is the Fourier component of the relative amount by which the pumping exceeds the threshold level. This component is a function of the difference between the wave numbers and the relative arrangement and length of the tubes containing the active medium. In the approximation

$$\left\{\begin{aligned}k_{prs}=k_{pr-s}\equiv k_{pr},\\ k_{pn}=-k_{pm}\equiv k_p>0\end{aligned}\right\} \tag{5}$$

we can write N_2/N as (see ref. 7 for more details)

$$\frac{N_2}{N}=\frac{\frac{1}{L}\int\limits_0^L N(z)\exp[-i(k_p-k_{p'})z]\,dz}{\frac{1}{L}\int\limits_0^L N(z)\,dz}. \tag{6}$$

Taking account of the total angular momenta j_a and j_b for a single-isotope gaseous medium in the case

$$\left.\begin{aligned}\eta^2=\left(\frac{\gamma_{ab}}{ku}\right)^2\ll 1,\\ (\omega_{\mathrm{I}}-\omega_{\mathrm{II}})^2\ll(ku)^2\end{aligned}\right\} \tag{7}$$

[where $\gamma_{ab}\geq 1/2(\gamma_a+\gamma_b)$ is the homogeneous half-width of the radiation line, $1/\gamma_a$ and $1/\gamma_b$ are the lifetimes of excited levels *a* and b, and ku is the half-width of the Doppler amplification spectrum], we can write the coefficients for the linear and nonlinear wave interactions in Eq. (4) as

$$\begin{aligned}
\chi^{(p)}_{rs}&=-i\frac{N\delta\omega_p}{2N_{\mathrm{thr}}}(1-\eta^2f^2_{prs})+\frac{\eta}{2\sqrt{\pi}}\frac{N\delta\omega_p}{N_{\mathrm{thr}}}f_{prs},\\
\chi^{(p,p)}_{rsrs}&=iB_0\left(\frac{1}{\varkappa_a}+\frac{1}{\varkappa_b}\right),\\
\chi^{(p,p)}_{rsr-s}&=iB_1\left(\frac{1}{\varkappa_a\zeta^{pr-s}_{prs}}+\frac{1}{\varkappa_b\zeta^{pr-s}_{prs}\zeta^{pr-s(b)}_{prs}}\right)+iB_2\,(a\leftrightarrow b),\\
\chi^{(p,p)}_{rsr's}&=\frac{iB_0}{\xi^{pr's}_{prs}}\left(\frac{1}{\varkappa_a}+\frac{1}{\varkappa_b}\right),\\
\chi^{(p,p)}_{rsr'-s}&=\frac{i}{\xi^{pr'-s}_{prs}}\left(\frac{B_1}{\varkappa_a}+\frac{B_2}{\varkappa_b}\right),\\
\chi^{(p,p')}_{rsrs}&=\frac{iB_0}{\zeta^{p'rs}_{prs}}\left(\frac{1}{\varkappa_a}+\frac{1}{\varkappa_a\zeta^{p'rs(a)}_{prs}}\right)+iB_0\,(a\leftrightarrow b),\\
\chi^{(p,p')}_{rsr-s}&=\frac{iB_1}{\zeta^{p'r-s}_{prs}}\left(\frac{1}{\varkappa_a}+\frac{1}{\varkappa_b\zeta^{p'r-s(b)}_{prs}}\right)+iB_2\,(a\leftrightarrow b),\\
\chi^{(p,p')}_{rsr's}&=\frac{iB_0}{\xi^{p'r's}_{prs}}\left(\frac{1}{\varkappa_a}+\frac{1}{\varkappa_b}\right),\\
\chi^{(p,p')}_{rsr'-s}&=i\left(\frac{B_2}{\varkappa_b}+\frac{B_1}{\varkappa_a}\right)\frac{1}{\xi^{p'r'-s}_{prs}},\\
\chi^{(p,p)}_{rsr-sr'sr'-s}&=\frac{iB_1}{\xi^{pr's}_{prs}}\left(\frac{1}{\varkappa_b\zeta^{pr-s(b)}_{prs}}\right)+iB_2\,(a\leftrightarrow b),\\
\chi^{(p,p')}_{rsr-srsr-s}&=\frac{iB_1}{\zeta^{p'r-s}_{prs}}\left(\frac{1}{\varkappa_a\zeta^{p'r-s(a)}_{prs}}+\frac{1}{\varkappa_b\zeta^{pr-s(b)}_{prs}}\right)+iB_2\,(a\leftrightarrow b),\\
\chi^{(p,p')}_{rsr-sr'sr'-s}&=iB_1\left(\frac{1}{\varkappa_b\zeta^{pr-s(b)}_{prs}\xi^{p'r's}_{prs}}\right)+iB_2\,(a\leftrightarrow b),\\
\chi^{(p,p')}_{rsr'srsr's}&=iB_0\left(\frac{1}{\varkappa_a\zeta^{p'r's(a)}_{pr's}\left(\xi^{pr's}_{prs}+\frac{i\Delta_{pp'}}{2}\right)}\right)+iB_0\,(a\leftrightarrow b),\\
\chi^{(p,p')}_{rsr'sr-sr'-s}&=iB_1\left(\frac{1}{\varkappa_b\zeta^{p'r'-s(b)}_{pr's}\left(\xi^{pr's}_{prs}+\frac{i\Delta_{pp'}}{2}\right)}\right)+iB_2\,(a\leftrightarrow b),\\
\chi^{(p,p')}_{rsr'-srsr'-s}&=iB_1\left(\frac{1}{\varkappa_a\zeta^{p'r'-s(a)}_{pr'-s}\left(\xi^{pr'-s}_{prs}+\frac{i\Delta_{pp'}}{2}\right)}\right)+iB_2\,(a\leftrightarrow b),\\
&p\neq p',\quad r\neq r'.
\end{aligned} \tag{8}$$

In Eq. (8) we have used

$$\left.\begin{aligned}
\frac{N}{N_{\mathrm{thr}}}&=\frac{(N_a-N_b)4\pi^{3/2}Q_{pr}|(j_a\|d\|j_b)|^2}{3\hbar ku\varepsilon},\\
B_i(j_a,\ j_b)&=\frac{3}{2}\frac{N\delta\omega_p}{N_{\mathrm{thr}}}\frac{|(j_a\|d\|j_b)|^2}{\hbar^2\gamma^2_{ab}}G_i(j_a,\ j_b)\quad(i=0,\ 1,\ 2),\\
f_{prs}&=\frac{\omega_{prs}-\omega_0+s\Omega}{\gamma_{ab}},\ \zeta_{prs}=1-if_{prs},\\
f^{p'r's'}_{prs}&=f_{prs}-f_{p'r's'},\quad \zeta^{p'r's'}_{prs}=1-\frac{i}{2}f^{p'r's'}_{prs},\\
\xi^{p'r's'}_{prs}&=1-\frac{i}{2}(f_{prs}+f_{p'r's'}),\ \zeta^{p'r's'(a)}_{prs}=1-\frac{i}{\varkappa_a}f^{p'r's'}_{prs},\\

\end{aligned}\right\}. \tag{9}$$

The coefficients $G_i(j_a,\ j_b)$ ($i=0,\ 1,\ 2$) are the sums of the products of the Wigner 3j symbols. These are given in Table 1 for the cases $|j_a-j_b|=(0;1)$ (see also refs. 2, 3).

The physical meaning of interaction coefficients (8) is clear from the solution of the system of equations for the density matrix describing a set of atoms in a fixed magnetic field between the two excited states of which a dipole transition is allowed.[1] The field (1) consists of waves of different origins, $\mathcal{E}_{p_1r_1s}$ and $\mathcal{E}_{p_2r_2-s}$ (ref. 2), propagating in the same and different directions, i.e., the laser field is a mixture of the σ^+ and σ^- polarization components ("coherent" polarization[1]). Under the influence of the pump the atoms are in the Zeeman sublevels of the excited upper (*a*) and lower (b) levels. As they interact with the field of coherent polarization the atoms convert from the Zeeman sublevels to a coherent superposition of sublevels (a Hertz coherence). Dips (Bennett peaks[9]) form in the Maxwell velocity distributions of the atoms in the Zeeman sublevels. In two-mode lasing, the population difference consists of two terms, one is constant in space and time and the other is a function of the phase difference between the

TABLE 1

$G_i(j_a, j_b)$	$\lvert j_a - j_b \rvert = 0$	$\lvert j_a - j_b \rvert = 1$
$G_0(j_a, j_b)$	$G_0(j, j) = \frac{2j^2 + 2j + 1}{15j(j+1)(2j+1)}$	$G_0(j, j+1) = \frac{6j^2 + 12j + 5}{15(j+1)(2j+1)(2j+3)}$ $G_0(j+1, j) = G_0(j, j+1)$
$G_1(j_a, j_b)$	$G_1(j, j) = \frac{(2j-1)(2j+3)}{30j(j+1)(2j+1)}$	$G_1(j, j+1) = \frac{(j+2)(2j+5)}{30(j+1)(2j+1)(2j+3)}$ $G_1(j+1, j) = \frac{j(2j-1)}{30(j+1)(2j+1)(2j+3)}$
$G_2(j_a, j_b)$	$G_2(j, j) = G_1(j, j)$	$G_2(j+1, j) = G_1(j, j+1)$ $G_2(j, j+1) = G_1(j+1, j)$

traveling waves and varies in space and time (the modulation of the population) (ref. 10). These effects are described by nonlinear polarizability $P_{prs}(t)$ [see Eq. (14)]. The nonlinear susceptibilities in polarizability (4), $\chi^{(p,p')}_{rsr_1s_1r_2s_2r_3s_3}$, are fourth-rank tensors and characterize the linear properties of the active medium.[2]

The susceptibilities which describe the interactions between waves (of different modes) travelingin the opposite directions are not functions of the population modulation; all the other nonlinear two-mode interaction coefficients are functions of this modulation.[10] Furthermore, it can be shown that in the Doppler limit the quantities $\chi^{(p,p')}_{rsrsr'sr's}$ and $\chi^{(p,p')}_{rsrsr'-sr'-s}$ describe Bennett dips (or peaks); the terms in the susceptibilities which are proportional to $G_0(j_a, j_b)$, and $G_1(j_a, j_b)$ correspond to Bennett dips, while those which are proportional to $G_0(j_b, j_a)$ and $G_1(j_b, j_a)$ corresponds to Bennett peaks. The nonlinear susceptibility $\chi^{(p,p')}_{rsrsr-sr-s}$ describes both Bennett dips and Hertz coherence, while $\chi^{(p,p')}_{rsr-sr'sr'-s}$ describes Hertz coherence, where the terms proportional to $G_2(j_a, j_b)$ correspond to Hertz coherence of the upper level, and those proportional to $G_2(j_b, j_a)$ correspond to that of the lower level. The condition for the appearance of coherent terms in the emission is the existence of Zeeman sublevels of lower level b which are common to the σ^+ and σ^- transitions, and the condition for the appearance of coherent terms in the absorption is the existence of analogous sublevels of upper level *a*. As the magnetic field H is strengthened, the Hertz coherence is disrupted, and the effect of H on the polarizability $P_{prs}(t)$ decreases.

Accordingly, the nonlinear interaction of modes in a gas ring laser with a broad Doppler gain spectrum is due primarily to three effects: 1) the formation of Bennett dips (or peaks), 2) modulation of the population, and 3) the excitation of atoms in a coherent superposition of Zeeman sublevels (a Hertz coherence).

The authors thank É. E. Fradkin for useful discussions.

---

[1] The two-mode interaction coefficients in (8) differ from those given in ref. 4.

[2] The quantities $\chi^{(p)}_{rs}$ and $\chi^{p,p'}_{rsr's}$ were analyzed in detail previously.[2,3]

Theory of the cathode lens.
III. Derivation of equations for composite cathode lenses

We consider the motion of charged particles in a composite cathode lens formed by an electric field and a superimposed magnetic field with a common z axis of symmetry. By means of the substitution $z = \zeta + \eta(\zeta)$ where $\zeta = [-(2e/m)\Phi(\zeta)]^{1/2}$, and $\eta(\zeta)$ is a small quantity, time is eliminated from the differential equations of motion written in the cylindrical coordinate system r, ψ, z. The quantity $\Phi(z)$ is the distribution of the scalar potential along the lens axis. The specified substitution makes it possible to bring the equations for the trajectories to a form in which the smallness of the nonlinear terms in the paraxial region is preserved when the initial angles of the trajectories with the axis of the lens reach $\pi/2$ and the spread in particle energies is of the order of the initial energy. The resulting equations are solved by successive approximations to third order. The solution is obtained in the form of coordinate dependence on the variable ζ. However, because of the smallness of the quantity $\eta(\zeta)$, all the functions of the variable ζ appearing in the solution far from the cathode surface can be expanded in powers of this quantity and are represented in a trajectory in the form of explicit dependence of the coordinates r and ψ on z. The solution thus obtained is suitable for investigation of the electron-optical properties of cathode lenses, including aberration.

As has been shown,[1-4] the quality of an image obtained with a cathode lens is improved considerably if a magnetic field is used together with the electrostatic field. The use of magnetic cathode lenses in an emission electron microscope made it possible to obtain resolutions[5] down to 100 Å. For this reason, there is considerable interest in the electron-optical properties of such lenses, including their aberration. Studies in this field have been made by a number of authors within the limits of geometric electron optics.[6,7] However, the assumption introduced in these papers – a finite (though small) value for the initial longitudinal velocity of the electrons – is at variance with a characteristic of a cathode lens where electrons with infinitely small, and even zero, initial energy can, in principle, participate in image formation.

In a cathode lens the initial particle energy ε and the distance from the symmetry axis r are considered small quantities. Although these quantities are unlike by their very nature, when ε is not equal to zero it can be considered a quantity of second-order smallness[8,9] with respect to r. The theory of the cathode lens must also include the case in which ε becomes an infinitesimally small quantity.

In studies of cathode lenses it is necessary to bring the equation for the trajectory of charged particles to a form in which the contribution of nonlinear terms is of higher order than r. By using successive approximations one can then determine the paraxial properties of cathode lenses and their aberrations just as is done for immersion and unipotential lenses.

Since we are considering third-order aberrations in this paper the contribution of nonlinear terms must be taken into account to third order in deriving equations for the trajectories. Orders of magnitude are indicated with reference to r, with ε being considered a quantity of second order. The total magnitude of nonlinear terms must remain small even when the slope of a trajectory relative to the lens axis becomes infinitely large near the cathode surface.

We locate the origin of a cylindrical coordinate system r, ψ, z on the cathode surface and make the z axis coincide with the principal optical axis of the cathode lens. The electric field will be characterized by a scalar potential $\varphi = \varphi(r, z)$ and the magnetic field by a vector potential with the components $A_r = A_z = 0$, $A_\psi = A(r, z)$. We assume the potential of the cathode to be zero so that the equation

$$\varphi(r_0, z_0) = 0 \tag{1}$$

will determine the cathode surface, which need not be planar in the general case. The subscript "0" indicates the value of a quantity at the cathode.

The equations of motion for a particle of charge e and mass m leaving the cathode with an energy $\varepsilon = e\varphi_z$ take the form

$$\ddot{r} = r\dot{\psi}^2 - \frac{e}{m}\frac{\partial\varphi}{\partial r} + \frac{e}{m}\dot{\psi}\frac{\partial}{\partial r}(rA), \tag{2}$$

$$\dot{z}^2 + \dot{r}^2 + r^2\dot{\psi}^2 = -\frac{2e}{mc}[\varphi(r, z) + \varphi_1], \tag{3}$$

$$mr^2\dot{\psi} + \frac{e}{c}rA = -\frac{e}{c}C, \tag{4}$$

where C is a constant and c is a quantity numerically equal to the speed of light.

We introduce the complex variable

$$u = re^{i\varkappa} \tag{5}$$

with

$$\varkappa = \psi + \frac{e}{mc}\int\frac{A}{r}\,dt, \tag{6}$$

where t is the time. The system of equations (2), (3), and (4) then takes the following form:

$$\frac{m}{e}\ddot{u} + 2\left[\frac{\partial\varphi}{\partial(r^2)} - k^2\frac{A^2}{r^2}\right]u = 4k^2(C + Ar)u\frac{\partial}{\partial(r^2)}\left(\frac{A}{r}\right), \tag{7}$$

$$\frac{m}{2e}\dot{z}^2+\varphi(r,\ z)=-\frac{m}{2e}\dot{u}\dot{\bar{u}}-\varphi_i+k^2\left(\frac{2C}{r^2}+\frac{A}{r}\right)\frac{A}{r}u\bar{u}, \tag{8}$$

where $k = 1/c\,(-e/2m)^{1/2}$ and

$$C=\frac{imc}{2e}(\dot{u}\bar{u}-u\dot{\bar{u}}). \tag{9}$$

The next problem is the elimination of time from the system of equations (7) and (8). To do this, we introduce a new variable ζ, which satisfies

$$\zeta=\sqrt{-\frac{2e}{m}\Phi(\zeta)} \tag{10}$$

and assume

$$z=\zeta+\eta, \tag{11}$$

where η is a function of ζ in which the initial conditions appear as parameters. The quantity $\Phi(z) = \zeta(0, z)$ is the φ potential distribution function along the lens axis and $\Phi(\zeta)$ is the same function for the argument ζ. Using Eqs. (10) and (11), we eliminate the time t and the coordinate z from Eqs. (7) and (8) by introducing ζ as an independent variable,

$$\Phi(\zeta)\frac{d^2u}{d\zeta^2}+\frac{1}{2}\frac{d\Phi(\zeta)}{d\zeta}\frac{du}{d\zeta}+\frac{1}{4}\left[\frac{d^2\Phi(\zeta)}{d\zeta^2}+k^2H^2(\zeta)\right]u=F_n, \tag{12}$$

$$2\Phi(\zeta)\frac{d\eta}{d\zeta}-\frac{d\Phi(\zeta)}{d\zeta}\eta=f_n. \tag{13}$$

Here

$$F_n=\left[\frac{\partial\varphi(r,\ \zeta+\eta)}{\partial(r^2)}+\frac{1}{4}\frac{d^2\Phi(\zeta)}{d\zeta^2}-k^2\frac{A^2(r,\ \zeta+\eta)}{r^2}+\frac{k^2}{4}H^2(\zeta)\right]u$$
$$+2k\left\{\frac{i}{2}\sqrt{\Phi(\zeta)}\left[\bar{u}\frac{du}{d\zeta}-u\frac{d\bar{u}}{d\zeta}\right]-kA(r,\ \zeta+\eta)r\right\}u\frac{\partial}{\partial(r^2)}\left[\frac{A(r,\ \zeta+\eta)}{r}\right], \tag{14}$$

$$f_n=\varphi(r,\ \zeta+\eta)-\frac{d\Phi(\zeta)}{d\zeta}\eta-\Phi(\zeta)\left(\frac{d\eta}{d\zeta}\right)^2+\varphi_i-\Phi(\zeta)\left(1+\frac{du}{d\zeta}\frac{d\bar{u}}{d\zeta}\right)$$
$$+k\left[i\frac{\sqrt{\Phi(\zeta)}}{u\bar{u}}\left(\bar{u}\frac{du}{d\zeta}-u\frac{d\bar{u}}{d\zeta}\right)-k\frac{A(r,\ \zeta+\eta)}{r}\right]\frac{A(r,\ \zeta+\eta)}{r}u\bar{u}, \tag{15}$$

H(z) is the distribution function for the magnetic field along the principal optical axis of the lens and $H(\zeta)$ is the same function for the argument ζ.

Equation (13) indicates that the quantity η can be assumed to be zero for particles moving along the principal optical axis of the lens when $\varphi_i = 0$. This means that there is a particular solution of Eq. (13) $\eta = \eta(\zeta)$ which is small for small values of φ_i and r. We use this solution. In addition, we require that $d\eta/d\zeta$ remain a bounded quantity near the cathode. No approximations are introduced in the derivation of Eqs. (12) and (13); therefore these equations are valid for any values of r and φ_i. We seek solutions of these equations for a region near the principal optical axis of the lens and for small values of the initial energies. Equations (12) and (13) are written in a form such that they allow solution by successive approximation under the conditions specified.

Using the well-known representations of field potentials near the symmetry axis of the system

$$\varphi(r,\ z)=\Phi(z)-\frac{r^2}{4}\frac{d^2\Phi(z)}{dz^2}+\frac{r^4}{64}\frac{d^4\Phi(z)}{dz^4}-\dots, \tag{16}$$

$$\frac{A(r,z)}{r}=\frac{1}{2}H(z)-\frac{r^2}{16}\frac{d^2H(z)}{dz^2}+\dots \tag{17}$$

and the expansions

$$\Phi(z)=\Phi(\zeta)+\frac{d\Phi(\zeta)}{d\zeta}\eta+\dots, \tag{18}$$

$$H(z)=H(\zeta)+\frac{dH(\zeta)}{d\zeta}\eta+\dots, \tag{19}$$

we write Eqs. (12) and (13) in the form

$$\Phi u''+\frac{1}{2}\Phi'u'+\frac{1}{4}Q_2u=F_n^{(3)}, \tag{20}$$

$$2\Phi\eta'-\Phi'\eta=f_n^{(3)} \tag{21}$$

with

$$F_n^{(3)}=-\frac{Q_2'}{4}\eta u+\frac{Q_4}{32}u^2\bar{u}-\frac{ik}{16}H''\sqrt{\Phi}(u'\bar{u}-u\bar{u}')u, \tag{22}$$

$$f_n^{(3)}=-\Phi u'\bar{u}'-\frac{Q_2}{4}u\bar{u}+\frac{ik}{2}H\sqrt{\Phi}(u'\bar{u}-u\bar{u}')+\varphi_n. \tag{23}$$

Here

$$Q_2=\Phi''+k^2H^2, \tag{24}$$

$$Q_4=\Phi^{\mathrm{IV}}+4k^2HH''. \tag{25}$$

Primes indicate differentiation with respect to the independent variable ζ.

In the derivation of Eqs. (20) and (21) terms above third order relative to r are dropped. The quantity $f_n^{(3)}$ is second order. The fact that u' can become infinite near the cathode does not contradict this statement since $\Phi \to 0$. The term in Eq. (23)

$$\Phi u'\bar{u}' = -\frac{m}{2e}(\dot{r}^2+r^2\dot{\psi}^2),$$

i.e., it is proportional to the square of the transverse velocity. The magnitude of this term near the cathode, like that of φ_i, is of second-order smallness. This same order is also maintained with particle separation from the cathode because the variation of the quantity $\Phi u'\bar{u}'$ is quadratic with respect to r. The other term in Eq. (23) containing u' and ū' is also of second-order smallness. Since the quantity η will be of the same order of smallness as $f_n^{(3)}$, i.e., second order, the right side of Eq. (20) is a quantity of third order. Note that on the right side of Eqs. (20) and (21), the product $u'(\Phi)^{1/2}$, and the quantity u' itself, appear as quantities of small magnitude. Therefore, the smallness of the quantities $F_n^{(3)}$ and $f_n^{(3)}$, which is necessary for the use of successive approximation, is ensured either by the smallness of Φ, which occurs near the cathode surface, or by the smallness of u' at sufficient separation from that surface. The equations (20) and (21) differ from the corresponding equations written for immersion and unipotential lenses[10] in which the smallness of the right sides is ensured only by the smallness of the slope of the trajectory; these are therefore unsuitable for the analysis of cathode systems.

To solve the equations (20) and (21) we first find a quantity U which determines u in first approximation by setting $F_n^{(3)} = 0$ in Eq. (20) and then compute η by substituting U in the right side of Eq. (21); then, by substituting U and η in the right side of Eq. (20), we obtain a linear inhomogeneous equation for the third-order correction:

$$\chi = u - U. \tag{26}$$

When $F_n^{(3)} = 0$, we have

$$\Phi U'' + \frac{1}{2}\Phi' U' + \frac{1}{4} Q_2 U = 0. \tag{27}$$

This equation has a singularity at $\zeta = 0$ which is a pole of first order for the coefficients of U' and U since it is assumed that the electric field is different from zero at the cathode surface. According to the theory for this type of equation, there are two linearly independent real particular solutions of Eq. (27) of which one, $p(\zeta)$, is an analytic function; the other is

$$g(\zeta) = q(\zeta)\sqrt{\Phi(\zeta)}, \tag{28}$$

where $q(\zeta)$ is an analytic function satisfying

$$\Phi q'' + \frac{3}{2}\Phi' q' + \frac{1}{4}(3\Phi'' + k^2 H^2)\, q = 0. \tag{29}$$

We assign the initial conditions

$$p(0) = q(0) = 1. \tag{30}$$

Then, from Eqs. (27) and (29)

$$p'(0) = -\frac{1}{2\Phi_0'} Q_{20} = \frac{1}{R} - \frac{k^2 H_0^2}{2\Phi_0'}, \tag{31}$$

$$q'(0) = \frac{1}{R} - \frac{k^2 H_0^2}{6\Phi_0'}. \tag{32}$$

Here, H_0 is the magnetic field and Φ_0' is the electric field on the lens axis at the cathode surface. The quantity

$$R = -\frac{2\Phi_0'}{\Phi_0''} \tag{33}$$

is the radius of curvature of the cathode surface when r = 0. We take R > 0 for a convex cathode and R < 0 for a concave cathode.

Note that by using Eqs. (27) and (29) one can determine derivatives of any order with respect to p and q for $\zeta = 0$; this can be necessary in the numerical integration of these equations.

The particular solutions p and g are connected by the following relation:

$$\sqrt{\Phi}\,(pg' - p'g) = \frac{\Phi_0'}{2}. \tag{34}$$

The general solution of Eq. (27) will be

$$U = ap + bg, \tag{35}$$

where *a* and b are arbitrary constants, generally complex, and of first-order smallness. Substituting this solution in place of u in Eq. (23) and keeping Eq. (34) in mind, we obtain

$$f_n^{(3)} = -a\bar{a}\left(\Phi p'^2 + \frac{1}{4} Q_2 p^2\right) - \bar{a}b\left(\Phi p'g' + \frac{1}{4} Q_2 pg - \frac{ik}{4}\Phi_0' H\right) - a\bar{b}\left(\Phi p'g' + \frac{1}{4} Q_2 pg + \frac{ik}{4}\Phi_0' H\right) - bb\left(\Phi g'^2 + \frac{1}{4} Q_2 g^2\right) + \varphi_H. \tag{36}$$

A solution of Eq. (21) will be sought in the form

$$\eta = a\bar{a}\eta_1 + a\bar{b}(\eta_2 - i\eta_5) + \bar{a}b(\eta_2 + i\eta_5) + b\bar{b}\eta_3 + \varphi_H\,\eta_4. \tag{37}$$

Equation (21) then breaks down into a number of equations for which the solutions are

$$\eta_1 = -\frac{pp'}{2} + \sqrt{\Phi}\int_0^{\zeta} \frac{pp''}{\sqrt{\Phi}}\, d\zeta, \tag{38}$$

$$\eta_2 = \frac{\sqrt{\Phi}}{2}\int_0^{\zeta} (p''q - p'q')\, d\zeta, \tag{39}$$

$$\eta_3 = \frac{\Phi'}{4} q^2 - \frac{\Phi}{2} q'q + \sqrt{\Phi}\int_0^{\zeta} \sqrt{\Phi}\, qq''\, d\zeta, \tag{40}$$

$$\eta_4 = -\frac{1}{\Phi_0'} + \frac{\sqrt{\Phi}}{2\Phi_0'}\int_0^{\zeta} \frac{\Phi_0' - \Phi}{\Phi\sqrt{\Phi}}\, d\zeta, \tag{41}$$

$$\eta_5 = -\frac{k}{4} H_0 + \frac{k}{8}\sqrt{\Phi}\int_0^{\zeta} \frac{\Phi_0' H - \Phi' H_0}{\Phi\sqrt{\Phi}}\, d\zeta. \tag{42}$$

The quantities η_1-η_5 are finite everywhere together with their first derivatives. This ensures second-order smallness of the functions η and η' according to Eq. (37).

Substituting Eqs. (35) and (37) into Eq. (22), on the basis of Eqs. (20) and (26) we obtain an equation for χ, a solution of which will be sought in the form

$$\chi = a^2\bar{a}\chi_1 + a^2\bar{b}\chi_2 + a\bar{a}b\chi_3 + \bar{a}a^2\chi_4 + ab\bar{b}\chi_5 + b^2\bar{b}\chi_6 + \varphi_H(a\chi_7 + b\chi_8). \tag{43}$$

In this case, Eq. (20) breaks down into a series of equations

$$\Phi\chi_j'' + \frac{1}{2}\Phi'\chi_j' + \frac{1}{4} Q_2 \chi_j = F_{nj}^{(3)}, \quad (j = 1, 2, \ldots, 8), \tag{44}$$

where

$$F_{n1}^{(3)} = \frac{Q_4}{32} p^3 - \frac{Q_2'}{4}\eta_1 p, \tag{45}$$

$$F_{n2}^{(3)} = \frac{Q_4}{32} p^2 g - \frac{Q_2'}{4}(\eta_2 - i\eta_5)\, p + \frac{ik}{32}\Phi_0' H'' p, \tag{46}$$

$$F_{n3}^{(3)} = \frac{Q_4}{16} p^2 g - \frac{Q_2'}{4}[(\eta_2 + i\eta_5)\, p + \eta_1 g] - \frac{ik}{32}\Phi_0' H'' p, \tag{47}$$

$$F_{n4}^{(3)} = \frac{Q_4}{32} pg^2 - \frac{Q_2'}{4}\Big[(\eta_2 + i\eta_5)\, g - \frac{ik}{32}\Phi_0' H'' g, \tag{48}$$

$$F_{n5}^{(3)} = \frac{Q_4}{16} pg^2 - \frac{Q_2'}{4}[(\eta_2 - i\eta_5)\, g + \eta_3 p] + \frac{ik}{32}\Phi_0' H'' g, \tag{49}$$

$$F_{n6}^{(3)} = \frac{Q_4}{32} g^3 - \frac{Q_2'}{4}\eta_3 g, \tag{50}$$

$$F^{(3)}_{n7} = -\frac{Q_2'}{4}\eta_4 p, \tag{51}$$

$$F^{(3)}_{n8} = -\frac{Q_2'}{4}\eta_4 g. \tag{52}$$

Solving Eq. (44) we find

$$\chi_j = -\frac{2}{\Phi_0'}\left\{p\int_0^{\zeta}\frac{F^{(3)}_{nj}}{\sqrt{\Phi}}g\,d\zeta - g\int_0^{\zeta}\frac{F^{(3)}_{nj}}{\sqrt{\Phi}}p\,d\zeta\right\} \quad (j = 1, 2, \ldots, 8). \tag{53}$$

Equations (26), (35), and (43) together with Eq. (53) determine the quantity u as a function of ζ. In order to determine r and ψ as functions of ζ on the basis of these equations, it is necessary to eliminate the time t from Eq. (6). Using the relations (10) and (17) and eliminating unnecessary terms, we write

$$\varkappa = \phi - \theta - \varkappa_1, \tag{54}$$

where

$$\Theta = \frac{ik}{2}\int_0^{\zeta}\frac{H}{\sqrt{\Phi}}\,d\zeta, \tag{55}$$

$$\varkappa_1 = \frac{k}{2}\int_0^{\zeta}\left(H'\eta - \frac{H''}{8}u\bar{u}\right)\frac{d\zeta}{\sqrt{\Phi}}. \tag{56}$$

The constant of integration in Eq. (54) is set equal to zero, which does not limit the generality of the discussion because of the arbitrariness of *a* and b.

From Eq. (5) we have

$$u = re^{i(\psi - \Theta - \varkappa_1)} = U + \chi, \tag{57}$$

whence

$$re^{i(\psi - \Theta)} = U + \chi + i\varkappa_1 U. \tag{58}$$

We transform Eq. (56) by subtituting U and η into it. From Eqs. (35) and (37) we have

$$\varkappa_1 = a\bar{a}\varkappa_{11} + a\bar{b}(\varkappa_{12} - i\varkappa_{15}) + \bar{a}b(\varkappa_{12} + i\varkappa_{15}) + b\bar{b}\varkappa_{13} + \varphi_1\varkappa_{14}. \tag{59}$$

Here

$$\varkappa_{11} = \frac{k}{2}\int_0^{\zeta}\left(H'\eta_1 - \frac{H''}{8}p^2\right)\frac{d\zeta}{\sqrt{\Phi}}, \tag{60}$$

$$\varkappa_{12} = \frac{k}{2}\int_0^{\zeta}\left(H'\eta_2 - \frac{H''}{8}pg\right)\frac{d\zeta}{\sqrt{\Phi}}, \tag{61}$$

$$\varkappa_{13} = \frac{k}{2}\int_0^{\zeta}\left(H'\eta_3 - \frac{H''}{8}g^2\right)\frac{d\zeta}{\sqrt{\Phi}}. \tag{62}$$

$$\varkappa_{14} = \frac{k}{2}\int_0^{\zeta}H'\eta_4\frac{d\zeta}{\sqrt{\Phi}}, \tag{63}$$

$$\varkappa_{15} = \frac{k}{2}\int_0^{\zeta}H'\eta_5\frac{d\zeta}{\sqrt{\Phi}}. \tag{64}$$

Using Eqs. (35), (37), (43), and (59), we write in parametric form the equations for the trajectory of a charged particle in the field of a composite cathode lens

$$\begin{aligned} re^{i(\psi - \Theta)} = {} & ap(\zeta) + bg(\zeta) + a^2\bar{a}[\chi_1(\zeta) + i\varkappa_{11}(\zeta)p(\zeta)] \\ & + a^2\bar{b}\{\chi_2(\zeta) + i[\varkappa_{12}(\zeta) - i\varkappa_{15}(\zeta)]p(\zeta)\} \\ & + a\bar{a}b\{\chi_3(\zeta) + i[\varkappa_{12}(\zeta) + i\varkappa_{15}(\zeta)]p(\zeta) + i\varkappa_{11}(\zeta)g(\zeta)\} \\ & + \bar{a}b^2\{\chi_4(\zeta) + i[\varkappa_{12}(\zeta) + i\varkappa_{15}(\zeta)]g(\zeta)\} \\ & + ab\bar{b}\{\chi_5(\zeta) + i[\varkappa_{12}(\zeta) - i\varkappa_{15}(\zeta)]g(\zeta) + i\varkappa_{13}(\zeta)p(\zeta)\} \\ & + b^2\bar{b}[\chi_6(\zeta) + i\varkappa_{13}(\zeta)g(\zeta)] + a\varphi_1[\chi_7(\zeta) + i\varkappa_{14}(\zeta)p(\zeta)] \\ & + b\varphi_1[\chi_8(\zeta) + i\varkappa_{14}(\zeta)g(\zeta)], \end{aligned} \tag{65}$$

$$\begin{aligned} z = {} & \zeta + a\bar{a}\eta_1(\zeta) + a\bar{b}[\eta_2(\zeta) - i\eta_5(\zeta)] + \bar{a}b[\eta_2(\zeta) + i\eta_5(\zeta)] \\ & + b\bar{b}\eta_3(\zeta) + \varphi_1\eta_4(\zeta). \end{aligned} \tag{66}$$

We determine the arbitrary constants *a* and b on the basis of the initial conditions at the cathode surface. We first determine the value $\zeta = \zeta_0$ at the point of particle emission. At this point,

$$\dot{z}_0^2 = -\frac{2e}{m}\varphi_1\cos^2\vartheta_0, \tag{67}$$

where ϑ_0 is the angle between the initial velocity of the emerging particle and the z axis. On the other hand, we have on the basis of Eqs. (10) and (11)

$$\dot{z}_0 = \left(\dot{\zeta}\frac{dz}{d\zeta}\right)_{\zeta = \zeta_0} = [1 + \eta'(\zeta_0)]\sqrt{-\frac{2e}{m}\Phi(\zeta_0)}. \tag{68}$$

On the basis of the last two equations we write

$$\Phi(\zeta_0) = \frac{\varphi_1\cos^2\vartheta_0}{[1 + \eta'(\zeta_0)]^2}, \tag{69}$$

whence it follows that to third order

$$\zeta_0 = \frac{\varphi_1}{\Phi_0'}\cos^2\vartheta_0. \tag{70}$$

The direction of particle emission from the cathode is characterized by the two angles γ_0 and ω_0. When $\psi_0 = 0$, γ_0 is the angle between the initial velocity of the particle and the normal to the surface of the cathode at the emission point. These directions define a plane; the angle of this plane with respect to the plane $\psi = 0$ is designated by ω_0. Using the notation introduced for the angle we write

$$\cos\vartheta_0 = \cos\gamma_0 - \frac{r_0}{R}\cos\omega_0\sin\gamma_0. \tag{71}$$

In our approximation the angle between the normal and the z axis is r_0/R. At the point of particle emission, Eq. (65) is

$$r_0e^{-i\Theta(\zeta_0)} = ap(\zeta_0) + bg(\zeta_0) + \chi(\zeta_0) + i\varkappa_1(\zeta_0)[ap(\zeta_0) + bg(\zeta_0)]. \tag{72}$$

Differentiation of Eq. (65) with respect to time yields for the same point

$$\begin{aligned} & \left[\dot{r}_0 + ir_0\dot{\psi}_0 - ir_0\theta'(\zeta_0)\sqrt{-\frac{2e}{m}\Phi(\zeta_0)}\right]e^{-i\Theta(\zeta_0)} \\ & = \{ap'(\zeta_0) + bg'(\zeta_0) + \chi'(\zeta_0) + i[ap'(\zeta_0) + bg'(\zeta_0)]\varkappa_1(\zeta_0) \\ & \quad + i[ap(\zeta_0) + bg(\zeta_0)]\varkappa_1'(\zeta_0)\}\sqrt{-\frac{2e}{m}\Phi(\zeta_0)}. \end{aligned} \tag{73}$$

Equations (72) and (73) must be solved with respect to the constants *a* and b. This solution must be carried out to third-order. For convenience in calculation we convert these equations to the forms

$$a=\frac{1}{p(\zeta_0)}[r_0e^{i-\Theta(\zeta_0)}-bg(\zeta_0)], \tag{74}$$

$$b=\frac{2\sqrt{\Phi(\zeta_0)}}{\Phi_0'}\left\{\left[\frac{\dot{r}_0+ir_0\dot{\psi}_0}{\sqrt{-\frac{2e}{m}\Phi(\zeta_0)}}-ir_0\theta'(\zeta_0)\right]p(\zeta_0)\cdot\right.$$
$$\left.-r_0p'(\zeta_0)\right\}e^{-i\Theta(\zeta_0)}-\frac{i2a}{\Phi_0'}\varkappa_1'(\zeta_0)\sqrt{\Phi(\zeta_0)}. \tag{75}$$

Here, Eq. (34) is used. The quantities $\dot{r}_0$ and $r_0\dot{\psi}$ appearing in the last equation can be expressed in terms of the initial energy of the particle

$$\dot{r}_0=\sqrt{-\frac{2e}{m}\varphi_1}\left(\sin\gamma_0\cos\omega_0+\frac{r_0}{R}\cos\gamma_0-\frac{r_0^2}{2R^2}\sin\gamma_0\cos\omega_0\right), \tag{76}$$

$$r_0\dot{\psi}=\sqrt{-\frac{2e}{m}\varphi_1}\,\sin\gamma_0\sin\omega_0. \tag{77}$$

The quantities $\Theta(\zeta_0)$ and $g(\zeta_0)$ in this approximation can be represented by

$$\Theta(\zeta_0)=\frac{k}{2}\int_0^{\zeta_0}\frac{H}{\sqrt{\Phi}}d\zeta=\frac{kH_0}{\Phi_0'}\sqrt{\varphi_1}\left(\cos\gamma_0-\frac{r_0}{R}\sin\gamma_0\cos\omega_0\right), \tag{78}$$

$$g(\zeta_0)=q(\zeta_0)\sqrt{\Phi(\zeta_0)}=\sqrt{\varphi_1}\left(\cos\gamma_0-\frac{r_0}{R}\sin\gamma_0\cos\omega_0\right). \tag{79}$$

Substituting Eqs. (70), (76)-(79) into Eqs. (74) and (75) and carrying out the expansion over small quantities, we find

$$a=r_0-\frac{\varphi_1}{\Phi_0'}e^{i\omega_0}\sin 2\gamma_0+r_0^3\left(\frac{k^4H_0^4}{4\Phi_0'^2}+\frac{k^2H_0^2}{4R\Phi_0'}\right)$$
$$+ir_0^2\left[\left(\frac{kH_0}{2R}+\frac{k^3H_0^3}{4\Phi_0'}\right)\bar{b}_1-\frac{k^3H_0^3}{2\Phi_0'}b_1\right]$$
$$+r_0\left[\left(\frac{\Phi_0'}{4R}-\frac{k^2H_0^2}{4}\right)b_1^2+\left(\frac{\Phi_0'}{2R}+\frac{k^2H_0^2}{2}\right)b_1\bar{b}_1\right]$$
$$-ib_1^2\bar{b}_1\frac{k}{4}H_0\Phi_0'-r_0\frac{\varphi_1}{\Phi_0'}\left(\frac{k^2H_0^2}{\Phi_0'}+\frac{1}{R}\right)+ib\varphi_1\frac{kH_0}{\Phi_0'}, \tag{80}$$

$$b=b_1-i\varphi_1k\frac{H_0}{\Phi_0'^2}e^{i\omega_0}\sin 2\gamma_0+ir_0^3\left(\frac{k^5H_0^5}{4\Phi_0'^3}+\frac{kH_0'}{2R\Phi_0'}+\frac{kH_0''}{8\Phi_0'}\right)$$
$$+r_0^2\left[\left(\frac{k^4H_0^4}{2\Phi_0'^2}-\frac{k^2H_0^2}{2R\Phi_0'}+\frac{1}{4R^2}\right)b_1+\left(\frac{1}{4R^2}-\frac{k^4H_0^4}{4\Phi_0'^2}-\frac{k^2H_0^2}{4R\Phi_0'}\right)\bar{b}_1\right]$$
$$+ir_0\left[\left(\frac{kH_0}{2R}-\frac{k^3H_0^3}{4\Phi_0'}\right)b_1^2+\frac{k^3H_0^3}{2\Phi_0'}b_1\bar{b}_1\right]+\left(k^2\frac{H_0^2}{4}-\frac{\Phi_0'}{4R}\right)b_1^2\bar{b}_1$$
$$-ir_0\varphi_H\frac{k^3H_0^3}{\Phi_0'^3}+b_1\frac{\varphi_1}{\Phi_0'}\left(\frac{1}{R}-\frac{k^2H_0^2}{\Phi_0'}\right), \tag{81}$$

where

$$b_1=\frac{2\sqrt{\varphi_1}}{\Phi_0'}e^{i\omega_0}\sin\gamma_0-ir_0\frac{kH_0}{\Phi_0'}. \tag{82}$$

Equations (65) and (66) are valid over the entire length of the trajectory, including the cathode region. Therefore these equations can be used to determine the constants a and b through the initial conditions at the cathode.

We now turn to the determination of the explicit dependence of r and ψ on z. Solving Eq. (66) by successive approximation and eliminating terms of order higher than third, we find

$$\zeta=z-\eta[z-\eta(\zeta)]=z-\eta(z). \tag{83}$$

Substituting Eq. (83) into Eq. (65) and expanding functions with argument $z-\eta(z)$ with respect to $\eta(z)$, we find

$$re^{i\Psi}=ap(z)+bg(z)+\chi(z)-\eta(z)[ap'(z)+bg'(z)]$$
$$+i[ap(z)+bg(z)]\left[\varkappa_1(z)-\frac{kH(z)\eta(z)}{2\sqrt{\Phi(z)}}\right], \tag{84}$$

where

$$\Psi=\psi-\frac{k}{2}\int_0^z\frac{H(z)}{\sqrt{\Phi(z)}}dz. \tag{85}$$

The functions p(z), g(z), η(z), χ(z), and $\varkappa_1$(z) in Eq. (84) were defined earlier as functions of ζ. Equation (84) determines the trajectory of a charged particle in a rotating coordinate system; the angle of rotation as a function of z is given by

$$\Theta(z)=\frac{k}{2}\int_0^z\frac{H(z)}{\sqrt{\Phi(z)}}dz. \tag{86}$$

Expansion of the functions $g[z-\eta(z)]$, $\theta[z-\eta(z)]$, and $\varkappa_1[z-\eta(z)]$ with respect to $\eta(z)$ will not be valid in the cathode region, where the derivatives of these functions increase without limit. Therefore Eqs. (84) and (85), which are determined with the help of the expansion, describe the trajectory at some distance from the cathode surface, i.e., in the region where the condition $\Phi(z)\gg\varphi_1$ is satisfied. Investigation of trajectories in this region is of greatest practical interest because it contains the position of the minimum beam cross section in electron guns and the image plane in emission electron microscopes. In view of the fact that the constants a and b are already determined by Eqs. (80) and (81), the simpler equation (84) can be used in a subsequent study of aberrations at sufficient separation from the cathode surface without recourse to analysis of Eqs. (65) and (66) which are valid everywhere, including the near-cathode region.

(Submitted August 10, 1973)
Zh. Tekh. Fiz., 44, 938-943 (May 1974)

Aberrations are classifed and aberration coefficients calculated for a composite cathode lens formed by superposition of axisymmetric electric and magnetic fields. All types of aberrations characteristic of ordinary electron lenses are present in a composite cathode lens. In addition, if the magnetic field at the cathode surface is nonzero four additional terms appear in the expression for the total aberration of the cathode lens.

This paper is a continuation of ref. 1. The same notation is used and the numbering of the equations is continued so that it is possible to refer to previously derived relations without indicating the source. We investigate aberrations at considerable separation from the cathode surface, making it possible to analyze trajectories on the basis of Eqs. (84) and (85), which determine the explicit dependence of the coordinates r and ψ on z. The functions of z appearing in Eq. (84) have been defined[1] as functions of the argument ζ. In subsequent use of equations given in ref. 1 it is necessary to take this situation into account by replacing the argument ζ by the coordinate z everywhere.

All functions appearing in subsequent expressions are given as functions of this coordinate and the primes indicate differentiation with respect to it.

In the analysis of aberrations it is necessary to represent Eq. (84) in the form of a sum, from which the dependence of the trajectory on the initial conditions r_0 and

$$b_1=\frac{2\sqrt{\varphi_1}}{\Phi_0'}e^{i\omega_0}\sin\gamma_0-ir_0\frac{kH_0}{\Phi_0'}$$

can be seen explicitly.

Substituting for the functions $\eta(z)$, $\chi(z)$, and $\varkappa_1(z)$ in Eq. (84) in accordance with Eqs. (37), (43), and (59) and the values of the constants a and b from Eqs. (80) and (81), after performing a number of complicated transformations we obtain

$$\begin{gathered}w(z)=re^{i\Psi}=r_0p(z)+b_1g(z)\\
-p(z)\frac{\varphi_1}{\Phi_0'}e^{i\omega_0}\sin 2\gamma_0-ig(z)\frac{kH_0}{\Phi_0'^2}\varphi_1e^{i\omega_0}\sin 2\gamma_0\\
+r_0^3[B_1(z)+ic_1(z)]+r_0^2\{[B_2(z)+ic_2(z)]\bar{b}_1+[B_3(z)+ic_3(z)]b_1\}\\
+r_0\{[B_4(z)+ic_4(z)]b_1^2+[B_5(z)+ic_5(z)]b_1\bar{b}_1\}\\
+[B_6(z)+ic_6(z)]b_1^2\bar{b}_1+\varphi_H\{[B_7(z)+ic_7(z)]r_0\\
+[B_8(z)+ic_8(z)]b_1\}.\end{gathered}\tag{87}$$

Here,

$$B_1(z)=p\left(\frac{1}{2R^2}-\frac{k^2H_0^2}{4R\Phi_0'}+\frac{3k^4H_0^4}{8\Phi_0'^2}-J_1\right)+gJ_2,\tag{88}$$

$$B_2(z)=p\left(\frac{k^2H_0H}{8\sqrt{\Phi}}-J_3\right)+g\left(J_1+\frac{1}{2}p'^2-\frac{1}{4R^2}+\frac{k^2H_0^2}{4R\Phi_0'}-\frac{3k^4H_0^4}{8\Phi_0'^2}\right),\tag{89}$$

$$\begin{gathered}B_3(z)=-p\left(\frac{k^2H_0H}{8\sqrt{\Phi}}+2J_4\right)+p'\frac{\Phi_0'}{4\sqrt{\Phi}}\\
+g\left(2J_1+\frac{3}{2}p'^2-\frac{3}{4R^2}+\frac{k^2H_0^2}{2R\Phi_0'}+\frac{k^4H_0^4}{4\Phi_0'^2}\right),\end{gathered}\tag{90}$$

$$B_4(z)=-p\left(\frac{k^3H_0^2}{8}+J_5\right)+g\left(J_3-k^2\frac{H_0H}{8\sqrt{\Phi}}+\frac{1}{2}p'g'\right),\tag{91}$$

$$B_5(z)=p\left(\frac{3}{4}k^3H_0^2-2J_5\right)+g\left(2J_4+\frac{1}{2}p'g'+k^2\frac{H_0H}{8\sqrt{\Phi}}\right),\tag{92}$$

$$\begin{gathered}B_6(z)=-pJ_6+g\Big[J_5+\frac{1}{2}g'^2-\frac{1}{2}gg'\frac{\Phi'}{\Phi}+\frac{k^2H_0^2}{8}\\
-\frac{\Phi'}{\Phi_0'\sqrt{\Phi}}p'g^2g'+\frac{Q_2}{\Phi}g^2\left(\frac{1}{8}-\frac{\Phi'}{4\Phi_0'\sqrt{\Phi}}pg\right)\Big],\end{gathered}\tag{93}$$

$$B_7(z)=p\left(J_7-\frac{3k^2H_0^2}{2\Phi_0'^2}\right)-gJ_8,\tag{94}$$

$$B_8(z)=pJ_9+g\left[\frac{\Phi'}{2\Phi_0'\Phi\sqrt{\Phi}}pg-\frac{p}{\Phi_0'}\frac{d}{dz}\left(\frac{g}{\sqrt{\Phi}}\right)+\frac{p'g}{\Phi_0'\sqrt{\Phi}}-\frac{k^2H_0^2}{2\Phi_0'^2}-J_7\right],\tag{95}$$

$$c_1(z)=p\left(\frac{kH}{4\sqrt{\Phi}}pp'-\mu_1\right)+g\left(\frac{kH_0'}{2R\Phi_0'}+\frac{kH_0''}{8\Phi_0'}+\frac{k^5H_0^5}{4\Phi_0'^3}\right),\tag{96}$$

$$c_2(z)=p\left(\frac{k^3H_0^3}{4\Phi_0'}+\frac{kH_0}{2R}-\mu_2\right)+g\left(\mu_1-\frac{kH}{4\sqrt{\Phi}}pp'\right),\tag{97}$$

$$c_3(z)=-p\frac{k^3H_0^3}{2\Phi_0'}+g\left(\frac{kH}{2\sqrt{\Phi}}pp'-2\mu_1\right),\tag{98}$$

$$\begin{gathered}C_4(z)=p\mu_3\\
+g\left\{p\frac{kH}{4}\left[\frac{\Phi'}{2\Phi\sqrt{\Phi}}g-\frac{d}{dz}\left(\frac{g}{\sqrt{\Phi}}\right)\right]+\frac{kH_0}{2R}-\frac{k^3H_0^3}{4\Phi_0'}-\mu_2\right\},\end{gathered}\tag{99}$$

$$C_5(z)=-2p\mu_3+g\left\{\frac{k^3H_0^3}{2\Phi_0'}-p\frac{kH}{2}\left[\frac{\Phi'}{2\Phi\sqrt{\Phi}}g-\frac{d}{dz}\left(\frac{g}{\sqrt{\Phi}}\right)\right]\right\},\tag{100}$$

$$c_6(z)=-pkH_0\frac{\Phi_0'}{4}-g\left\{\frac{kH}{4}\left[\frac{\Phi'}{2\Phi\sqrt{\Phi}}g^2-g\frac{d}{dz}\left(\frac{g}{\sqrt{\Phi}}\right)\right]+\mu_3\right\},\tag{101}$$

$$c_7(z)=p\left(\frac{kH}{2\Phi_0'\sqrt{\Phi}}-\mu_4\right)-g\frac{k^3H_0^3}{\Phi_0'^3},\tag{102}$$

$$c_8(z)=p\frac{kH_0}{\Phi_0'}+g\left(\frac{kH}{2\Phi_0'\sqrt{\Phi}}-\mu_4\right).\tag{103}$$

The integrals J_1-J_9 and μ_1-μ_4 in the equations above have the form

$$J_1=\frac{1}{16\Phi_0'}\int_0^z\frac{g}{\sqrt{\Phi}}[p^2(Q_4p+4Q_2'p')+8p''(4\Phi p'^2+Q_2p^2)]\,dz,\tag{104}$$

$$J_2=\frac{1}{16\Phi_0'}\int_0^z\frac{p}{\sqrt{\Phi}}[p^2(Q_4p+4Q_2'p')+8p''(4\Phi p'^2+Q_2p^2)]\,dz,\tag{105}$$

$$\begin{gathered}J_3=\frac{1}{16\Phi_0'}\int_0^z\frac{1}{\sqrt{\Phi}}\Big[pg^2(Q_4p+4Q_2'p')+8p''g(4\Phi p'g'+Q_2pg)\\
+k^2\Phi_0'\left(2H_0H'+H\frac{\Phi_0'H-\Phi'H_0}{\Phi}\right)\Big]dz,\end{gathered}\tag{106}$$

$$\begin{gathered}J_4=\frac{1}{16\Phi_0'}\int_0^z\frac{1}{\sqrt{\Phi}}\Big[pg^2(Q_4p+4Q_2'p')+4p''g(4\Phi p'g'+Q_2pg)\\
+4pp''(4\Phi g'^2+Q_2g^2)-k^2\Phi_0'\left(H_0H'+H\frac{\Phi_0'H-\Phi'H_0}{2\Phi}\right)\Big]dz,\end{gathered}\tag{107}$$

$$J_5=\frac{1}{16\Phi_0'}\int_0^z\frac{g}{\sqrt{\Phi}}[g^2(Q_4p+4Q_2'p')+8p''(4\Phi g'^2+Q_2g^2)]\,dz,\tag{108}$$

$$\begin{gathered}J_6=\frac{1}{16\Phi_0'}\int_0^z g\Big[\frac{g^2}{\sqrt{\Phi}}\left(Q_4g-4\frac{\Phi'}{\Phi}Q_2'g+4Q_2'g'\right)\\
+8(4\Phi g'^2+Q_2g^2)\frac{d^2}{dz^2}\left(\frac{g}{\sqrt{\Phi}}\right)\Big]dz,\end{gathered}\tag{109}$$

$$J_7=\frac{2}{\Phi_0'}\int_0^z p''\frac{g}{\sqrt{\Phi}}dz, \tag{110}$$

$$J_8=\frac{2}{\Phi_0'}\int_0^z \frac{pp''}{\sqrt{\Phi}}dz, \tag{111}$$

$$J_9=\frac{2}{\Phi_0'}\int_0^z g\left[\frac{d^2}{dz^2}\left(\frac{g}{\sqrt{\Phi}}\right)\right]dz, \tag{112}$$

$$\mu_1=\frac{k}{2}\int_0^z\left(\frac{H''}{8}p^2+\frac{H'}{2}pp'+Hpp''\right)\frac{dz}{\sqrt{\Phi}}, \tag{113}$$

$$\mu_2=k\int_0^z\left[\frac{H''}{8\sqrt{\Phi}}pg+\frac{H}{2\sqrt{\Phi}}p''g-Hp'\frac{d}{dz}\left(\frac{g}{2\sqrt{\Phi}}\right)\right]dz, \tag{114}$$

$$\mu_3=\frac{k}{2}\int_0^z\left[\frac{H''}{8\sqrt{\Phi}}g^2-\frac{H'\Phi'}{4\Phi\sqrt{\Phi}}g^2\right.$$
$$\left.+H'g\frac{d}{dz}\left(\frac{g}{2\sqrt{\Phi}}\right)+Hg\frac{d^2}{dz^2}\left(\frac{g}{\sqrt{\Phi}}\right)\right]dz, \tag{115}$$

$$\mu_4=\frac{k}{2\Phi_0'}\int_0^z\left[H'+H\left(\frac{\Phi_0'-\Phi'}{2\Phi}\right)\right]\frac{dz}{\sqrt{\Phi}}. \tag{116}$$

These integrals assume constant values if the upper limit of integration falls outside the field of the lens. Double integrals obtained in the transformations are reduced to single integrals by integration by parts and use of the following relations:

$$\frac{d}{dz}(4\Phi p'^2+Q_2p^2)=Q_2'p^2, \tag{117}$$

$$\frac{d}{dz}(4\Phi p'g'+Q_2pg)=Q_2'pg, \tag{118}$$

$$\frac{d}{dz}(4\Phi g'^2+Q_2g^2)=Q_2'g^2. \tag{119}$$

We first consider paraxial trajectories, which are limited to terms of first order relative to r. In this approximation, the equation for a trajectory is

$$W(z)=re^{i\Psi}=r_0p+\left(\frac{2\sqrt{\varphi_1}}{\Phi_0'}e^{i\omega_0}\sin\gamma_0-ir_0\frac{kH_0}{\Phi_0'}\right)g. \tag{120}$$

We consider the plane z = 0 (tangent to the cathode surface) as the object plane. According to the definition (28), g(0) = 0 in this plane since the potential at the cathode surface is assumed to be zero.

The image plane $z = z_b$ will be determined by the relation $g(z_b) = 0$. As is obvious from Eq. (120), a true image of the cathode surface is obtained in this plane.

In accordance with Eq. (85), the presence of a magnetic field gives rise to a rotation of this image by an angle

$$\Theta_b=\frac{k}{2}\int_0^{z_b}\frac{H}{\sqrt{\Phi}}dz. \tag{121}$$

In this approximation, the variation of initial energy φ_1 of emerging particles from zero to a maximum value and also the variation in the emergence angles γ_0 and ω_0 from zero to $\pi/2$ cause neither distortion nor smearing of the image. Since p(0) = 1 from Eq. (30), the lateral magnification of the system is

$$M=p(z_b). \tag{122}$$

In an electrostatic cathode lens, there is considerable interest in the determination of the size of the beam cross section in the crossover plane $z = z_k$, where z_k satisfies the equation $p(z_k) = 0$.

In this plane, the area of the beam cross section is independent of the cathode dimensions and can be made considerably smaller than the area of the latter.

With a magnetic field the analogous situation will occur only when the magnetic field is $H_0 = 0$ at the cathode surface, as can be seen from Eq. (120).

If $H_0 \neq 0$, the distance from the axis at which a charged particle crosses the plane $z = z_k$ is

$$r_k^{(1)}=\frac{g(z_k)}{\Phi_0'}\sqrt{4\varphi_H\sin^2\gamma_0+r_0^2k^2H_0^2-4r_0\sqrt{\varphi_H}kH_0\sin\omega_0\sin\gamma_0}. \tag{123}$$

Aberrations of a cathode lens in the image plane are determined by

$$\Delta w=\Delta w^{(2)}+\Delta w^{(3)}, \tag{124}$$

where aberrations of the second order are

$$\Delta w^{(2)}=-M\frac{\varphi_H}{\Phi_0'}e^{i\omega_0}\sin 2\gamma_0, \tag{125}$$

and aberrations of the third order are

$$\begin{aligned}\Delta w^{(3)}=&\,r_0^3[B_1(z_b)+ic_1(z_b)]+r_0^2\{[B_2(z_b)\\&+ic_2(z_b)]\bar{b}_1+[B_3(z_b)+ic_3(z_b)]b_1\}\\&+r_0\{[B_4(z_b)+ic_4(z_b)]b_1^2+[B_5(z_b)\\&+ic_5(z_b)]b_1\bar{b}_1\}+[B_6(z_b)+ic_6(z_b)]b_1^2\bar{b}_1\\&+\varphi_H\{[B_7(z_b)+ic_7(z_b)]r_0+[B_8(z_b)+ic_8(z_b)]\bar{b}_1\}.\end{aligned} \tag{126}$$

Here,

$$\left.\begin{aligned}B_1(z_b)&=M\left[\frac{1}{2R^2}-\frac{k^2H_0^2}{4R\Phi_0'}+\frac{3k^4H_0^4}{8\Phi_0'^2}-J_1(z_b)\right],\\B_2(z_b)&=M\left[k^2\frac{H_0H_b}{8\sqrt{\Phi_b}}-J_3(z_b)\right],\\B_3(z_b)&=p_b'\frac{\Phi_0'}{4\sqrt{\Phi_b}}-M\left[k^2\frac{H_0H_b}{8\sqrt{\Phi_b}}+2J_4(z_b)\right],\\B_4(z_b)&=-M\left[\frac{k^2H_0^2}{8}+J_5(z_b)\right],\\B_5(z_b)&=M\left[\frac{3}{4}k^2H_0^2-2J_5(z_b)\right],\\B_6(z_b)&=-MJ_b(z_b),\\B_7(z_b)&=M\left[J_7(z_b)-\frac{3k^2H_0^2}{2\Phi_0'^2}\right],\\B_8(z_b)&=MJ_9(z_b),\end{aligned}\right\} \tag{127}$$

$$\left.\begin{aligned}c_1(z_b)&=M\left[\frac{kH_b}{4\sqrt{\Phi_b}}Mp_b'-\mu_1(z_b)\right],\\c_2(z_b)&=M\left[\frac{k^3H_0^3}{4\Phi_0'}+\frac{kH_0}{2R}-\mu_2(z_b)\right],\quad c_3(z_b)=-M\frac{k^3H_0^3}{2\Phi_0'},\\2c_4(z_b)&=-c_5(z_b)=2M\mu_3(z_b),\quad c_6(z_b)=-MkH_0\frac{\Phi_0'}{4},\\c_7(z_b)&=M\left[\frac{kH_b}{2\Phi_0'\sqrt{\Phi_b}}-\mu_4(z_b)\right],\quad c_8(z_b)=M\frac{kH_0}{\Phi_0'}.\end{aligned}\right\} \tag{128}$$

We obtain the radius of the circle of confusion resulting from the presence of aberrations of second order by setting $\gamma_0 = 45°$ in Eq. (125),

$$\Delta r^{(2)}=\frac{M\varphi_H}{\Phi_0'}. \tag{129}$$

It is then clear that the size of the circle of confusion referred to the object plane is independent of the existence of a magnetic field.

The quantity $\Delta w^{(3)}$ represents the total aberration of third order of a beam not defined by a diaphragm. We introduce a defining diaphragm in the plane $z = z_d$. In accordance with Eq. (120), we shall have in this plane

$$b_1 = \frac{W_d - r_0 p_d}{g_d}. \tag{130}$$

The subscript d denotes values of quantities in the plane of the diaphragm. We substitute the value of b_1 expressed in this manner in Eq. (126), and having grouped terms of the sum in the appropriate manner, we find

$$\begin{aligned}\Delta W_d^{(3)} = {}& (B + ib_m) W_d^2 \bar{W}_d + r_0 \{(F - if) W_d^2 + [2F + F_m \\ & + i(2f + f_m)] W_d \bar{W}_d\} + r_0^2 [(C + D + id_m) W_d + (C + ic) \bar{W}_d] \\ & + r_0^3 (E + ie) + \varphi_H [(G + ig_m) W_d + (J + ij) r_0],\end{aligned} \tag{131}$$

where

$$B = -\frac{M}{g_d^3} J_6(z_b), \tag{132}$$

$$F = \frac{M}{g_d^2}\left[J_6(z_b)\frac{p_d}{g_d} - J_5(z_b) - \frac{k^2 H_0^2}{8}\right], \tag{133}$$

$$\begin{aligned}C = \frac{M}{g_d}\Big\{& k^2 \frac{H_0 H_b}{8\sqrt{\Phi_b}} - J_3(z_b) \\ & + \left[2J_5(z_b) - \frac{3}{4}k^2 H_0^2\right]\frac{p_d}{g_d} - J_6(z_b)\frac{p_d^2}{g_d^2}\Big\},\end{aligned} \tag{134}$$

$$\begin{aligned}D = \frac{M}{g_d}\Big\{& J_3(z_b) - 2J_4(z_b) - \frac{k^2 H_0 H_b}{4\sqrt{\Phi_b}} \\ & + \left[2J_5(z_b) + \frac{k^2 H_0^2}{4}\right]\frac{p_d}{g_d} - J_6(z_b)\frac{p_d^2}{g_d^2}\Big\} + \frac{p_b' \Phi_0'}{4 g_d \sqrt{\Phi_b}},\end{aligned} \tag{135}$$

$$\begin{aligned}E = M\Big\{& \frac{1}{2R^2} - \frac{k^2 H_0^2}{4R\Phi_0'} + \frac{3k^4 H_0^4}{8\Phi_0'^2} - J_1(z_b) + [J_3(z_b) + 2J_4(z_b)]\frac{p_d}{g_d} \\ & + \left[\frac{5}{8}k^2 H_0^2 - 3J_5(z_b)\right]\frac{p_d^2}{g_d^2} + J_6(z_b)\frac{p_d^3}{g_d^3}\Big\} - p_b' \frac{\Phi_0'}{4\sqrt{\Phi_b}}\frac{p_d}{g_d},\end{aligned} \tag{136}$$

$$f = -\frac{M}{g_d^2}\left[\mu_3(z_b) + kH_0\Phi_0'\frac{p_d}{4g_d}\right], \tag{137}$$

$$c = \frac{M}{g_d}\left\{\frac{k^3 H_0^3}{4\Phi_0'} + \frac{kH_0}{2R} - \mu_2(z_b) + 2\mu_3(z_b)\frac{p_d}{g_d} - kH_0\Phi_0'\frac{p_d^2}{4g_d^2}\right\}, \tag{138}$$

$$\begin{aligned}e = M\Big\{& Mp_b' \frac{kH_b}{4\sqrt{\Phi_b}} - \mu_1(z_b) + \left[\mu_2(z_b) - \frac{kH_0}{2R} + \frac{k^3 H_0^3}{4\Phi_0'}\right]\frac{p_d}{g_d} \\ & - \mu_3(z_b)\frac{p_d^2}{g_d^2} + kH_0\Phi_0\frac{p_d^3}{4g_d^3}\Big\},\end{aligned} \tag{139}$$

$$G = \frac{M}{g_d} J_g(z_b), \tag{140}$$

$$J = M\left[J_7(z_b) - \frac{3}{2}\frac{k^2 H_0^2}{\Phi_0'^2} - J_9(z_b)\frac{p_d}{g_d}\right], \tag{141}$$

$$j = M\left[\frac{kH_b}{2\Phi_0'\sqrt{\Phi_b}} - \mu_4(z_b) - \frac{kH_0}{\Phi_0'}\frac{p_d}{g_d}\right], \tag{142}$$

$$F_m = \frac{M}{g_d^2} k^2 H_0^2, \tag{143}$$

$$b_m = -\frac{M}{4g_d^3} kH_0\Phi_0', \tag{144}$$

$$f_m = MkH_0\Phi_0'\frac{p_d}{g_d^3}, \tag{145}$$

$$d_m = -\frac{M}{g_d}\left(\frac{k^3 H_0^3}{2\Phi_0'} + kH_0\Phi_0'\frac{p_d^2}{2g_d^2}\right), \tag{146}$$

$$g_m = M\frac{kH_0}{\Phi_0' g_d}. \tag{147}$$

Geometric aberrations are determined by the coefficients B, F, C, D, E, *f*, c, and e: spherical aberration, coma, astigmatism, curvature of image field, distortion, anisotropic coma, anisotropic astigmatism, and anisotropic distortion, respectively, which are also characteristic of ordinary electron lenses.[2] The coefficient G determines aperture chromatic aberration, and J and j, the variations in magnification and angular rotation of the image, respectively, which are associated with particles leaving the cathode with some energy.

Similar forms of chromatic aberration appear in ordinary lenses. The remaining four terms involving geometric aberrations, F_m, b_m, f_m, and d_m, and the one form of chromatic aberration, g_m, are not encountered in ordinary lenses. Furthermore, they are not found in composite cathode lenses if there is no magnetic field at the cathode surface ($H_0 = 0$).

Variational analysis of thermal breakdown of a semiconductor irradiated by light

V. L. Komolov

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad
(Submitted September 25, 1973)
Zh. Tekh. Fiz., 44, 944-949 (May 1974)

A variational method is given for solving problems involving the thermal breakdown of a semiconductor caused by light. Solutions are found for two simple one-dimensional problems; a disk of finite dimensions illuminated by a light beam with a Gaussian intensity distribution and boundary conditions of the third kind is also treated.

1. In this work we present a variational approach for solving problems involved in the thermal instability of a semiconductor irradiated by light. A mechanism leading to such an instability was proposed by Épshtein,[1] who also calculated the instability threshold for a long cylinder whose lateral surface is at a fixed temperature. Volod'kina and Komolov[2] solved two simple thermal-breakdown problems, using more general heat-transfer conditions at the boundary of a semiconductor; it turns out that the reasonable assumption of heat transfer due to air convection at the surface of the sample leads to a significant discrepancy with the threshold calculated in ref. 1.

Exact solutions can be found for the thermal-breakdown problem only for one-dimensional cases (infinite plate, long cylinder, sphere), but the problems of most practical interest are those involved in the design of the optical elements of CO_2 lasers (exit windows, filters, etc.), in which case it is necessary to deal with three-dimensional regions (which, however, show axial symmetry in the light-propagation direction). In certain cases it is also important to take account of the intensity distribution in the light beam. As shown below, all these features can be easily incorporated in a variational approach to the solution of the thermal-breakdown problem. Furthermore, the variational approach can also be used to solve idealized one-dimensional problems like those of refs. 1 and 2 since it yields results in a simple form – an important consideration for numerical calculations.

2. The threshold for the thermal breakdown of a semiconductor is defined as the light intensity above which there is no steady-state solution of the heat-conduction equation:

$$\lambda\nabla^2 T+\varkappa(T)\,q(r_\perp)=0 \qquad (1)$$

in region D for the specified heat-transfer conditions at boundary B. [Here λ is the thermal conductivity, $\varkappa(T)$ is the absorptivity, and $q(r_\perp)$ is the intensity profile of the light beam.] In the calculations below we use boundary conditions of the third kind:

$$\left[\lambda\frac{dT}{dn}+H(T-T_0)\right]_B=0, \qquad (2)$$

where n is the direction normal to the surface, H is the heat transfer coefficient, and T_0 is the temperature of the surrounding medium.

The stability conditions for the solutions of boundary-value problem (1), (2) can be obtained from a variational principle for the functional I, for which Eq. (1) is an Euler equation. It is necessary to choose trial functions satisfying boundary condition (2). A similar method has been used[3] to calculate the thresholds for the thermal explosion of a gas in which an exothermic chemical reaction occurs. An important feature of the semiconductor breakdown problem is the use of boundary conditions of the third kind. The boundary conditions must be written in the form of (2) because the surface of the semiconductor is ordinarily in contact with a gas (air or CO_2) whose thermal conductivity and heat capacity are much lower than those of the semiconductor; thus, the boundary temperature cannot be assumed to be constant, as in the case of the thermal explosion in an exothermic reaction; in this latter case, the gas, which conducts heat poorly, is enclosed in a massive metal vessel, which is a good thermal regulator. When boundary condition (2) is used it is necessary to seek a solution of the variational problem among functions which do not vanish at the boundary; accordingly, the form of the functional I would be different from that in ref. 3.

In analyzing the thermal breakdown of a semiconductor we assume that the light absorption is due to conduction electrons and is described as a function of the temperature by

$$\varkappa(T)=\varkappa_0\exp\left\{-\frac{E_g}{2kT}\right\}. \qquad (3)$$

This absorption relation leads to serious difficulties in the calculations; these can be avoided by approximating (3) by the power function

$$\left.\begin{aligned}\varkappa(T)&\approx\varkappa_0 e^{-\frac{E_g}{2kT_0}}(1+0.72\Theta+\Theta^2),\\ \Theta&=\frac{(T-T_0)E_g}{2kT_0^2},\end{aligned}\right\} \qquad (4)$$

which, according to ref. 4, is a good approximation over the interval $0\le\Theta\le 2.5$. It follows from the results of refs. 1 and 2 that Θ usually falls in this interval anywhere below the instability threshold.

Below we present the solutions for a plate and for a long cylinder as found by the variational method; we also present the solution of the problem of thermal breakdown of a cylinder of finite length irradiated by a light beam with a Gaussian intensity distribution.

3. In the case of an unbounded flat plate of thickness $2l$ Eqs. (1) and (2) become

$$\left.\begin{aligned}&\frac{d^2\Theta}{dz^2}+\mu(1+0.72\Theta+\Theta^2)=0,\\ &\left[\pm\frac{d\Theta}{dz}+\beta\Theta\right]_{z=\pm1}=0,\end{aligned}\right\} \qquad (5)$$

where $z = x/l$; $q(r_\perp) \equiv q_0$, $\beta = Hl/\lambda$, and $\mu = [\varkappa(T_0)q(r_\perp)]\cdot[\lambda(E_g l^2)/(2kT_0^2)]^{-1}$.

The functional I corresponding to this equation is

$$I=\frac{1}{\beta}\left(\frac{d\Theta}{dz}\right)^2\Big|_{z=1}+\int_0^1\left[\left(\frac{d\Theta}{dz}\right)^2-2\mu\left(\Theta+0.36\Theta^2+0.33\Theta^3\right)\right]dz. \quad (6)$$

Choosing the simplest trial function which satisfies the boundary condition

$$\Theta=C\left(1+\frac{2}{\beta}-z^2\right), \quad (7)$$

where C is an adjustable parameter, and substituting in (6), we find

$$I=2aC^2-2\mu\left(aC+bC^2+pC^3\right). \quad (8)$$

Here

$$\left.\begin{aligned}a&=2\left(\frac{1}{\beta}+\frac{1}{3}\right),\\ b&=0.72\left[\frac{1}{2}\left(1+\frac{2}{\beta}\right)^2-\frac{1}{3}\left(1+\frac{2}{\beta}\right)+\frac{1}{10}\right],\\ p&=\left[\frac{1}{3}\left(1+\frac{2}{\beta}\right)^3-\frac{1}{3}\left(1+\frac{2}{\beta}\right)^2+\frac{1}{5}\left(1+\frac{2}{\beta}\right)-\frac{1}{21}\right].\end{aligned}\right\} \quad (9)$$

The condition that the variation vanish,

$$\delta I=\frac{dI}{dC}=4aC-2\mu\left(a+2bC+3pC^2\right)=0, \quad (10)$$

leads to a quadratic equation in C which has real roots only when $\mu < \mu_{cr}$, where the dimensionless threshold for thermal breakdown is

$$\mu_{cr}=\frac{a}{b+\sqrt{3ap}}. \quad (11)$$

The maximum temperature in the steady state, which corresponds to (11), is

$$\Theta_{max}=\sqrt{\frac{a}{3p}}\left(1+\frac{2}{\beta}-z^2\right). \quad (7a)$$

For small values of β we find $\mu_{cr} \approx \beta/2.72$ from Eqs. (9) and (11); in the opposite limiting case, $\beta=\infty$, we find $\mu_{cr} \approx 0.89$. Both these results agree with those found through an exact solution of the problem.[2]

As another example of the application of this variational procedure we consider a long cylinder; in this case we can take account of the effect of the generating surface alone and can neglect heat transfer at the ends of the cylinder. In this case the breakdown is described by

$$\left.\begin{aligned}&\frac{d^2\Theta}{dz^2}+\frac{1}{z}\frac{d\Theta}{dz}+\mu\left(1+0.72\Theta+\Theta^2\right)=0,\\ &\left[\pm\frac{d\Theta}{dz}+\beta\Theta\right]_{z=\pm1}=0,\end{aligned}\right\} \quad (12)$$

where the notation is the same as that of (5), except that l is the radius of the cylinder. The functional for (12) is

$$I=\frac{1}{\beta}\left(\frac{d\Theta}{dz}\right)^2\Big|_{z=1}+\int_0^1 z\,dz\left[\left(\frac{d\Theta}{dz}\right)^2-2\mu\left(\Theta+0.36\Theta^2+0.33\Theta^3\right)\right]; \quad (13)$$

substituting trial function (7) we find an equation like (11) for μ_{cr}:

$$\mu^0_{cr}=\frac{2a_0}{b_0+\sqrt{3a_0p_0}}, \quad (14)$$

where

$$\left.\begin{aligned}a_0&=\frac{1}{\beta}+\frac{1}{4},\\ b_0&=0.36\left[\frac{1}{2}\left(1+\frac{2}{\beta}\right)^2-\frac{1}{2}\left(1+\frac{2}{3}\right)+\frac{1}{6}\right],\\ p_0&=\frac{1}{3}\left[\frac{1}{2}\left(1+\frac{2}{\beta}\right)^3-\frac{3}{4}\left(1+\frac{2}{\beta}\right)^2+\frac{1}{2}\left(1+\frac{2}{3}\right)-\frac{1}{8}\right].\end{aligned}\right\} \quad (15)$$

Equations (14) and (15) are obtained for the case $q(r_\perp)=q_0$, but we could obviously substitute any distribution $q(r_\perp)$ into (13); if the corresponding integrals exist, we can find an expression for the threshold value of μ. As an example we give the solution of the problem for a Gaussian distribution $q(z)=q_0\exp(-z^2/z_0^2)$, with $z_0 \gg 1$ (a more general case is analyzed below). For a broad Gaussian beam the value of μ_{cr} is again given by Eq. (14), where the quantities a_0, b_0, and p_0 are replaced by

$$\left.\begin{aligned}a_0'&=a_0-\frac{1}{2z_0^2}\left(\frac{1}{6}+\frac{1}{\beta}\right),\\ b_0'&=b_0-\frac{0.36}{z_0^2}\left[\frac{1}{4}\Pi^2-\frac{1}{3}\Pi+\frac{1}{8}\right],\\ p_0'&=p_0-\frac{1}{3z_0^2}\left[\frac{1}{4}\Pi^3-\frac{1}{2}\Pi^2+\frac{3}{8}\Pi-\frac{1}{10}\right];\ \ \Pi=1+\frac{2}{\beta}.\end{aligned}\right\} \quad (16)$$

It is evident that the results obtained for a long cylinder also agree with the results of the exact solutions, where the latter can be found. For example, with $\beta=\infty$ we find $\mu_{cr}=2.1$ and $\Theta_{max}|_{z=0}=1.41$, and the corresponding exact values[1] are 2.0 and 1.39.

4. We turn now to the solution of the problem of the thermal breakdown of a semiconductor which is a cylinder of length $2l$ and radius R. In the solution of this problem we assume that the heat-transfer conditions at the bases and generating surface of the cylinder are different, being characterized by heat-transfer coefficients H_1 and H_2, respectively. This assumption corresponds to the usual experimental conditions, under which the sample is placed in a holder (which is usually a good heat conductor), or to the operating conditions of the exit window of a CO_2 laser. Furthermore, we incorporate in the absorptivity an additional term $\varkappa_1$, which is not a function of the temperature, in order to take account of possible absorption by impurities or other absorption processes not involving conduction electrons.

Under these assumptions Eqs. (1) and (2) become

$$\left.\begin{aligned}&\frac{\partial^2\Theta}{\partial z^2}+b^2\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial\Theta}{\partial\rho}\right)+\mu_1+\mu_2\left(1+0.72\Theta+\Theta^2\right)=0,\\ &\left[\pm\frac{\partial\Theta}{\partial z}+\beta_1\Theta\right]\Big|_{z=\pm1}=0;\ \left[\pm\frac{\partial\Theta}{\partial\rho}+\frac{\beta_2}{b}\Theta\right]_{\rho=\pm1}=0.\end{aligned}\right\} \quad (17)$$

Here,

$$\left.\begin{aligned}&z=\frac{x}{l},\ \ \rho=\frac{r}{R},\ \ b=\frac{l}{R},\\ &\Theta=\frac{(T-T_0)E_g}{2kT_0^2},\ \ \beta_1=\frac{H_1l}{\lambda},\ \ \beta_2=\frac{H_2l}{\lambda},\\ &\mu_1=\varkappa_1\frac{q(\rho)}{\lambda}\frac{E_gl^2}{2kT_0^2},\ \ \mu_2=\varkappa(T_0)\frac{q(\rho)}{\lambda}\frac{E_gl^2}{2kT_0^2}.\end{aligned}\right\} \quad (18)$$

It is easy to see that the following functional corresponds to Eq. (17):

$$
\begin{aligned}
I = &-\frac{1}{2\beta_1}\int\limits_0^1\left(\frac{\partial\Theta}{\partial z}\right)^2\Big|_{z=1}\rho d\rho - \frac{b^3}{2\beta_2}\int\limits_0^1\left(\frac{\partial\Theta}{\partial\rho}\right)^2\Big|_{\rho=1}dz \\
&+\int\limits_0^1\int\limits_0^1\rho d\rho dz\left\{-\frac{1}{2}\left[\left(\frac{\partial\Theta}{\partial z}\right)^2 + b^2\left(\frac{\partial\Theta}{\partial\rho}\right)^2\right]\right. \\
&\left.+\mu_1\Theta + \mu_2(\Theta + 0.36\Theta^2 + 0.33\Theta^3)\right\}. \qquad (19)
\end{aligned}
$$

As a trial function we choose $\Theta = C(1 + 2/\beta_1 - z^2)(1 + 2/\beta_2 - \rho^2)$, and for definiteness we assume a Gausian intensity distribution

$$
q(\rho) = q_0\exp\left\{-\frac{\rho^2}{\rho_0^2}\right\}. \qquad (20)
$$

Here we have

$$
\left.\begin{aligned}
\mu_1(\rho) &= \mu_1^0\exp\left\{-\frac{\rho^2}{\rho_0^2}\right\}, \\
\mu_2(\rho) &= \mu_2^0\exp\left\{-\frac{\rho^2}{\rho_0^2}\right\},
\end{aligned}\right\} \qquad (21)
$$

where the values of $\mu_{1,2}^0$ are found from Eq. (18) with $q(\rho) = q_0$. This problem can be solved in the same way as the one-dimensional problems treated above. The critical value of μ_2^0 is

$$
\mu_{cr}^0 = \frac{A}{D + \sqrt{3BF\left(1 + \frac{\varkappa_1}{\varkappa(T_0)}\right)}}. \qquad (22)
$$

The coefficients in (22) are given in the Appendix.

5. We turn now to numerical estimates of the threshold for the thermal instability. We first write an explicit equation for the threshold density of the light flux. According to (5) and (18), and under the assumption that no light is reflected from the surface, we find this critical density to be

$$
q_{cr} = \frac{2\lambda k T_0^2}{\varkappa(T_0) E_g l^2}\mu_{cr}, \qquad (23)
$$

where μ_{cr} is given by the equations derived in the preceding sections. Since these equations are cumbersome, we carry out numerical estimates for only two limiting cases:

1. $\varkappa_1 = 0$, $q(\rho) = q_0$, $\beta_1 = \beta_2 = \infty$. In this case we obtain

$$
\mu_{cr} \approx 0.9 + 2.1 b^2. \qquad (24)
$$

2. $\varkappa_1 = 0$, $q(\rho) = q_0$, $\beta_1 = 1$, $\beta_2 = \infty$. In this case we obtain

$$
\mu_{cr} \approx 0.3 + 2.1 b^2. \qquad (25)
$$

Obviously, although the first case does not arise ordinarily, it gives us an upper limit on the breakdown threshold, since any degradation of the heat transfer would lead to an instability at a lower light intensity. The second case, on the other hand, corresponds to a situation frequently met in practice, in which the heat transfer at the ends occurs as a result of the natural convection of air while the heat transfer at the generating surface is due to contact with a massive metal holder. It is interesting to compare the threshold predicted by Eqs. (23) and (25) with the experimental data available on the breakdown threshhold for germanium irradiated by a CO_2 laser.[5] We should stipulate, however, that the experimental boundary conditions are slightly different from those we have assumed here, so that we can expect only an order-of-magnitude agreement between theory and experiment.

Substituting the values $T_0 = 20°C$, $\varkappa(T_0) = 0.07\ cm^{-1}$, and $l = 0.3$ cm from ref. 5 into Eqs. (23) and (25), we find $q_{cr} \approx 410\ W/cm^2$; for comparison, the experimental thresholds vary over the range 20-90 W/cm^2, depending on the cooling efficiency. In view of our reservation above we conclude that this agreement is satisfactory; this method should be useful for designing the elements of CO_2 lasers.

In conclusion the author thanks S. I. Anisimov for useful comments and I. N. Yassievich for discussion.

APPENDIX

The coefficients in Eq. (2) are

$$
\left.\begin{aligned}
A = {} & 2\left[\frac{1}{\beta_1}\left(\frac{1}{4}+\frac{b}{\beta_2}\right)+\frac{2b^3}{\beta_2}\left(\frac{1}{3}+\frac{1}{\beta_1}\right)\right] \\
& +\frac{2}{3}\left[\frac{1}{2}\Pi_2^2-\frac{1}{2}\Pi_2+\frac{1}{6}\right]+\frac{1}{2}b^2\left[\Pi_1^2-\frac{2}{3}\Pi_1+\frac{1}{5}\right], \\
B = {} & \left(\frac{1}{3}+\frac{1}{\beta_1}\right)\rho_0^2\left[(\Pi_2-\rho_0^2)(1-e^{-1/\rho_0^2})+e^{-1/\rho_0^2}\right], \\
D = {} & 0.36\left[\Pi_1^2-\frac{2}{3}\Pi_1+\frac{1}{5}\right]\left\{\frac{1}{2}\Pi_2^2\rho_0^2(1-e^{-1/\rho_0^2})\right. \\
& \left.-\Pi_2\rho_0^2\left[\rho_0^2(1-e^{-1/\rho_0^2})-e^{-1/\rho_0^2}\right]-\rho_0^6-\frac{1}{2}e^{-1/\rho_0^2}(\rho_0^2+2\rho_0^4+2\rho_0^6)\right\}, \\
F = {} & \frac{1}{6}\left[\Pi_1^3-\Pi_1^2+\frac{3}{5}\Pi_1-\frac{1}{7}\right]\rho_0^2\left\{\Pi_2^3(1-e^{-1/\rho_0^2})\right. \\
& -3\Pi_2^2\left[\rho_0^2(1-e^{-1/\rho_0^2})-e^{-1/\rho_0^2}\right]+3\Pi_2 \\
& \times\left[2\rho_0^4(1-e^{-1/\rho_0^2})-(1+2\rho_0^2)e^{-1/\rho_0^2}\right]-6\rho_0^6 \\
& \left.+e^{-1/\rho_0^2}(1+3\rho_0^2+6\rho_0^4+6\rho_0^6)\right\}, \\
\Pi_1 = {} & 1+\frac{2}{\beta_1};\quad \Pi_2 = 1+\frac{2b}{\beta_2}.
\end{aligned}\right\} \qquad (A.1)
$$

In the case of a broad Gaussian distribution ($\rho_0 \gg 1$) we can use $\exp(-\rho^2/\rho_0^2) = 1 - (\rho^2/\rho_0^2) + \ldots$, so Eqs. (A.1) are simplified; to terms of order $1/\rho_0^2$ the coefficients are

$$
\left.\begin{aligned}
A' = {} & A, \\
B' = {} & \left(\frac{1}{3}+\frac{1}{\beta_1}\right)\left[\Pi_2\left(1-\frac{1}{2\rho_0^2}\right)-\frac{1}{2}+\frac{1}{3\rho_0^2}\right], \\
D' = {} & 0.36\left[\Pi_1^2-\frac{2}{3}\Pi_1+\frac{1}{5}\right] \\
& \times\left[\frac{1}{2}\Pi_2^2\left(1-\frac{1}{2\rho_0^2}\right)-\Pi_2\left(\frac{1}{2}-\frac{1}{3\rho_0^2}\right)+\frac{1}{2}\left(\frac{1}{3}-\frac{1}{4\rho_0^2}\right)\right], \\
F' = {} & \frac{1}{6}\left[\Pi_1^3-\Pi_1^2+\frac{3}{5}\Pi_1-\frac{1}{7}\right]\left[\Pi_2^3\left(1-\frac{1}{2\rho_0^2}\right)\right. \\
& \left.-3\Pi_2^2\left(\frac{1}{2}-\frac{1}{3\rho_0^2}\right)+3\Pi_2\left(\frac{1}{3}-\frac{1}{4\rho_0^2}\right)-\frac{1}{4}+\frac{1}{5\rho_0^2}\right].
\end{aligned}\right\} \qquad (A.2)
$$

In the limit $\rho_0 = \infty$ Eqs. (A.2) hold for the case of a uniform illumination of the entire end of the cylinder.

Reflection of finite amplitude electromagnetic waves from a semiconductor plasma

Yu. F. Filippov
Institute of Radiophysics and Electronics,
Academy of Sciences of the USSR, Khar'kov

(Submitted June 25, 1973)
Zh. Tekh. Fiz., 44, 950-955 (May 1974)

The present work considers two circularly polarized waves of finite but small amplitude with arbitrary frequencies incident on a plasma–vacuum boundary. It is shown that nonlinear effects lead to an intensity dependence of the Fresnel coefficients and to the appearance of waves at combination frequencies. The effects are most pronounced at the plasma cyclotron resonance.

The nonlinear effects which occur in the interaction of strong electromagnetic waves with semiconductors are utilized in a variety of devices: detectors, multipliers, mixers, and so on. For small pump powers (of the order of a tenth of a watt), the effects away from resonance are small. However, near resonance (cyclotron resonance, for example), the waves are strongly attenuated in the plasma. When there is a plasma–vacuum interface, reflected waves appear in the vacuum at the fundamental and at combination frequencies. It is shown below that at the cyclotron and plasma cyclotron frequencies there is a significant increase in the amplitudes of these waves and in the dependence of the Fresnel coefficients on the incident amplitude.

WAVE INTERACTION IN A PLASMA

Assume that a multicomponent collisionless cold plasma occupies the half-space $z \geq 0$. The properties of a finite-amplitude wave propagating in this plasma can be described by the solutions of the following nonlinear system:

$$\left.\begin{aligned} &C\,\mathrm{curl}\,\mathbf{E} = -\frac{\partial \mathbf{H}}{\partial t}, \quad C\,\mathrm{curl}\,\mathbf{H} = \varepsilon_l \frac{\partial \mathbf{E}}{\partial t} + \sum 4\pi \mathbf{j}_\alpha, \\ &\mathrm{div}\,\mathbf{H} = 0, \quad e_\alpha \frac{\partial n_\alpha}{\partial t} + \mathrm{div}\,\mathbf{j}_\alpha = 0, \\ &\frac{\partial \mathbf{j}_\alpha}{\partial t} - \frac{\omega_{p\alpha}^2}{4\pi}\mathbf{E} - \frac{\omega_{H\alpha}}{H_0}[\mathbf{j}_\alpha \mathbf{H}_0] = \frac{4\pi}{c}\phi_\alpha. \end{aligned}\right\} \qquad (1)$$

Here E and H are the wave fields; e_α, m_α, $N_{0\alpha}$, $\omega_{p\alpha}$ and $\omega_{H\alpha}$, n_α and j_α are respectively the charge, effective mass, equilibrium density, plasma and cyclotron frequencies, and the varying density and current density components for particles of species α caused by the wave fields; ε_e is the dielectric constant due to the lattice; $\sum_\alpha$ denotes summation over all particles α. We consider a quasineutral plasma, for which $\sum_\alpha e_\alpha N_{0\alpha} = 0$.

The influence of the nonlinear effects on the wave is determined by the function ψ_α

$$\frac{4\pi}{c}\phi_\alpha = \frac{e_\alpha}{m_\alpha}\left\{e_\alpha n_\alpha \mathbf{E} + \frac{1}{c}[\mathbf{j}_\alpha \mathbf{H}] - \sum_i \frac{\partial}{\partial x_i}(\mathbf{j}_\alpha j_{\alpha i})\right\} \qquad (1a)$$

($\sum_i$ denotes summation over coordinates).

We choose the z axis in the direction of propagation of the wave. In a longitudinal field ($\mathbf{H}_0 \parallel \mathbf{i}_z$), the system (1) admits the following exact solution describing the propagation of a single transverse wave of finite amplitude:

$$H_x = h_0 \cos(\omega t - kz), \quad H_y = \frac{\eta}{\omega}\frac{\partial H_x}{\partial t},$$

$$\frac{4\pi}{c}\mathbf{j}_{\alpha\perp} = -\frac{\omega\omega_{p\alpha}^2}{kc^2(\omega_{H\alpha} - \eta\omega)}\mathbf{H}_\perp,$$

$$j_{z\alpha} = n_\alpha = E_z = \phi_\alpha = 0, \qquad (2)$$

where k and ω are the propagation constant and frequency of the wave and are related by the usual dispersion equation:

$$k^2c^2 = \omega^2\left[\varepsilon_l - \sum_\alpha \frac{\omega_{p\alpha}^2(\omega - \eta\omega_{H\alpha})^{-1}}{\omega}\right]. \qquad (2a)$$

The solutions (2) and (2a) describe the properties of the ordinary ($\eta = -1$) or extraordinary ($\eta = 1$) wave and show that the propagation of one of these waves along the magnetic field does not produce any change in the plasma parameters. Thus an intense wave propagates in exactly the same way as a wave of infinitesimal amplitude. This result does not contradict the conclusions reached in other papers which consider the nonlinearity produced by electron heating leading to a dependence of the dielectric constant on the power even when only one wave propagates (see, for example, ref. 1). In our case $\nu \ll \omega$, ω_H, and so the effect of heating on the wave can be neglected. Nonlinear effects occur in a longitudinal magnetic field only when several waves propagate.

We limit ourselves here to a study of the case in which the wave is normally incident from vacuum on a vacuum–plasma interface. For longitudinal incidence of a circularly polarized wave ($\mathbf{k} \parallel \mathbf{H}_0$) there is no change of polarization across the boundary and hence nonlinear effects do not occur. If the incident wave is linearly polarized, it splits into two waves, circularly polarized in opposite directions, and these propagate into the plasma with different phase velocities. For sufficiently high incident power an interaction is set up between the waves and this leads to the appearance of longitudinal and transverse waves at twice and three times the frequency respectively. The phase velocities and the Fresnel coefficients then depend on the amplitude of the primary wave. It is not possible to analyze these effects in the general case. We therefore limit ourselves to waves of finite, but small, amplitude.

We expand the system (1) in a series in the small parameter defined as the ratio of the wave amplitude to the strength of the external magnetic field; retaining terms up to the third order in small quantities, we reduce (1) to the form

$$(\hat{L}_1^2 + \hat{L}_2^2)H_x = -\frac{\partial}{\partial z}\left\{\sum_\alpha \hat{L}_{H\alpha}\left[\frac{\partial}{\partial t}(\hat{L}_1 + \hat{L}_2\omega_{H\alpha})\psi_{y\alpha} + \left(\hat{L}_2\frac{\partial^2}{\partial t^2} - \hat{L}_1\omega_{H\alpha}\right)\psi_{x\alpha}\right]\right\}, \qquad (3a)$$

$$\varepsilon_l\frac{\partial^2 E_z}{\partial t^2} + \sum_\alpha \omega_{p\alpha}^2 E_z = -c\sum \psi_{z\alpha}, \qquad (3b)$$

$$\frac{\partial j_{z\alpha}}{\partial t} = \frac{\omega_{p\alpha}^2}{4\pi} E_z + \frac{c}{4\pi} \psi_{z\alpha}, \qquad (3c)$$

where ψ_α is defined by (1a) and

$$c^2 \hat{L}_1 = \left(\varepsilon_l \frac{\partial^2}{\partial t^2} - c^2 \frac{\partial^2}{\partial z^2}\right) + \sum_\alpha \omega_{p\alpha}^2 \hat{L}_{H\alpha}^{-1} \frac{\partial^2}{\partial t^2},$$
$$c^2 \hat{L}_2 = \sum \omega_{H\alpha} \omega_{p\alpha}^2 \hat{L}_{H\alpha}^{-1}, \quad \hat{L}_{H\alpha} = \omega_{H\alpha}^2 + \frac{\partial^2}{\partial t^2}.$$

Since the nonlinear effects are small, all the field and current components in ψ_α can be expressed in terms of H_x from (2).

We first consider the interaction of circular waves with different amplitudes and frequencies and arbitrary directions of rotation (as given by the parameter η)

$$H_x = \sum_{j=1}^{2} \frac{a_j}{2} e^{i\eta_j\varphi_j} + \text{c.c.}, \qquad (4)$$

where $\varphi_j = \omega_j t - k_j z_j$, $\eta_j = \pm 1$.

Substituting (4) into (3b), we see that a longitudinal wave is produced at the combination frequency $\eta_1\omega_1 - \eta_2\omega_2$

$$E_z = a_1 a_2 \sum_\alpha \left(\frac{\omega_{H\alpha}\omega_{p\alpha}^2}{2icH_0}\right) \left[\sum_{\alpha'} \omega_{p\alpha'}^2 - \varepsilon_l (\eta_1\omega_1 - \eta_2\omega_2)^2\right]^{-1}$$
$$\times \left\{\omega_1 \frac{(\omega_{H\alpha} - \eta_1\omega_1)^{-1}}{k_1 - \omega_2 (\omega_{H\alpha} - \eta_2\omega_2)^{-1}/k_2}\right\} e^{i(\eta_1\varphi_1 - \eta_2\varphi_2)} + \text{c.c.} \qquad (5)$$

We can conclude from (5) that if the original waves have the same sense ($\eta_1 = \eta_2$), they give rise to a longitudinal wave at the difference frequency ($\omega_{l0} = |\omega_1 - \omega_2|$); whereas if they have opposite senses ($\eta_1 = -\eta_2$), the resultant wave is at the sum frequency ($\omega_{l0} = \omega_1 + \omega_2$). The amplitude becomes significantly greater near resonance.

Cyclotron resonances are observed in a two-component plasma: ion cyclotron in the ordinary wave (α = i, e) and electron cyclotron in the extraordinary wave ($\omega_{Hi} = \omega$, $\eta = -1$). It is also possible to have a nonlinear plasma resonance when $\varepsilon_l(\eta_1\omega_1 - \eta_2\omega_2)^2 = \omega_{pe}^2 + \omega_{pi}^2$. The longitudinal wave reaches its greatest amplitude at the double resonance $\varepsilon_l(\omega_1 = \eta_2\omega_2)^2 = \omega_{pe}^2 + \omega_{pi}^2$, $\omega_1 = \omega_{He}$, $\eta_1 = 1$. The inverse effect of a longitudinal wave on transverse waves results in the dependence of the phase velocities on intensity and to the appearance of transverse waves at the combination frequencies

$$H_{x1}(\omega_1^+) = b_1^+ \exp[i(2\eta_1\varphi_1 - \eta_2\varphi_2)] + \text{c.c.},$$
$$H_{x2}(\omega_2^-) = b_2^- \exp[i(2\eta_2\varphi_2 - \eta_1\varphi_1)] + \text{c.c.},$$
$$\omega_j^\pm = \eta_j\omega_j \pm (\eta_1\omega_1 - \eta_2\omega_2).$$

We omit the cumbersome intermediate steps and quote the results for the nonlinear corrections to the wave vectors and for the amplitudes $b_j^\pm$:

$$\left.\begin{aligned} \Delta k_1 &= -\frac{\eta_1}{2} \sum_\alpha \psi_{2\alpha}^\pm (\omega_{H\alpha} - \eta_1\omega_1)^{-1} \frac{a_1}{a_2}; \\ \Delta k_2 &= -\frac{\eta_2}{2} \sum_\alpha \psi_{1\alpha}^- (\omega_{H\alpha} - \eta_2\omega_2)^{-1} \frac{a_2}{a_1}; \end{aligned}\right\} \qquad (6a)$$

$$b_j^\pm = -\sum_\alpha \frac{a_j k_j^\pm \psi_{j\alpha}^\pm (\omega_{H\alpha} - \omega_j^\pm)^{-1}}{\Delta_j^\pm}, \qquad (6b)$$

where

$$k_j^\pm = \eta_j k_j \pm (\eta_1 k_1 - \eta_2 k_2), \qquad (7a)$$

$$\Delta_j^\pm c^2 = k_j^{\pm 2} c^2 - \omega_j^{\pm 2} \left[\varepsilon_e + \sum_\alpha \frac{\omega_{p\alpha}^2 (\omega_{H\alpha} - \omega_j^\pm)^{-1}}{\omega_j^\pm}\right], \qquad (7b)$$

$$\psi_{j\alpha}^\pm = \left(\frac{a_1 a_2 \omega_{H\alpha}}{2H_0^2 C^2}\right) (\eta_1\omega_1 - \eta_2\omega_2)^{-1} \left[1 - \frac{\omega_j}{k_j} \frac{\eta_1 k_1 - \eta_2 k_2}{\eta_1\omega_1 - \eta_2\omega_2}\right.$$
$$\left. + \frac{\omega_j}{k_j} k_j^\pm (\omega_{H\alpha} - \eta_j\omega_j)^{-1}\right] \left[R_{z\alpha} - \frac{\omega_{p\alpha}^2 \sum_{\alpha'} R_{z\alpha'}}{\left[\sum_{\alpha'} \omega_{p\alpha'}^2 - \varepsilon_e (\eta_1\omega_1 - \eta_2\omega_2)^2\right]}\right], \qquad (7c)$$

$$R_{z\alpha} = \omega_{H\alpha}\omega_{p\alpha}^2 \left[\frac{\omega_1 (\omega_{H\alpha} - \eta_1\omega_1)^{-1}}{k_1 - \omega_2 (\omega_{H\alpha} - \eta_2\omega_2)^{-1}/k_2}\right]. \qquad (7d)$$

Interaction in a longitudinal magnetic field leads to the appearance of a virtual longitudinal wave characterized by a frequency $|\eta_2\omega_2 - \eta_1\omega_1|$ and a propagation constant $\eta_1 k_1 - \eta_2 k_2$. This is not a characteristic wave in a magnetoactive plasma: If thermal effects are neglected the only waves which can occur are plasma oscillations. The reaction of these waves on the primary waves leads to a dependence of the phase velocities on the power of the interacting waves and to the appearance of transverse waves at frequencies ω_1^+ and ω_2^- with propagation constants which can be expressed in terms of k_1 and k_2. The frequency and propagation constant of the characteristic wave are related by the dispersion equation (2a). Since the wave vectors $H_{x1}(\omega_1^+)$ and $H_{x2}(\omega_2^-)$ do not satisfy this condition, the above interaction does not apply to the resonance wave, which is characterized by the possibility of a total jump in energy from one wave to another. All of these effects are in general small. Thus, for example, in the "opposed" interaction ($\eta_2 = -\eta_1$) when the frequencies are such that $\omega_{Hi} \ll \omega_1$, $\omega_2 \ll \omega_{He}$, ω_{pe} the relative change in the propagation constant of the helicon ($\eta_2 = 1$) is

$$\frac{\Delta k_2}{k_2} \approx \frac{a_1^2}{4H_0^2} \varepsilon_l \left[\varepsilon_e - \frac{\omega_{pe}^2}{\omega\omega_{He}}\right]^{1/2} = \left(\frac{\pi\varepsilon_l P_\omega}{cH_0^2 S_0}\right) \left(\varepsilon_l - \frac{\omega_{pe}^2}{\omega\omega_{He}}\right)^{-1/2}, \qquad (8)$$

where k_2 is the propagation constant of the ordinary wave, P_ω is the power of this wave ($\eta_1 = -1$) through the cross section S_0. With $\varepsilon_l = 16$, $H_0 \sim 1$ kOe, $S_0 = 1\ \text{mm}^2$, $\omega^2_{pe} \cdot (\omega\omega_{He}\varepsilon_e)^{-1} \sim 15$, we find from (8) that the relative shift in the helicon wave vector for $P_\omega = 10$ W is of the order of $(\Delta k_2)/k_2 \sim 10^{-6}$.

It can be shown in a similar way that the power of the harmonics is very small. This is in agreement with experimental results[2] at $\lambda = 3.2$ cm, where with $P_\omega = 20$ kW, the power of the third harmonic is $5 \cdot 10^{-5}$ W with pulsed excitation.

RESONANCES IN THE PLASMA

The strongest nonlinear effects occur at the resonances. We first consider the interaction between ordinary and extraordinary waves with the same frequency ($\eta_1 = -\eta_2 = 1$, $\omega_1 = \omega_2 = \omega$) and neglect the effect on these waves of all the charged particles except electrons ($\omega \gg \omega_{H\alpha}$ when $\alpha \neq e$).

Electron cyclotron resonance ($\omega = \omega_{He}$). When $\omega = \omega_{He}$, a singularity appears in (7) and the expressions for Δk_j and the harmonic amplitudes go to infinity. The singularity results from neglecting the particle collisions, which always occur in a real plasma. It can be shown that the inclusion of collisions in the original equations leads to finite values of Δk and b_j

$$\left.\begin{aligned}\frac{\Delta k_1}{k_1} &\approx \frac{a_2^2}{4H_0^2}\frac{\omega}{i\nu}\varepsilon_l\omega^2(\omega_{pe}^2-4\varepsilon_l\omega^2)^{-1},\\ \frac{\Delta k_2}{k_2} &\approx \frac{a_1^2}{4H_0^2}\frac{\omega}{i\nu}\varepsilon_l\omega^2(\omega_{pe}^2-4\varepsilon_l\omega^2)^{-1};\end{aligned}\right\} \tag{9a}$$

$$\left.\begin{aligned}b_1^+ &\approx -\frac{a_1^2a_2}{2H_0^2}\frac{\omega}{i\nu}\varepsilon_l\omega^2(\omega_{pe}^2-4\varepsilon_l\omega^2)^{-1},\\ b_2^- &\approx \frac{a_1a_2^2}{4H_0^2}\frac{\omega_{pe}^2}{k_1k_2c^2}\frac{\omega}{i\nu}\frac{\varepsilon_l\omega_p^2}{1}(\omega_{pe}^2-4\varepsilon_l\omega^2)^{-1}.\end{aligned}\right\} \tag{9b}$$

Here, ν_e is the effective collision frequency, b_1 and b_2 are the amplitudes of the ordinary and extraordinary waves, and k_1 and k_2 are given by $\sqrt{2}k_1 \approx (1-i)\left(\frac{\omega_{pe}^2\omega}{\nu c^2}\right)^{1/2}$ and $k_2 \approx \frac{\omega}{c}\left(\frac{\varepsilon_l-\omega_{pe}^2}{2\omega^2}\right)^{1/2}$. Equation (9a), which describes the nonlinear shift in the wave vector, shows that the nonlinear effects produce wave attentuation in the plasma. Expressions (9b) describe the amplitude of the two third harmonics which propagate with different phase velocities. Since the propagation constants depend on k_1, these waves are also strongly attenuated inside the plasma.

Cyclotron plasma resonance ($\omega = \omega_{He} = \omega_{pe}/2\sqrt{\varepsilon_e}$). We note from (9a) and (9b) that the amount of shift and the amplitudes of the harmonics are significantly greater than $\omega_{pe} = 2\sqrt{\varepsilon_e}\omega$. It follows from (5) that under these conditions there will be a nonlinear plasma resonance in the longitudinal wave. In order to obtain finite amplitudes at the double resonance we must take account of the effect of collisions on the propagation of the longitudinal wave. It can be shown that (9a) and (9b) then reduce to

$$2\frac{\Delta k_1}{k_1} \approx -\left(\frac{a_2\omega}{2H_0\nu}\right)^2,\quad 2\frac{\Delta k_2}{k_2} \approx -\left(\frac{a_1\omega}{2H_0\nu}\right)^2; \tag{10a}$$

$$b_1^+ \approx a_2\left(\frac{a_1\omega}{2H_0\nu}\right)^2,\quad b_2^- \approx \frac{i-1}{\sqrt{2}}a_1\left(\frac{a_2\omega}{2H_0\nu}\right)^2\sqrt{\frac{\nu}{\omega}}. \tag{10b}$$

Thus, when $\omega \gg \nu$ the nonlinear shift in the wave vector and the amplitude of the harmonics are much greater at resonance than in normal cases.

The other resonances can be studied in the same way. In particular, a triple resonance is possible when $\omega_{Hi} = \omega_2 \ll \omega_1 = (\omega_{0e}^2 + \omega_{0i}^2)^{1/2}/\sqrt{\varepsilon_l}$. Estimates show, however, that the values of Δk_j and b_j are of the same order as in the double resonance and so we will not go into the details here.

As a result of the strong wave attenuation in the plasma at the resonances, the effects cannot be utilized to construct semiconductor devices. It is therefore necessary to investigate the influence of the nonlinear effects on the waves which are reflected from the plasma.

THE INFLUENCE OF THE BOUNDARY ON THE WAVE INTERACTION

We consider normal incidence of circularly polarized waves of arbitrary sense with frequencies ω_1 and ω_2 and amplitudes h_{01} and h_{02}. As a result of the interaction reflected waves are produced in the vacuum at the fundamentals and at the combination frequencies $|2\eta_1\omega_1-\omega_2\eta_2|$ and $|2\eta_2\omega_2-\eta_1\omega_1|$. Since circularly polarized waves propagating longitudinally in a magnetized plasma ($\mathbf{k} \parallel \mathbf{H}_0$) are normal waves, there is no transformation into waves of the opposite sense at the vacuum – plasma boundary. Thus the tangential components of the E and H fields of each type must be continuous at this boundary. We also note that in order to satisfy these conditions for the fields at the frequencies ω_1^+ and ω_2^- we must use the full solution of (3a) consisting of the particular solution (7) which we have already discussed and the solution of the homogeneous equation

$$(\hat{L}_1^2+\hat{L}_2^2)H_x = 0.$$

With these preliminary remarks, we now quote the expressions for the amplitudes of the H_x field components:

$$a_j = \frac{2h_{0j}k_jc}{(\omega_j+k_jc)}, \tag{11a}$$

$$b_j^\pm = -2k_jk_j^\pm ch_{0j}(k_jc+\omega_j)^{-1}\sum\frac{\psi_{\alpha j}^\pm(\omega_{H\alpha}-\omega_j^\pm)^{-1}}{\Delta_j^\pm}, \tag{11b}$$

$$\tilde{b}_j^\pm = (k_j^\pm c+\omega_j^\pm)(\tilde{k}_j^\pm c+\omega_j^\pm)^{-1}\frac{b_j^\pm \tilde{k}_j^\pm}{k_j^\pm}, \tag{11c}$$

$$f_j = (k_jc-\omega_j)(k_jc+\omega_j)^{-1}h_{0j}, \tag{11d}$$

$$g_j^\pm = \omega_j^\pm(k_j^\pm-\tilde{k}_j^\pm)(\omega_j^\pm \mp k_j^\pm c)^{-1}\frac{b_j^\pm}{k_j^\pm}. \tag{11e}$$

Here h_{0j}, a, b_1^+, b_2^-, $\tilde{b}_1^+$, $\tilde{b}_2^-$ and f_j, g_1^+, g_2^- are respectively the amplitudes of the incident, transmitted (plasma) and reflected (vacuum) waves at the frequencies ω_1, ω_2, $\omega_1^+ = |2\eta_1\omega_1-\eta_2\omega_2|$, $\omega_2^- = |2\eta_2\omega_2-\eta_1\omega_1|$,

$$\tilde{k}_j^\pm = \left(\frac{|\omega_j^\pm|}{c}\right)\left[\varepsilon_l-\sum_\alpha\frac{\omega_{p\alpha}^2(\omega_j^\pm-\omega_{H\alpha})^{-1}}{\omega_j^\pm}\right]^{1/2}$$

are the propagation constants of the normal waves of frequency ω_1^+ (ω_2^-) and amplitude $\tilde{b}_1^+$ ($\tilde{b}_2^-$).

The effect of the boundary is that in addition to the forced waves b_1^+ and b_2^- in the plasma, natural waves b_1^+ and b_2^- are also formed with the same frequencies but with wave numbers k_1^+ and k_2^-. The sense of the rotation in the plane of rotation is determined by the signs of ω_1^+ and ω_2^-. As for the other waves, the amplitudes are significantly higher near the resonances. In particular, if a linearly polarized wave of frequency ω is incident, the third harmonic is produced in the plasma. At the cyclotron plasma resonance ($\omega_{Hi} \ll \omega = \omega_{He} = \omega_{pe}/2\sqrt{\varepsilon_l}$), the forced third harmonic waves are rapidly attenuated away from the boundary, but this is not true of the natural waves, for which

$$b_2^- \approx \frac{h_0}{2}\sqrt{\frac{\nu}{i\omega}}(1+i\sqrt{\varepsilon_l})^{-2}\left(\frac{h_0\omega}{H_0\nu}\right)^2,\quad \tilde{k}_2^- \approx \sqrt{6\varepsilon_l}\frac{\omega}{c}$$

for the ordinary wave,

$$b_1^+ \approx 2i\sqrt{\varepsilon_l}h_0(1+i\sqrt{\varepsilon_l})^{-1}\left(\frac{h_0\omega}{H_0\nu}\right)^2,\quad \tilde{k}_1^+ \approx \sqrt{3\varepsilon_l}\frac{\omega}{c}$$

for the helicon.

If $\varepsilon_l = 16$, $\omega = 10^{12}$ sec^{-1}, $S_0 = 1$ mm^2, $H_0 = 0.7 \cdot 10^3$

Oe, $\nu = 10^{10}$ sec^{-1} and the incident power $P_\omega = 10$ W, the output power of the helicon will be of the order of $P_{3\omega} \approx 10^{-3}$ W and this is considerably higher than the effect observed experimentally in ref. 2. Similar estimates can be made for the powers reflected from the plasma.

The nonlinear effects also cause the Fresnel coefficients to depend on the incident power. In particular, at the double resonance

$$2\Delta R_1 = \sqrt{\frac{i\nu}{\omega}}\left(\frac{h_0\omega_p}{2\nu H_0}\right)^2 (1 + i\sqrt{\varepsilon_l})^{-2} R_1,$$

$$\Delta R_2 = i\sqrt{\varepsilon_l}\,(1 + \varepsilon_l)^{-1}\left(\frac{h_0\omega}{H_0\nu}\right)^2 R_2,$$

where R_j is the reflection coefficient in the linear approximation. The change is of the order of a few per cent for the parameter values given above.

(Submitted July 4, 1973; resubmitted October 1, 1973)
Zh. Tekh. Fiz., 44, 956-964 (May 1974)

A hydrodynamic theory is derived for the Cerenkov instability of a monoenergetic, relativistic electron beam in a periodic plasma-filled waveguide. The frequencies and growth rates are found for the limiting cases of strong and weak magnetic fields. Under certain conditions the presence of a plasma can strongly influence the interaction of the beam with a periodic waveguide.

INTRODUCTION

The theory of collective interactions of a relativistic electron beam with slow-wave structures and plasmas is of interest in connection with the development of methods for accelerating ions by charge-density waves and the resulting electromagnetic waves,[1,2] with the development of new microwave-generation methods based on the use of the collective interaction of intense relativistic electron beams with a plasma1) (refs. 3, 4), with the possibility of increasing the efficiency of this interaction by premodulation of the beam,[7] and with the determination of the threshold and critical currents and their functional dependences on the beam and plasma parameters.[8] We report here on a comparative analysis of the optimum conditions and efficiency of the collective Cerenkov interaction of a cylindrical, monoenergetic electron beam with a slow-wave structure in the form of a periodic waveguide filled with the plasma.

The collective interaction of a beam with a periodic retarding structure was first studied by Akhiezer et al.,[9] who calculated the growth rates for the Cerenkov instability of a beam in a chain of cavities for an axisymmetric mode (m = 0). Experiments carried out in linear electron accelerators[10-12] have shown that an axially asymmetric wave can also be excited in an accelerating structure with a single field cycle in the azimuthal direction; this mode throws the beam against the accelerator walls.[12-14] Furthermore, a dense plasma can form when high-current beams pass through such structures; the collective interaction of the beam with this plasma can compete with the excitation of waveguide modes. Accordingly, effective control of the instabilities of a relativistic beam in this system requires a theoretical study of the conditions under which a collective interaction can occur between the beam and the plasma and waveguide modes; it is also necessary to calculate the functional dependences of the corresponding growth rates on the parameters of the beam and the system. This problem is the subject of the present paper.

STATEMENT OF THE PROBLEM

We consider a waveguide with conducting walls of radius R, loaded periodically (at a spacing of d) with infinitesimally thin conducting disks with inner radius b. A monoenergetic beam moves along the z axis with velocity v_0, and the equilibrium density $n_b(r)$ of the beam falls off radially, so $n_b(a) = 0$. With no external magnetic field or plasma the Coulomb charge of the beam in the equilibrium state is partially neutralized by the ion background whose density $n_+(r)$ is such that the radial force acting on a beam particle vanishes: $n_+(r) \equiv n_b(r)/\gamma^2$ $[\gamma \equiv (1 - v_0^2/c^2)^{-1/2}]$.

The starting point for this problem is the system of hydrodynamic equations of motion, the continuity equation for the beam particles,2) and the Maxwell equations for the field:

$$\frac{d}{dt}\frac{m_0}{\left(1-\frac{v_0^2}{c^2}\right)^{1/2}}\mathbf{v} = e\mathbf{E} + \frac{e}{c}[\mathbf{vH}], \quad \frac{\partial\rho}{dt} + \operatorname{div}\mathbf{j} = 0, \tag{1}$$

$$\operatorname{curl}\mathbf{E} = -\frac{1}{c}\partial\mathbf{H}, \operatorname{curl}\mathbf{H} = \frac{1}{c}\frac{\partial\mathbf{D}}{\partial t} + \frac{4\pi}{c}\mathbf{j}, \tag{2}$$

where ρ and $\mathbf{j}$ are the beam charge density and current; $D_i \equiv \hat{\varepsilon}_{ik}E_k$, and $\hat{\varepsilon}_{ik}$ is the dielectric tensor of the plasma in an external magnetic field, given by

$$\hat{\varepsilon}_{ik} \equiv \begin{pmatrix} \varepsilon_1 & i\varepsilon_2 & 0 \\ i\varepsilon_2 & \varepsilon_1 & 0 \\ 0 & 0 & \varepsilon_3 \end{pmatrix} \begin{array}{l} \varepsilon_1 \equiv 1 + \sum\limits_\alpha \frac{\omega_{p\alpha}^2}{\omega_{H\alpha}^2 - \omega^2}, \quad \varepsilon_2 \equiv \sum\limits_\alpha \frac{\omega_{H\alpha}\omega_{p\alpha}^2}{(\omega_{H\alpha}^2 - \omega^2)\,\omega}, \\ \varepsilon_3 \equiv 1 - \sum\limits_\alpha \frac{\omega_{p\alpha}^2}{\omega^2}, \end{array}$$

where $\omega_{p\alpha} \equiv (4\pi e n_{p\alpha}/m_\alpha)^{1/2}$ is the plasma frequency for particles of species α, and $\omega_{H\alpha} = (eH_0/m_\alpha c)$ is the Larmor frequency for particles of species α.

Equations (1), (2) must be solved taking account of the boundary conditions at the surface of the plasma and of the slow-wave structure. Solving this problem for the general case is quite complicated, so we consider separately the collective interaction of the beam with the periodic waveguide and with the plasma.

COLLECTIVE INTERACTION OF A RELATIVISTIC BEAM WITH A PERIODIC STRUCTURE IN THE ABSENCE OF A PLASMA

In the absence of a plasma ($n_p = 0$, $\hat{\varepsilon}_{ik} = 1$), Eqs. (1), (2) describe the collective interaction of a beam with a slow-wave structure. If the beam current is not too high, so that the growth rate δ is small in comparison with the frequency of the excited waves, ω_0, we can use a variational method,[15,16] finding an analytic expression for the growth rate which is valid to terms of order $(\delta/\omega_0)^2$. The calculations are very complicated for an arbitrary value of the external magnetic field H_0; hence we consider the limiting cases of strong and weak fields, in which it is possible to obtain relatively simple analytic expressions. We analyze the interaction of the beam with axially symmetric and axially asymmetric modes.

1. Symmetric Waves (m = 0)

The field profile and the dispersion in a waveguide with relatively thick disks ($d \ll \lambda_g$) are studied in refs. 17 and 18. Accordingly, we give only the equations for the growth rates of Cerenkov instabilities excited in the system by a monoenergetic beam.

a. Strong magnetic field. For a strong external field the high-frequency beam current j induced by the field of this wave contains only one nonvanishing component, the longitudinal component,

$$j_z = \frac{ie^2 n_b \omega E_z}{m_z (\omega - k_z v_0)^2}.$$

The corresponding equation for the growth rate of the Cerenkov instability of the symmetric mode is

$$\delta = \frac{3^{1/3}}{2}\omega_0 \left(\frac{2\pi r_0 \lambda_0^2 N}{\gamma^3 W_0}\right)^{1/3}, \qquad (3)$$

where $r_0 \equiv e^2/m_0c^2$ is the classical radius of the electron, $N \equiv 2\pi \int_0^a r n_b(r) dr$ is the density of beam particles per unit length, and $W_0 \equiv 2\pi \int_0^R E_z^2(r) r dr$ is the normalization field.

Equation (3) is the same as the corresponding equation of ref. 9, except that the beam density n_b is replaced by its average value $\bar{n}_b = N/W_0$.

To determine the functional dependence of the growth rate on the profile of the beam density, we consider the case of a beam of homogeneous density (n_b = const for $r < a$, $n_b = 0$ for $r > a$), for which the dispersion relation can be derived in analytic form (for the case of thick disks and axisymmetric waves) for an arbitrary value of the total beam current. In this case the growth rate is[19]

$$\delta = \frac{3^{1/3}}{2}\omega_0 \left\{\frac{2r_0 N}{\gamma^3} \frac{Z_0^2(k_0 b)}{I_0^2\left(k_0 \frac{b}{\gamma}\right)} \left[\frac{dZ_0(k_0 b)}{dk_0 b} Z_1(k_0 b) - \frac{dZ_1(k_0 b)}{dk_0 b} Z_0(k_0 b)\right]\right\}^{1/3}. \qquad (4)$$

A comparison shows that when both (3) and (4) are applicable the predicted growth rates are identical in terms of functional dependence on the parameters of the beam and the system, differing only in numerical factors of order unity.

b. Vanishing magnetic field. We recall that in this case the beam is held in equilibrium in the steady state by the ion background, whose density n+ is $n_+ = n_b/\gamma^2$. When the beam density $n_b(r)$ is radially inhomogeneous, the growth rate of the Cerenkov instability can be found by a variational method. Writing the longitudinal current in terms of the field on the basis of the continuity equation and the equation of motion, we find

$$j_z = \frac{ie^2 n_b E_z \omega}{m_0 \gamma^3 (\omega - k_z v_0)^2} + \frac{e^2 v_0}{m_0 \gamma (\omega - k_z v_0)^2} \frac{1}{r} \frac{\partial}{\partial r} [r n_b(r)(E_r - \beta_0 H_\varphi)].$$

Substituting this result into the equations for the field, we find the growth rate as given by (3).

To determine the influence of the shape of the beam-density profile on the growth rate we again consider the case of a homogeneous density, for which the dispersion relation can be obtained in analytic form.[19] Analysis of this equation shows that for beam currents which are not too high, $\omega a_{b\perp}/c < 1$, the frequency spectrum and the growth rate are the same as in a strong magnetic field. The physical interpretation of this result is that the condition $\omega a_{b\perp}/c < 1$ is equivalent to the requirement that the beam radius be small in comparison with the skin depth $\delta_{sk} = c/\omega_{b\perp}$. In this case the field penetrates well into the beam, so that the frequency and growth rate are the same as in a strong magnetic field. When $\omega_{b\perp} a/c > 1$, and the beam radius is larger than the skin depth, the high-frequency field does not penetrate into the beam, which serves as a conductor in this case. Accordingly, the skin effect of the field in the beam region $r < a$ leads to a frequency spectrum different from that for the case of a strong magnetic field and to a reduction proportional to $(a\omega_{b\perp}/c)^{1/3}$ in the growth rate.

2. Asymmetric Modes (m = 1)

These modes are particularly interesting, since they lead to beam collapse. When the wave field is characterized by the m = 1 azimuthal mode the amplitude of its transverse components does not vanish at the axis as $v_\Phi \to c$. The field profile and the dispersion relation of this wave (for the case of thick disks) are studied in ref. 20.

The excitation of an asymmetric mode by a relativistic beam in the absence of an external magnetic field is solved by a variational method since the exact solution requires finding the roots of a seventh-order determinant.

Substituting the expression for the longitudinal current,

$$j_z = \frac{ie^2}{m_0(\omega - k_z v_0)^2}\left\{\frac{n_b \omega E_z}{\gamma^3} - \frac{iv_0}{\gamma}\frac{1}{r}\frac{\partial}{\partial r} \times [r n_b(r)(E_r - \beta_0 H_\varphi)] + \frac{n_b v_0}{\gamma}\frac{1}{r}(E_\varphi + \beta_0 H_r)\right\}$$

into the equation for the field, and integrating the result over the waveguide cross section, we find the growth rate to be

$$\delta = \frac{3^{1/3}}{2}\omega_1 \left(\frac{4\pi r_0 \lambda_1^2 N}{W_1 \gamma}\right)^{1/3}. \qquad (5)$$

Accordingly, the growth rate of the Cerenkov instability for an axially asymmetric mode, which causes beam collapse, falls off more slowly with increasing energy than the growth rate for a symmetric mode.[21] It must be emphasized that this result holds for the case of minimum neutralization of the beam space charge by the ion background ($n_+ = n_{cr} = n_b/\gamma^2$), with no synchrotron oscillations of the beam particles. With $n_+ > n_{cr}$ the additional focusing of the beam by the ion background can suppress the transverse instability; however, in the steady state the beam particles move along nonlinear trajectories so that a special investigation is required to determine the equilibrium configurations of the system and the stability in this case. An external magnetic field can also suppress the transverse instability of a beam in a slow-wave structure.

COLLECTIVE INTERACTION OF A RELATIVISTIC BEAM WITH SLOW WAVES IN A GYROTROPIC PLASMA WAVEGUIDE

We have neglected the electron plasma in the waveguide, even though ionization of the residual gas leads to the formation of a plasma in the interaction region in a real experiment. The result is that plasma and waveguide modes begin to compete. It is therefore worthwhile to determine the conditions under which the collective interaction of the beam with the plasma is stronger than the interaction with the slow-wave structure.

1. Plasma Instabilities

We consider a circular waveguide of radius a filled with a plasma of density n_p. A fixed magnetic field H_0 is imposed along the axis of the waveguide. A relativistic electron beam with density $n_b(r)$ = const and radius equal to that of the waveguide moves at a velocity v_0 parallel to the axis of the system. Solving Eqs. (1) and (2), we find the following equations for the longitudinal field components:

$$E_z = \sum_{s=1}^{2} A_s J_m(k_s r), \quad H_z = \sum_{s=1}^{2} B_s J_m(k_s r),$$

where k_s is the transverse wave number, which satisfies the biquadratic equation

$$Ak_s^4 + Bk_s^2 + C = 0, \tag{6}$$

where

$$A \equiv \varepsilon_1 - \frac{\omega_{b\perp}^2 (1 - \beta_0^2 \varepsilon_1)}{(\omega_x^2 - \omega_{Hb}^2)},$$

$$B \equiv -k_{\perp p}^2 \left[\frac{\omega_{b\parallel}^2}{\omega_x^2} + \frac{\omega_{b\perp}^2 (1 - \beta_0^2 \varepsilon_1)}{\omega_x^2 - \omega_{Hb}^2}\right] + (\varepsilon_1 + \varepsilon_3)\left[k_{\perp p}^2 + \frac{\omega_{b\perp}^2 \omega_x^2}{(\omega_x^2 - \omega_{Hb}^2) c^2}\right]$$
$$- \frac{\omega_{b\perp}^2 \omega_{b\parallel}^2}{(\omega_x^2 - \omega_{Hb}^2) c^2} - \frac{\omega_{b\perp}^4 (1 - \beta_0^2 \varepsilon_1)}{(\omega_x^2 - \omega_{Hb}^2) c^2}$$
$$+ \varepsilon_2 \left[k^2 \varepsilon_2 \left(1 + \frac{\omega_{b\perp}^2 \beta_0^2}{\omega_x^2 - \omega_{Hb}^2}\right) - 2k \frac{\omega_{b\perp}^2 \omega_{Hb}}{(\omega_x^2 - \omega_{Hb}^2) c}\right],$$

$$C \equiv \left(\varepsilon_3 - \frac{\omega_{b\parallel}^2}{\omega_x^2}\right)\left\{k_{\perp p}^4 + (2k_{\perp p}^2 c^2 + \omega_{b\perp}^2) \frac{\omega_{b\perp}^2 \omega_x^2}{(\omega_x^2 - \omega_{Hb}^2) c^4}\right.$$
$$\left. + \varepsilon_2 k^2 \left[\frac{2\omega_{b\perp}^2 \omega_x \omega_{Hb}}{(\omega_x^2 - \omega_{Hb}^2) c^2} - \varepsilon_2 k^2\right]\right\},$$

$$k_{\perp p}^2 \equiv k_s^2 - k^2 \varepsilon_1, \quad \omega_x \equiv \omega - k_z v_0, \quad \omega_{Hb} \equiv \frac{eH_0}{m_0 \gamma c}.$$

In the case of a limited gyrotropic beam–plasma waveguide an equation for the spectrum of transverse wave numbers can be derived from the condition that the tangential components of the electromagnetic field vanish at the waveguide wall:

$$J_m(k_1 a) = \frac{R_1 k_1 a J_m(k_2 a) J_m'(k_1 a)}{m (P_2 - P_1) J_m(k_2 a) + R_2 k_2 a J_m'(k_2 a)} \tag{7}$$

(we omit the equations for P_s and R_s because of their length). Together with (6) this equation determines the dispersion of the characteristic modes of the system. To find analytic solutions of (6) and (7), we consider the limiting cases of strong and weak external magnetic fields.

a. Strong magnetic field. The magnetic field is such that the inequalities $\omega_p^2 \ll \omega_{Hp}^2$ and $\omega^2 \ll \omega_{Hp}^2$ are satisfied.

Expanding (6) and (7) in terms of these small parameters, we find the frequency spectrum of the waves in the absence of a beam:

$$\omega_{0H}^2 = \omega_p^2 \left\{\left(1 - \frac{\gamma^2}{N_s}\right) + \frac{\omega_p^2}{\omega_{Hp}^2} \gamma^4 \frac{(\gamma^2 + 2)}{N_s}\right\}, \tag{8}$$

where

$$N_s \equiv \frac{4\pi r_0 n_p a^2}{\lambda_{s\infty}^m}, \quad J_m(\lambda_{s\infty}) = 0.$$

We see from this equation that there exists a threshold density per unit length of the beam above which the beam becomes influential. At $N_s < \gamma^2$, in which case the phase velocity of the wave is lower than the beam velocity, and the condition $V_\Phi = V_0$ does not hold,[22,23] the Cerenkov instability does not occur.[3)]

It follows from (8) that in the relativistic case with high-frequency waves ($\omega^2 \gg \omega_{Hp}^2 m_0/M_0$, where m_0 and M_0 are the electron and ion masses), the beam can be considered magnetized only in strong magnetic fields, for which the inequality $\omega_p^2 \gamma^4 \ll \omega_{Hp}^2$ holds. Analysis of Eq. (6) shows that the off-diagonal (gyrotropic) components of tensor $\hat{\varepsilon}_{ik}$ make the most important contribution to the dispersion of relativistic waves of a plasma waveguide in a strong field.

The corrections to (8) due to the finite beam current lead to the growth rate

$$\delta = \frac{3^{1/2}}{2^{4/3}} \omega_{0H} \left(\frac{\omega_{b\parallel}^2}{\omega_{0H}^2}\right)^{1/3}. \tag{9}$$

b. Weak magnetic field. We assume that the magnetic field is such that the inequalities $\omega_{Hp}^2/\omega_p^2 = \mu \ll 1$ and $(\omega - \omega_p)/\omega_p = \eta \ll 1$ hold.

Expanding (6) in terms of these small parameters, we find $k_1^2 a^2 = \lambda_s^2$,

$$\eta(\mu) = \mu/[2(1 + N_s)^2], \quad a^2 k_2^2 = -N/(2 + N_s), \tag{10}$$

where $N \equiv \omega_p^2 a^2/c^2$, and $N_s \equiv N/\lambda_s^2$.

The spectrum of this system is thus governed by the single parameter λ_s, which must be found from dispersion relation (7). In this particular limiting case this dispersion relation can be reduced to

$$\frac{\lambda_s J_m'(\lambda_s)}{J_m(\lambda_s)} = \frac{\varkappa_s^2 I_m'(\varkappa_s a)}{I_m(\varkappa_s a)} \frac{\gamma^2 (1 + N_s) - \varkappa_s^2}{\gamma^2 (1 + N_s) - \lambda_s^2}, \tag{11}$$

where $\varkappa_s^2 \equiv \lambda_s^2 N_s/(2 + N_s)$.

Knowing the solutions λ_s of transcendental equation (11), we can easily calculate the frequencies of the waves excited by the beam in this system and the corresponding growth rates:

$$\omega_{0s}^2 = \omega_p^2 \left[1 + \frac{\omega_{Hp}^2}{\omega_p^2} \frac{1}{(1 + N_s)^2}\right], \tag{12}$$

$$\left.\begin{aligned} &\delta = \frac{3^{1/2}}{2^{4/3}} \omega_p \left(\frac{\omega_{bs}^2}{\omega_p^2}\right)^{1/3} \left[\frac{N_s^2 (2 + N_s)}{2(1 + N_s)^2}\right]^{1/3}, \\ &1 \gg \frac{\omega_{Hp}^2}{\omega_p^2} \gg \left(\frac{n_b}{n_p}\right)^{1/3} \frac{1}{\gamma}\left[1 + \gamma\left(\frac{n_b}{n_p}\right)^{1/3}\right]. \end{aligned}\right\} \tag{13}$$

In the case of a weak magnetic field the frequencies of the excited waves are concentrated near the upper hybrid frequency,[27] and the growth rates are of the same order of magnitude as those for a strong external magnetic field.

2. Budker Instabilities of a Bounded Relativistic Beam in the Absence of an External Magnetic Field

A high-current electron beam held in an equilibrium state by the charge of the ion background ($n_+ = n_b/\gamma^2$) can be unstable with respect to the excitation of ion waves. The corresponding analysis for the case of an infinitely strong external magnetic field ($\omega_{Hi}^2 \gg \omega^2$) is given in ref. 22. We consider the stability of an electron beam neutralized by an ion background in the absence of an external magnetic field.

We consider a bounded relativistic electron beam of radius a moving along the z axis through an ion background whose density is radially homogeneous, $n_+ \equiv n_b/\gamma^2$. Assuming $\hat{\varepsilon}_{ik} = \delta_{ik}\varepsilon_+$ [$\varepsilon_+ \equiv 1 - 4\pi e^2 n_+/(M_0\omega^2)$, where M_0 is the ion mass] in Eqs. (1) and (2) for this case, and incorporating the surface currents[28] in the boundary conditions at $r = a$, we find the dispersion relation (m = 0):

$$\left.\begin{aligned} &F_0 \frac{I_1(\varkappa_1 a)}{\varkappa_1 a I_0(\varkappa_1 a)} = \frac{K_1(k_\perp a)}{k_\perp a K_0(k_\perp a)},\\ &F_0 \equiv \nu\left\{1 + \frac{\beta_0^2\omega_{b\perp}^2(1-\varepsilon_+)}{\varepsilon_+\omega_z^2 - \omega_{b\perp}^2(1-\beta_0^2\varepsilon_+)}\right\} \equiv \nu\frac{\varkappa_1^2}{\varkappa^2},\\ &\varkappa^2 \equiv k_s^2 - k^2\varepsilon_+ + \frac{\omega_{b\perp}^2}{c^2}, \quad \nu \equiv \frac{\omega_{b\perp}^2}{\omega_z^2} - \varepsilon_+\left(1 + \frac{\beta_0^2\omega_{b\perp}^2}{\omega_z^2}\right). \end{aligned}\right\} \tag{14}$$

This equation has two kinds of solutions, corresponding to the surface modes and volume modes. The fields of the volume modes are oscillatory in the radial direction and the corresponding dispersion relation is

$$\varkappa_1^2 a^2 = -\lambda_s^2. \tag{15}$$

The field of the surface waves decays toward the waveguide axis, $\varkappa_1^2 > 0$, so these waves can exist only at values of the parameters such that the condition $F_0 > 1$ is satisfied.

It can be shown that at beam-particle densities (per unit length) such that $\omega_{b\perp}^2 a^2 \ll c^2\lambda_s^2$ the solutions of (15) are concentrated near the pole $\varkappa_1^2 a^2$ and are given by (cf. refs. 22, 29)

$$\left.\begin{aligned} &k_s = \pm\omega_{bs}/v_0, \quad \delta = \frac{3^{1/2}}{2^{4/3}}\omega_{bs}\left(\frac{m_0}{M_0}\gamma^3\right)^{1/3},\\ &m_0\gamma^3 \ll M_0, \quad \operatorname{Re}\omega \sim \delta. \end{aligned}\right\} \tag{16}$$

The growth rate in (16) is of the same order as the analogous quantity for the case of a strong longitudinal magnetic field.[22] The explanation is that in the absence of a magnetic field the increase in the growth rate due to the transverse mass of the beam electrons[21] is offset by a corresponding decrease in the density of the ion background ($n_+ \equiv n_b/\gamma^2$).

Analysis of Eq. (14) shows that the corresponding results for surface waves in the case $k_\parallel a \ll 1$ differ from the results in (16) only by corrections of order $k_\parallel^2 a^2$.

The growth rate of the volume modes is a weak function of the index of the azimuthal harmonic; hence axially asymmetric modes (m = ± 1) are also characterized by growth rates of the order of (16).

Since the radial defocusing force does not vanish for m = ± 1,

$$\left.\begin{aligned} &F_r = e(E_r - \beta_0 H_\varphi) \simeq \frac{ie(k\beta_0\varepsilon_+ - k_s)}{\varkappa^2}\frac{\partial E_z}{\partial r},\\ &\frac{F_r}{eA_r} = \frac{c\lambda_s}{\gamma\omega_{b\perp}a}J_0(\lambda_s) \gg 1, \quad J_1(\lambda_s) = 0, \end{aligned}\right\} \tag{17}$$

this wave defocuses the beam, as in the case of a collective interaction of the beam with the structure, considered above. This steady state is thus disrupted by the onset of a transverse instability. Comparison of (16) with the analogous result for the firehose instability[30,31] shows that the transverse instability, in contrast with the firehose instability, can appear even if there is no spread in transverse velocities ($\langle\Theta\rangle = 0$); in the case $\langle\Theta\rangle \neq 0$, the growth rate turns out to be larger than that of the firehose instability[32] when the inequality $\langle\Theta\rangle < (\omega_{b\perp}a/c)(M_0 - m_0)^{1/6}$ is satisfied.

CONCLUSION

This analysis thus shows that collective Cerenkov excitation of waveguide and plasma waves can occur in this system.

In a strong external magnetic field ($\omega_p^2\gamma^4 \ll \omega_{Hp}^2$), plasma waves can be excited only at sufficiently large densities per unit length of the plasma ($\omega_0^2 \geq \omega_{sk}^2 = \omega_0^2 + \gamma^2c^2\lambda_1^2/a^2$); at lower densities, the beam interacts only with the slow-wave structure, if the disk radius is not too large ($\omega_0 b < \gamma c$). At strong, but finite magnetic fields the most important contribution to the change in the dispersion characteristics of the plasma waveguide at relativistic phase velocities comes from the plasma gyrotropy, $\varepsilon_2 \neq 0$ [see Eqs. (6)-(8)]. In the case of a relatively weak external field ($\omega_{Hp}^2 \ll \omega_0^2$) the spectrum of excited frequencies is concentrated near the upper hybrid frequency [Eq. (12)]; as the plasma density is reduced the corresponding frequencies and growth rates decrease, so that the transition to the excitation of waveguide modes occurs at the plasma density n_{pcr} found from the condition $\delta_{volum}(n_{pcr}) = \delta_{str}(\omega_0)$: $n_{pcr} = \omega_0^2 m_0/(4\pi e^2)$.

In the absence of an external magnetic field the beam particles can move along straight trajectories in the equilibrium state only at the equilibrium density of the ion background, $n_+ = n_b/\gamma^2$. An equilibrium state of this type is unstable against excitation of an axially asymmetric mode of a limiting waveguide [see (5)], which throws the beam against the walls of the waveguide as it builds up. If the radius of the limiters is large enough so that there is no collective interaction between the beam and the limiting waveguide, the beam is unstable against collective excitation of waves of the ion background. The corresponding growth rates are comparable to those of Budker waves (cf. refs. 22, 29). The excitation of an axially asymmetric wave of this type also defocuses the beam.

This analysis has been based on the hydrodynamic approximation and has neglected the thermal spread in the energies of the beam particles and the increase in the plasma-density gradient over the cross section and the length of the waveguide.[32,33] The results can thus be used to evaluate the practical use of the beam–plasma interaction under optimum conditions, i.e., when the gradients and thermal energy spread are small.

---

1) The possibilities of using relativistic beams in vacuum electron systems are examined in refs. 5 and 6.

2) In the relativistic case ($\gamma \gg 1$) the kinetic effects are important only at relatively low currents.

3) Excitation of a plasma by a relativistic beam is also studied in refs. 24-26.

Local-potential study of the Bénard problem in a homogeneous magnetic field

A. I. Lopushanskaya and V. N. Kapranov

Chernovtsy State University

(Submitted August 2, 1973)
Zh. Tekh. Fiz., 44, 965-970 (May 1974)

A variational procedure related to the concept of a local potential is used to solve the Bénard problem in a homogeneous magnetic field for the case of fixed boundaries.

Steady states are usually established when time-independent boundary conditions are imposed on a system; whether these states are stable or unstable depends on the kinetics of the process and the imposed constraints. Since only stable states can actually be observed those are the ones of practical interest.

For motion to be stable any small perturbation must be damped; if an arbitrarily small perturbation grows in time, the system is absolutely unstable and cannot exist.

Thermodynamic approaches are being used with increasing frequency in stability studies; the approach we use below, the potential method, is of this class.[1-3]

We consider a thin layer of an electrically neutral, incompressible, conducting fluid of thickness d, in gravitational and homogenous magnetic fields, which is heated from below. The liquid is unpolarizable, and the displacement current is negligible. We use the Maxwell equations

$$\left.\begin{aligned} &\frac{\partial H_i}{\partial x_i}=0,\\ &\varepsilon_{ijk}\frac{\partial}{\partial x_j}H_k=4\pi I_1,\\ &\varepsilon_{ijk}\frac{\partial}{\partial x_j}E_k=-\mu\frac{\partial H_i}{\partial t}\end{aligned}\right\}\qquad(1)$$

and introduce the dimensionless variables

$$x_i=\frac{x_i}{d},\ v_i=v_i\frac{d}{\nu},\ t=t\frac{\nu}{d^2};\ H_i=\frac{H_i}{H^+};\ T=\frac{T}{\Delta T}.\qquad(2)$$

The balance equations for the mass, momentum, internal energy, and magnetic field take the following form in the Boussinesq approximation:[4]

$$\left.\begin{aligned} &\frac{\partial v_i}{\partial x_i}=0,\\ &P_1\frac{\partial V_i}{\partial t}+P_1V_j\frac{\partial V_i}{\partial x_j}-\frac{P_1}{P_2}QH_j\frac{\partial H_i}{\partial x_j}=-\frac{\partial}{\partial x_i}\left(P+\frac{P_1}{P_2}Q\frac{H^2}{2}\right)\\ &\qquad+P_1\nabla^2v_i+\frac{d^3}{\sigma x}(1+\alpha\Delta T)F_i,\\ &P_1\frac{\partial T}{\partial t}+P_1\frac{\partial T}{\partial x_j}V_j=\nabla^2T,\\ &P_1\frac{\partial H_i}{\partial t}=P_1H_j\frac{\partial V_i}{\partial x_j}+\frac{P_1}{P_2}\nabla^2H_i,\end{aligned}\right\}\qquad(3)$$

where V_i and H_i are the components of the barycentric velocity and the magnetic field intensity, ρ is the density, P is the pressure, μ is the permeability, $\varkappa$ is the thermal diffusivity, σ is the electrical conductivity, α is the thermal-expansion coefficient, ΔT is the temperature differential between the lower and upper boundaries, ν is the kinematic viscosity, ε_{ijk} is a unit antisymmetric tensor of rank 3 and

$$P_1=\frac{\nu}{\varkappa},\quad P_2=\frac{\nu}{\eta}=4\pi\sigma\nu\mu;\quad Q=\frac{\mu(H^+)^2}{4\pi\rho\nu\eta}d^2,\quad H^+=H_z.$$

We consider the stability of the steady state of a quiescent fluid layer between two fixed surfaces at temperatures T_0 and T_1, in a homogeneous magnetic field along the x axis; the state is described by

$$\left.\begin{aligned} &H_i^{st}=\lambda_i,\\ &T^{st}=T_0-z,\\ &\frac{\rho^{st}}{\rho_0}=[1-\alpha\Delta T(T^{st}-T_0)],\end{aligned}\right\}\qquad(4)$$

where T_0 and ρ_0 are the temperature and density at the lower boundary and where

$$\boldsymbol{\lambda}=\{0,0,1\}.$$

Setting

$$\left.\begin{aligned} &V_i=u_i,\quad H_i=H_i^{st}+h_i,\quad P=P^{st}+\delta P;\\ &T=T^{st}+\theta,\quad \rho=\rho^{st}+\delta\rho,\end{aligned}\right\}\qquad(5)$$

we find a system of equations for the perturbed motion:

$$\left.\begin{aligned} &\frac{\partial u_i}{\partial x_i}=0,\\ &P_1\frac{\partial\theta}{\partial t}-P_1u_i\lambda_i=\nabla^2\theta,\\ &P_1\frac{\partial u_i}{\partial t}=\frac{\partial}{\partial x_i}\left(\delta P+\frac{P_1}{P_2}Q\lambda_ih_i\right)+R\lambda_i\theta+P_1\nabla^2u_i+\frac{P_1}{P_2}Q\lambda_j\frac{\partial h_i}{\partial x_j},\\ &P_1\frac{\partial h_i}{\partial t}=P_1\lambda_j\frac{\partial u_i}{\partial x_j}+\frac{P_1}{P_2}\nabla^2h_i\end{aligned}\right\}\qquad(6)$$

where $R=d^3\Delta T\alpha g/\nu\varkappa$ is the Rayleigh number.

Taking the curl of the second equation twice and multiplying λ_i, we find

$$\left.\begin{aligned} &P_1\frac{\partial}{\partial t}\nabla^4u_z=R\left(\frac{\partial^2\theta}{\partial x^2}+\frac{\partial^2\theta}{\partial y^2}\right)+P_1\nabla^4u_z+\frac{P_1}{P_2}Q\frac{\partial}{\partial z}\nabla^2h_z,\\ &P_1\frac{\partial\theta}{\partial t}-P_1u_z=\nabla^2\theta,\\ &P_1\frac{\partial h_z}{\partial t}=P_1\frac{\partial u_z}{\partial z}+\frac{P_1}{P_2}\nabla^2h_z.\end{aligned}\right\}\qquad(7)$$

Substituting the perturbations

$$A_z=A(z)\cos k_xx\cos k_yy\exp\beta t$$

into (7), we find

$$\left.\begin{aligned} &P_1(D^2-k^2)(D^2-k^2-\beta)u+\frac{P_1}{P_2}QD(D^2-k^2)h=k^2R\theta,\\ &(D^2-k^2-P_1\beta)\theta=-P_1u,\\ &(D^2-k^2-P_2\beta)h=-P_2Du,\end{aligned}\right\}\qquad(8)$$

where $D^n=d^n/dz$ and $k^2=k_x^2+k_y^2$. The solution of this equation must satisfy the boundary conditions

$$\theta=u=h=0,\ Du=0\ \text{at}\ z=0,\ z=1.$$

The steady state described by (4) is unstable if $\mathrm{Re}\,\beta>0$ and stable if $\mathrm{Re}\,\beta<0$; the case $\mathrm{Re}\,\beta=0$ corresponds to the state of neutral stability, which separates the regions of stability and instability. If $\mathrm{Im}\,\beta=0$ (if the principle of the exchange of stabilities holds), the critical state is a steady state; otherwise, it is oscillatory.

When the principle of the exchange of stabilities holds, we find, by setting $\beta = 0$ in (8),

$$\left.\begin{aligned} P_1(D^2-k^2)^2u+\frac{P_1}{P_2}QD(D^2-k^2)h&=Rk^2\theta,\\ (D^2-k^2)\theta&=-P_1u,\\ (D^2-k^2)h&=-P_2Du; \end{aligned}\right\} \tag{9}$$

substituting the second equation into the first, we can reduce this system to

$$\left.\begin{aligned} P_1[(D^2-k^2)^2-QD^2]u&=+k^2R\theta,\\ (D^2-k^2)\theta&=-P_1u \end{aligned}\right\} \tag{10}$$

with the boundary conditions

$$\theta=u=Du=0 \quad\text{at}\quad z=0,\ z=1.$$

As a rule it is difficult or even impossible to find the exact eigenfunctions and eigenfrequencies, so we use a variational procedure which involves the concept of a local potential, a characteristic feature of which is a functional dependence on two types of variables: average and fluctuating.[5]

By definition,[2,6] a functional $\Phi(A_i, A_{i0}) = \int dVL(A_i, A_{i0})$ is a local potential if

$$\Phi(A_{i1}, A_{i0})-\Phi(A_{i0}, A_{i0})=\Delta\Phi>0 \tag{11}$$

and

$$\left(\frac{\delta L}{\delta A_i}\right)_{A_{i0},A_k}=0 \quad\text{for}\quad A_i=A_{i0}, \tag{12}$$

where i = 1, 2, ... denotes the differential equation of the original problem.

To find the local potential we multiply the second, third, and fourth equations in (6) by $-\delta\theta$, $-\delta u_i$, and $-\delta h_i$, respectively. We then combine them and integrate over the volume of the system. Using the boundary conditions and the equation

$$A_i=A_{i0}+\delta A_i, \tag{13}$$

and integrating by parts, we find the desired functional (the local potential):

$$\begin{aligned} \Phi=\int dV\Big\{&-\Big(\delta P_0+\frac{P_1}{P_2}\lambda_j h_{j0}Q\Big)\frac{\partial u_i}{dx_i}-R\theta_0\lambda_i u_i+\frac{P_1}{2P_2}\Big(\frac{\partial}{\partial x_j}h_i\Big)^2\\ &+\frac{P_1}{2}\Big(\frac{\partial u_i}{\partial x_j}\Big)^2+\frac{P_1}{P_2}Q\lambda_j h_{i0}\frac{\partial u_i}{\partial x_j}+\frac{1}{2}\Big(\frac{\partial\theta}{\partial x_j}\Big)^2+P_1\lambda_j u_{i0}\frac{\partial h_i}{\partial x_j}\\ &+P_1\Big[h_i\frac{\partial h_{i0}}{\partial t}+u_i\frac{\partial u_{i0}}{\partial t}+\theta_0\frac{\partial\theta}{\partial t}\Big]-P_1u_{i0}\lambda_i\theta\Big\}. \end{aligned} \tag{14}$$

We note that

$$\left.\begin{aligned} \Big(\frac{\partial L}{\delta u_i}\Big)_{h_i,\theta,u_{i0}}&=0=\frac{\partial}{\partial x_i}\Big(\delta P+\frac{P_1}{P_2}Q\lambda_i h_j\Big)_0-R\theta_0\lambda_i-P_1\nabla^2u_i\\ &\qquad-\frac{P_1}{P_2}Q\lambda_j\frac{\partial h_{i0}}{\partial x_j}+P_1\frac{\partial u_{i0}}{\partial t},\\ \Big(\frac{\delta L}{\delta\theta}\Big)_{h_i,u_i,\theta_0}&=0=-P_1u_{i0}\lambda_i-\nabla^2\theta_0+P_1\frac{\partial\theta_0}{\partial t},\\ \Big(\frac{\partial L}{\delta h_i}\Big)_{h_{i0},\theta,u_i}&=0=-P_1\lambda_j\frac{\partial u_{i0}}{\partial x_j}-\frac{P_1}{P_2}\nabla^2h_i+P_1\frac{\partial h_{i0}}{\partial E}, \end{aligned}\right\} \tag{15}$$

or the same as system (6) for $A_i = A_{i0}$.

Integrating the terms linear in $\delta\theta$, δu_i, and δh_i by parts, using (15), and the fact that the variations of the state variables vanish at the boundary, we find

$$\Delta\Phi=\frac{1}{2}\int\Big[\frac{P_1}{P_2}\Big(\frac{\partial\delta h_i}{\partial x_j}\Big)^2+\Big(\frac{\partial\delta\theta}{\partial x_j}\Big)^2+P_1\Big(\frac{\partial\delta u_i}{\partial x_j}\Big)^2\Big]dV>0. \tag{16}$$

Substituting the perturbations[4]

$$\left.\begin{aligned} u_z=u(z)\cos k_x x\cos k_y ye^{\beta t},\quad h_1&=h(z)\cos k_x x\cos k_y ye^{\beta t},\\ u_x&=-\frac{k_x}{k^2}Du\sin k_x x\cos k_y ye^{\beta t},\\ h_x&=-\frac{k_x}{k^2}Dh\sin k_x x\cos k_y ye^{\beta t},\\ u_y&=-\frac{k_y}{k^2}Du\cos k_x x\sin k_y ye^{\beta t},\\ h_y&=-\frac{k_y}{k^2}Dh\cos k_x x\sin k_y ye^{\beta t},\\ \theta&=\theta(z)\cos k_x x\cos k_y ye^{\beta t}. \end{aligned}\right\} \tag{17}$$

into (14) (analogous equations are written for the quantities not being varied), we find

$$\begin{aligned} \Phi=\int dz\Big\{&-R\theta_0u+\frac{P_1}{2}\Big[k^2u^2+\frac{1}{k^2}(D^2u)^2+2(Dh)^2\Big]\\ &-P_1u_0\theta+\frac{P_1}{2P_2}\Big[k^2h^2+\frac{1}{k^2}(D^2h)^2+2(Du)^2\Big]\\ &-\frac{P_1}{k^2}(D^2-k^2)hDu_0+\frac{1}{2}[k^2\theta^2+(D\theta)^2]-\frac{P_1}{P_2k^2}Q(D^2-k^2)h_0Du\\ &+P_1\beta_0\Big[\theta_0\theta+u_0u+h_0h+\frac{1}{k^2}Du_0Du+\frac{1}{k^2}Dh_0Dh\Big]\Big\}, \end{aligned} \tag{18}$$

whose Euler–Lagrange equations are the equations of system (8), with the auxiliary conditions $A_i = A_{i0}$; or

$$\begin{aligned} \Phi_1=\int dz\Big\{&-R\theta_0u+\frac{P_1}{2}\Big[k^2u^2+\frac{1}{k^2}(D^2u)^2+2(Du)^2\Big]\\ &+\frac{P_1}{2P_2}\Big[k^2h^2+\frac{1}{k^2}(D^2h)^2+2(Dh)^2\Big]-\frac{P_1}{k^2}(D^2-k^2)hDu_0-P_1u_0\theta\\ &-\frac{P_1}{k^2P_2}Q[D^2-k^2]h_0Du+\frac{1}{2}[k^2\theta^2+(D\theta)^2]\Big\}, \end{aligned} \tag{19}$$

corresponding to (9).

Integrating the term $(Dh)^2$ by parts, and setting h equal to zero at the boundary, we find

$$[k^4h^2-2k^2D^2hh+(D^2h)^2]=[k^2h-D^2h]^2=[(D^2-k^2)h]^2. \tag{20}$$

Accordingly, by using the third equation in system (9) to eliminate the terms containing the magnetic field, we find the local potential

$$\begin{aligned} \Phi_2=\int dz\Big\{&-R\theta_0u+\frac{P_1}{2}\Big[k^2u^2+\frac{1}{k^2}(D^2u)^2+2(Du)^2\Big]+\frac{P_1P_2}{2k^2}(Du)^2\\ &-\frac{P_1P_2}{k^2}DuDu_0+\frac{P_1}{k^2}QDu_0Du+\frac{1}{2}(k^2\theta^2+(D\theta)^2\Big\} \end{aligned} \tag{21}$$

of problem (10), or because with $u_0 = u$, we have $\theta = \theta_0$, so that

$$\Big(\frac{\delta L_1}{\delta u}\Big)_{u_0,\theta}=-R\theta_0+P_1k^2u_0+\frac{P_1}{k^2}D^4u_0-2P_1D^2u_0-\frac{P_1}{k^2}QD^2u_0=0, \tag{22}$$

$$\Big(\frac{\delta L_2}{\delta\theta}\Big)_{u,\theta_0}=P_1u_0+k^2\theta_0-D^2\theta_0=0; \tag{23}$$

setting

$$\theta=\theta_0+\delta\theta,$$
$$u=u_0+\delta u$$

TABLE 1. Critical Values of the Wave Numbers and Rayleigh Numbers

Q	k_{cr}	R	R [4]	$\frac{\Delta R}{R}$, %	$\frac{R}{R_1}$
0	3.117	1750	1707.8	2.45	1
10	3.26	1996.7	1945.9	2.62	1.14
50	3.69	2906.8	2802.1	3.71	1.66
100	4.00	3950	3757.4	5.13	2.26
200	4.46	5856	5488.6	6.68	3.36
500	5.21	11200	10119	10.7	6.4
1000	5.9	19445	17103	13.58	11.1
2000	6.68	34993	30125	16	20
4000	7.56	64752	54697	18.38	37
6000	8.13	93674	78391	19.5	53.5
8000	8.55	122137	101606	20.2	69.79
10000	8.9	150292	124509	20.7	85.88

and using (22), (23), and the boundary conditions, we find

$$\Delta\Phi_2 = \int dz \left\{ \frac{P_1}{2}\left[k^2(\delta u)^2 + \frac{(D^2\delta u)}{k^2} + 2\,(D\delta u)^2\right] + \frac{P_1P_2}{2k^2}(D\delta u)^2 + \frac{1}{2}\left[k^2(\delta\theta)^2 + (D\delta\theta)^2\right]\right\} > 0. \qquad (24)$$

We specify the unknown functions to be of the form

$$\left.\begin{aligned} u = A\,(1-z)^2 z^2, \quad u_0 = A_0\,(1-z)^2 z^2,\\ \theta = B\,(1-z)\,z, \quad \theta_0 = B_0\,(1-z)\,z, \end{aligned}\right\} \qquad (25)$$

where the constants A and B are governed by the conditions

$$\left.\begin{aligned} \left(\frac{\partial\Phi_2}{\partial A}\right)_{B_0, A_0, B} = 0\\ \left(\frac{\partial\Phi_2}{\partial B}\right)_{A_0, A, B_0} = 0 \end{aligned}\right\} \quad \begin{aligned} A_0 = A,\\ B_0 = B. \end{aligned} \qquad (26)$$

We thus find the following system of linear, homogeneous algebraic equations:

$$\left.\begin{aligned} P_1\left[\frac{4}{5k^2} + \frac{4}{105} + \frac{k^2}{630} + \frac{2Q}{105k^2}\right]A - \frac{R}{140}B = 0,\\ -\frac{P_1}{140}A + \frac{1}{3}\left[\frac{k^2}{10} + 1\right]B = 0, \end{aligned}\right\} \qquad (27)$$

which have a nontrivial solution if

$$\left[\frac{4}{5x} + \frac{4}{105} + \frac{2Q}{105x} + \frac{x}{630}\right]\left[\frac{x}{30} + \frac{1}{3}\right] = \frac{R}{(140)^2} \qquad (28)$$

$(x = k^2)$.

Equation (28) gives the values of the Rayleigh numbers corresponding to the stability limit as a function of the wave number k and the parameter Q, related to the magnetic field. The Rayleigh number determined for a fixed Q and for the critical wave number is lower than for all other wave numbers, and it determines the largest temperature gradients which do not disrupt the stability of the system.

The critical wave number is found from the condition dR/dx = 0. Differentiating (28) we find

$$x^3 + 17x^2 - 60\,(42 + Q) = 0. \qquad (29)$$

Table 1 shows the solutions of Eqs. (29) and (28), along with data obtained through the use of a variational formulation of the classical structure. However, finding a variational functional for which the characteristic-value problem is written in the form of the corresponding Euler–Lagrange equations in the latter case is actually more heuristic than an approach based on physical principles; hence, certain unique difficulties arise in each problem. On the other hand, the variational formulation based on the local-potential concept is extremely general in nature and can be used to solve a broad class of problems, including nonlinear and non-self-adjoint problems.[7]

We see from this table that even the first approximation gives comparatively satisfactory results, at least up to Q = 500, at which point the critical temperature gradient is six times above the Bénard point in the absence of a magnetic field. The agreement could undoubtedly be improved by increasing the number of parameters in the trial functions.

Plasma

Linear theory for the low-frequency electromagnetic properties of an isotropic turbulent plasma

K. Komilov, F. Kh. Khakimov, and V. N. Tsytovich

V. I. Lenin Tadzhik State University, Dushanbe

(Submitted August 29, 1973)
Zh. Tekh. Fiz., 44, 971-976 (May 1974)

The low-frequency electromagnetic properties of an isotropic turbulent plasma are studied. An expression is obtained for the permittivity by expanding the collision integrals of the plasma particles and the fluctuations in terms of the turbulence energy, allowance being made for a weak correlation between the turbulent fluctuations. Spectra are found for the longitudinal perturbations of an isotropic turbulent plasma.

GENERAL STATEMENT OF THE PROBLEM

At the present time, one of the important theoretical and experimental problems of the physics of the turbulent plasma is the study of its electromagnetic properties. The radical changes in the electromagnetic properties of a plasma in the low-frequency region caused by high-frequency turbulence are of great importance; in particular, this is true for low-frequency instabilities, which are the most dangerous from the point of view of plasma containment. The low-frequency properties of a turbulent plasma can be described by means of the electrical conductivity tensor σ_{ij} when an expansion in the turbulence energy W is impossible and one must take account of a continuous series of terms of the expansion in W. A criterion for choosing these is the smallness of the frequency ω and the wave number **k** of the low-frequency perturbation.

The main aim of the present investigation is to find the actual form of the tensor σ_{ij} or the permittivity tensor ε_{ij} as a function of the frequency ω and wave number **k** of the perturbing electromagnetic field[1-4] $\varepsilon_{ij} = \varepsilon_{ij}(\omega, \mathbf{k})$ in a form convenient for investigating the low-frequency properties of the plasma. Let us elucidate the meaning of our physical assumptions. In a turbulent plasma the tensor ε_{ij} depends functionally on the spectral energy density $W_{\mathbf{k}_1}$ of the turbulence,[5,6] which is defined by the equation

$$W = \int W_{\mathbf{k}_1} d\mathbf{k}_1, \tag{1}$$

where W is the total energy of the turbulence per cubic centimeter of plasma.

In what follows, to be specific, we shall consider turbulence due to electron plasma waves. We note that the effective collision frequencies in a turbulent plasma depend on $W_{\mathbf{k}_1}$: $\nu_{\text{eff}} = \nu_{\text{eff}}(W_{\mathbf{k}_1})$.

The problem is to find an analytic form of the low-frequency permittivity tensor of an isotropic turbulent plasma:

$$\varepsilon_{ij} = \varepsilon_{ij}(\omega, \mathbf{k}, W_{\mathbf{k}_1}) \tag{2}$$

for frequencies ω appreciably smaller than ν_{eff}. It can be shown that in this case ε_{ij} cannot be expanded with respect to $W_{\mathbf{k}_1}$. A similar problem for one-dimensional motion of the particles is the subject of ref. 6. These results cannot be transferred directly to the three-dimensional case. The task of the present paper is to construct a theory for the low-frequency properties of longitudinal plasma perturbations suitable for isotropic distributions of the particles and longitudinal turbulent oscillations. To construct the theory we use the method of ref. 7, in which an expansion is made with respect to the turbulence energy in the kernels of the collision integrals and allowance is made for renormalization processes by summing terms with an ever-increasing number of nonlinear interactions. The distribution function f and the longitudinal electric field **E** are split into the sum of turbulent, f^T, $\mathbf{E}^T$, and regular, f^R, $\mathbf{E}^R$, components:

$$f = f^T + f^R, \quad \mathbf{E} = \mathbf{E}^T + \mathbf{E}^R, \tag{3}$$

where $\langle f^T \rangle = 0$, $\langle \mathbf{E}^{T(0)} \rangle = 0$, and the averaging is taken over a statistical ensemble. Further, all the quantities ($\mathbf{E}^T$, $\mathbf{E}^R$, f^T, f^R are expanded with respect to $\mathbf{E}^R$ and the terms linear in $\mathbf{E}^R$ are retained. We give the treatment for longitudinal turbulent perturbations of an isotropic plasma. In contrast to ref. 6, in which the case $H \to \infty$ was considered, we assume $H_0 = 0$ here.

PERMITTIVITY TENSOR FOR AN ISOTROPIC TURBULENT PLASMA

We use the kinetic self-consistent field equation with $H_0 = 0$:

$$\frac{\partial f}{\partial t} + \mathbf{v}\frac{\partial f}{\partial \mathbf{r}} - \frac{e}{m_e}\mathbf{E}\frac{\partial f}{\partial \mathbf{v}} = 0, \tag{4}$$

where **v** is the particle velocity and **E** is the electric field. Using the method described above, from Eq. (4) we obtain a system of equations for the ground turbulent state (superscript (0)] and perturbations of this state (superscript (1)]:

$$-i(\omega - \mathbf{kv}) f_k^{R(1)} - \frac{eE_k^R}{m_e|\mathbf{k}|}\left(\mathbf{k}\frac{\partial \Phi}{\partial \mathbf{v}}\right) - \frac{\partial}{\partial \mathbf{v}}\langle D^* \rangle \frac{\partial \Phi}{\partial \mathbf{v}} = \frac{e}{m_e|\mathbf{k}|}\left(\mathbf{k}\frac{\partial}{\partial \mathbf{v}}\right) \times \int \delta(k - k_1 - k_2)\, dk_1 dk_2 (\langle E_{k_1}^{T(0)} f_{k_2}^{T(1)} + E_{k_1}^{T(1)} f_{k_2}^{T(0)} \rangle), \tag{5}$$

$$\varepsilon(k) E_k^{T(1)} = \frac{4\pi i e}{|\mathbf{k}|} \int f_k^{T(1)} d\mathbf{v}, \tag{6}$$

$$-i(\omega - \mathbf{kv}) f_k^{T(0)} - \frac{e}{m_e|\mathbf{k}|}\left(\mathbf{k}\frac{\partial}{\partial \mathbf{v}}\right) \int \delta(k - k_1 - k_2)\, dk_1 dk_2 \times (E_{k_1}^{T(0)} f_{k_2}^{T(0)} - \langle E_{k_1}^{T(0)} f_{k_2}^{T(0)} \rangle), \tag{7}$$

$$-i(\omega - \mathbf{kv}) f_x^{T(1)} - \frac{e}{m_e|\mathbf{k}|} \int \delta(k - k_1 - k_2)\, dk_1 dk_2 E_{k_1}^{T(0)} \left(\mathbf{k}_1 \frac{\partial f_{k_2}^{R(1)}}{\partial \mathbf{v}}\right) - \frac{\partial}{\partial \mathbf{v}}(D^* - \langle D^* \rangle)\frac{\partial \Phi}{\partial \mathbf{v}} - \frac{e}{m_e|\mathbf{k}_1|}\left(\mathbf{k}_1 \frac{\partial}{\partial \mathbf{v}}\right) \int \delta(k - k_1 - k_2)\, dk_1 dk_2$$

$$\times\left(E^{R}_{k_1} f^{T(0)}_{k_2} + E^{T(0)}_{k_1} \tilde f^{T(1)}_{k_2} - E^{T(1)}_{k_1} \tilde f^{T(0)}_{k_2} - \langle E^{T(0)}_{k_1} \tilde f^{T(1)}_{k_2} + E^{T(1)}_{k_1} \tilde f^{T(0)}_{k_2}\rangle\right) = 0. \tag{8}$$

Here, $\tilde f^{T(0)}_{k}$ and $\tilde f^{T(1)}_{k}$ are the renormalized distribution functions for the turbulent state,[6]

$$D^{*} = i(\omega - \mathbf{kv})\left(\frac{e}{m_e}\right)^2 \int \frac{\delta(k - k_1 - k_2)\, dk_1 dk_2}{(\omega_1 - \mathbf{k}_1\mathbf{v})(\omega_2 - \mathbf{k}_2\mathbf{v})} \frac{(\mathbf{k}_1\mathbf{k}_2)}{|\mathbf{k}_1||\mathbf{k}_2|} E^{T(0)}_{k_1} E^{T(1)}_{k_2} \tag{9}$$

and dk = dkdω. At low frequencies (k → 0) the collision integral in Eq. (5), which contains D*, is much greater than the remaining terms of the right-hand side of Eq. (5). We now derive an equation for D*, taking account of correlation effects and the renormalizations used in ref. 6.

Using Eqs. (6) and (8), we form an expression for $\langle E^{T(0)}_{k_1} E^{T(1)}_{k_2}\rangle$:

$$\varepsilon(k_2)\langle E^{T(0)}_{k_1} E^{T(1)}_{k_2}\rangle + \frac{ie}{m_e}\int dk_1' dk_2' \delta(k_2 - k_1' - k_2')\left(S_{k_2, k_1', k_2'} + \delta S_{k_2, k_1', k_2'}\right)$$
$$\times \langle E^{T(0)}_{k_1} E^{T(0)}_{k_1'} E^{T(1)}_{k_2'}\rangle + \frac{\omega_{pe}^2}{n_0|\mathbf{k}_2||\mathbf{k}_1'|}\int \frac{d\mathbf{v}\,\delta(k_2 - k_1' - k_2')\, dk_1' dk_2'}{\omega_2 - \mathbf{k}_2\mathbf{v}}$$
$$\times\left(\mathbf{k}_1' \frac{\partial}{\partial \mathbf{v}}\right)\left(\langle \tilde f^{T(0)}_{k_1'} E^{T(0)}_{k_1} E^{T(1)}_{k_2'}\rangle + \langle E^{T(0)}_{k_1} E^{T(0)}_{k_1'} \tilde f^{T(1)}_{k_2'}\rangle\right) \equiv G, \tag{10}$$

where

$$S_{k, k_1, k_2} = \frac{\omega_{pe}^2}{n_0|\mathbf{k}||\mathbf{k}_1||\mathbf{k}_2|}\int \frac{d\mathbf{v}}{(\omega - \mathbf{kv})} \frac{(\mathbf{k}_1\mathbf{k}_2)}{(\omega_1 - \mathbf{k}_1\mathbf{v})(\omega_2 - \mathbf{k}_2\mathbf{v})}\left(\mathbf{k}\frac{\partial\Phi}{\partial \mathbf{v}}\right), \tag{11}$$

$$\delta S_{k, k_1, k_2} = \frac{\omega_{pe}^2}{n_0|\mathbf{k}||\mathbf{k}_1||\mathbf{k}_2|}\int \frac{d\mathbf{v}}{(\omega_1 - \mathbf{k}_1\mathbf{v})^2} \frac{[\mathbf{k}_1\mathbf{k}_2]}{(\omega_2 - \mathbf{k}_2\mathbf{v})^2}\Phi.$$

Analysis shows that in the region of phase velocities comparable to those of the plasma waves, in which the instability is considered, $v_p > v_{Te}\sqrt{m_i/m_e}$, the quantity $\delta S_{k,k_1,k_2}$ is smaller than $S_{kk_1k_2}$ by a factor m_e/m_i; therefore (12) can be ignored in what follows.

The right-hand side of (10) does not contain $E^{T(1)}_{k}$, and it can therefore be calculated using (7):

$$G = -\frac{\omega_{pe}^2 J_{k_1}}{n_0|\mathbf{k}_1||\mathbf{k}_2|}\int \frac{d\mathbf{v}}{\omega_2 - \mathbf{k}_2\mathbf{v}}\left(\left(\mathbf{k}_1\frac{\partial f^{R(1)}_{k}}{\partial \mathbf{v}}\right)\right. \tag{12}$$

$$\left. + \frac{ieE^{R}_{k}}{m_0|\mathbf{k}|}\left(\mathbf{k}\frac{\partial}{\partial \mathbf{v}}\right)\frac{1}{(\omega_1 - \mathbf{k}_1\mathbf{v})}\left(\mathbf{k}_1\frac{\partial\Phi}{\partial \mathbf{v}}\right)\right). \tag{13}$$

Making more precise the mean value of the three fields in Eq. (10), using the assumption of a weak correlation of the fields, and splitting the mean value of four fields into binary products, we obtain

$$G = \tilde\varepsilon(k_2)\langle E^{T(0)}_{k_1} E^{T(1)}_{k_2}\rangle - \left(\frac{e}{m_e}\right)^2 J_{k_1}\int dk_1' \tilde\Sigma_{k_2, k_1', -k_1, k-k_2'}$$
$$\times\left(\langle E^{T(0)}_{k_1'} E^{T(1)}_{k-k_1'}\rangle + \langle E^{T(0)}_{k-k_1'} E^{T(1)}_{k_1'}\rangle\right) + \left(\frac{e}{m_e}\right)^2\int dk_2' J_{k_2-k_2'} S_{k_2, k_2', k_2-k_2'}$$
$$\times\frac{1}{\varepsilon(k_1)} S_{k_1, k_2'-k_2, k-k_2'}\langle E^{T(0)}_{k-k_2'} E^{T(1)}_{k_2'}\rangle, \tag{14}$$

where

$$\tilde\Sigma_{k_2, k_1', -k_1, k-k_1'} = \Sigma_{k_2, k_1', -k_1, k-k_1'}$$

$$- S_{k_2, k_1', k_2-k_1'}\frac{1}{\varepsilon(k_2 - k_1')} S_{k_2-k_1'', -k_1, k-k_1'}, \tag{15}$$

$$\tilde\varepsilon(k_2) = \varepsilon(k_2) - \left(\frac{e}{m_e}\right)^2\int J_{k_1'} dk_1' \tilde\Sigma_{k_2, k_1', -k_1', k_2}, \tag{16}$$

$$\Sigma_{k_2, k_1', -k_1, k-k_1'} = \frac{\omega_{pe}^2}{n_0|\mathbf{k}_2||\mathbf{k}_1'||\mathbf{k}_1||\mathbf{k} - \mathbf{k}_1'|}\int \frac{d\mathbf{v}\,(\mathbf{k}_1'\mathbf{k}_2)}{(\omega_2 - \mathbf{k}_2\mathbf{v})^2}\left[\frac{2(\mathbf{k}_1\mathbf{k}_2)}{(\omega_2 - \mathbf{k}_2\mathbf{v})}\right.$$
$$\left. + \frac{\mathbf{k}_1(\mathbf{k}_2 + \mathbf{k}_1')}{\omega_2 + \omega_1' - (\mathbf{k}_2 + \mathbf{k}_1')\mathbf{v}}\right]\frac{1}{(\omega_1 - \mathbf{k}_1\mathbf{v})(\omega - \omega_1' - (\mathbf{k} - \mathbf{k}_1')\mathbf{v})}(\mathbf{k} - \mathbf{k}_1')\frac{\partial\Phi}{\partial \mathbf{v}}. \tag{17}$$

We emphasize that (14) contains the operator $\tilde\varepsilon(k_2)$ and additional terms $\sim J_{k_1}$, which are of the same order as $\tilde\varepsilon(k_2)$ or $\varepsilon(k_2)$. Ignoring the last term of (14), which is equal to zero for nondecay turbulence, we obtain the equation

$$\tilde\varepsilon(k - k_1)\langle E^{T(0)}_{k_1} E^{T(1)}_{k-k_1}\rangle = -\frac{\omega_{pe}^2 J_{k_1}}{n_0|\mathbf{k}_1||\mathbf{k} - \mathbf{k}_1|}$$
$$\times\int \frac{d\mathbf{v}}{(\omega - \omega_1 - (\mathbf{k} - \mathbf{k}_1)\mathbf{v})}\left\{\left(\mathbf{k}_1\frac{\partial f^{R(1)}_{k}}{\partial \mathbf{v}}\right)\right.$$
$$\left. + \frac{ieE^{R}_{k}}{m_e|\mathbf{k}|}\left(\mathbf{k}\frac{\partial}{\partial \mathbf{v}}\right)\frac{1}{\omega_1 - \mathbf{k}_1\mathbf{v}}\left(\mathbf{k}_1\frac{\partial\Phi}{\partial \mathbf{v}}\right)\right\} + \left(\frac{e}{m_e}\right)^2 J_{k_1}\int dk_1'\langle E^{T(0)}_{k_1'} E^{T(1)}_{k-k_1'}\rangle$$
$$\times\left[\tilde\Sigma_{k-k_1, k_1', -k_1, k-k_1'} + \tilde\Sigma_{k-k_1, k-k_1', -k_1, k_1'}\right]. \tag{18}$$

If we solve the integral equation (18), we can also readily find the collision integral that contains ⟨D*⟩. Note that the collision integral on the right-hand side of (5) containing $\langle E^{T(1)}_{k_1} f^{T(0)}_{k_2}\rangle$ is of order W/n_0T_e with respect to the term with D*. This is the justification for only keeping the term with D* on the right-hand side.

We solve the resulting integral equation (18) in the limiting case $|\omega_1 - \omega'_1| \ll |\mathbf{k}_1 - \mathbf{k}'_1| v_{Ti}$, $\omega \ll k_1 v_{Ti}$. From (15), for this case we obtain the following approximate expression for $\tilde\Sigma$:

$$\tilde\Sigma_{k-k_1, k_1', -k_1, k-k_1'} \approx -\frac{\omega_{pe}^2 T_e \mathbf{k}_1'(\mathbf{k}_1' - \mathbf{k})}{(T_e + T_i) v_{Te}^2 |\mathbf{k}_1'||\mathbf{k}_1' - \mathbf{k}|\omega_1\omega_1'(\omega_1' - \omega)(\omega_1 - \omega)}. \tag{19}$$

This result holds for opposite signs of the frequencies ω_1 and ω_1'; when the signs of ω_1 and ω_1' are the same, (19) is equal to zero. Dividing (18) by $\tilde\varepsilon(k - k_1)$, [cf. ref. 6, where $S_\pm$ is different from (20)] we find an equation for

$$S_\pm(k) = \int \frac{\mathbf{k}_1(\mathbf{k}_1 - \mathbf{k})\langle E^{T(0)}_{k_1} E^{T(1)}_{k-k_1}\rangle}{|\mathbf{k}_1||\mathbf{k}_1 - \mathbf{k}|\omega_1(\omega - \omega)} dk_{1,\pm}, \tag{20}$$

where the integration in $S_+(k)$ is over positive frequencies, while in $S_-(k)$ it is over negative frequencies. From Eq. (18) we obtain a linear algebraic system of equations for $S_\pm(k)$; the solution is

$$S_+(k) + S_-(k) = -\left[1 + \frac{\omega_{pe}^4}{4\pi n_0(T_e + T_i)}\right.$$
$$\left.\times\int \frac{\mathbf{k}_1(\mathbf{k}_1 + \mathbf{k}) J_{k_1} dk_1}{|\mathbf{k}_1||\mathbf{k}_1 + \mathbf{k}|\omega_1^2(\omega_1 + \omega)^2\tilde\varepsilon(k_1 + k)}\right]^{-1}$$
$$\times\frac{\omega_{pe}^2}{n_0}\int \frac{\mathbf{k}_1(\mathbf{k}_1 + \mathbf{k}) J_{k_1} dk_1}{|\mathbf{k}_1|^2|\mathbf{k}_1 + \mathbf{k}|^2\omega_1(\omega_1 + \omega)^3\tilde\varepsilon(k_1 + k)}\int \frac{d\mathbf{v}}{(\omega_1 + \omega) - (\mathbf{k}_1 + \mathbf{k})\mathbf{v}}$$
$$\times\left\{\left(\mathbf{k}_1\frac{\partial f^{R(1)}_{k}}{\partial \mathbf{v}}\right) + \frac{ieE^{R}_{k}}{m_e|\mathbf{k}|}\left(\mathbf{k}\frac{\partial}{\partial \mathbf{v}}\right)\frac{1}{(\omega_1 - \mathbf{k}_1\mathbf{v})}\left(\mathbf{k}_1\frac{\partial\Phi}{\partial \mathbf{v}}\right)\right\}. \tag{21}$$

On the other hand, using Eq. (9) to the necessary accuracy we obtain

$$\langle D^{*}\rangle = -i(\omega - \mathbf{kv})\left(\frac{e}{m_e}\right)^2\left(S_+(k) + S_-(k)\right), \tag{22}$$

by means of which the diffusion coefficient can be determined:

$$D_1 = -i\frac{\omega_{pe}^2}{n_0}(\omega - \mathbf{kv})\, n_k^{(1)} \left(\frac{e}{m_e}\right)^2 \int \frac{J_{k_1} dk_1}{\tilde{\varepsilon}(k_1+k)\,\omega_1(\omega_1+\omega)^3}$$
$$\times\left[1 + \frac{\omega_{pe}^4}{4\pi n_0 (T_e+T_i)} \int \frac{\mathbf{k}_1(\mathbf{k}_1+\mathbf{k})\, J_{k_1} dk_1}{|\mathbf{k}_1|\,|\mathbf{k}_1+\mathbf{k}|\,\omega_1^2(\omega_1+\omega)^2\,\tilde{\varepsilon}(k_1+k)}\right]^{-1}. \quad (23)$$

From (23) and (5) we obtain the permittivity of the isotropic plasma in the form

$$\varepsilon(k) = \varepsilon_0^i(k) + (\varepsilon_0^e(k) - 1)\left(1 + \frac{n_0 m_e}{T_e+T_i} d_2\right)$$
$$\times\left(1 + \frac{(\varepsilon_0^e(k)-1)\, n_0 k^2}{\omega_{pe}^2} d_1 - \frac{n_0 m_e}{(T_e+T_i)} d_2\right)^{-1}, \quad (24)$$

where

$$d_1 = \frac{e^2\omega_{pe}^2}{n_0 m_e^2} \int \frac{J_{k_1} dk_1}{\tilde{\varepsilon}(k_1+k)\,\omega_1(\omega_1+\omega)^3}, \quad (25)$$

$$d_2 = \frac{e^2\omega_{pe}^2}{n_0 m_e^2} \int \frac{\mathbf{k}_1(\mathbf{k}_1+\mathbf{k})\, J_{k_1} dk_1}{|\mathbf{k}_1|\,|\mathbf{k}_1+\mathbf{k}|\,\omega_1^2(\omega_1+\omega)^2\,\tilde{\varepsilon}(k_1+k)}. \quad (26)$$

This result differs from the one-dimensional case[6] in that d_2 contains the factor $\frac{\mathbf{k}_1(\mathbf{k}_1+\mathbf{k})}{|\mathbf{k}_1|\,|\mathbf{k}_1+\mathbf{k}|}$.

INSTABILITIES OF LONGITUDINAL TURBULENT FLUCTUATIONS OF AN ISOTROPIC PLASMA

It is well known[6] that there is a radical change of the dispersion properties of an isotropic plasma in the region of low frequencies under the influence of high-frequency perturbations. As an example, let us consider turbulence due to electron plasma waves: $\omega_{\mathbf{k}_1} = \omega_{pe} + (3/2)(k_1^2 v_{Te}^2/\omega_{pe})$. In the region $v_p > (3v_{Te}^2)/v_{Ti}$ the group velocities of the plasmons change slowly. Using this fact and the inequalities $\omega \ll \omega_{\mathbf{k}_1}$, $\mathbf{k} \ll \mathbf{k}_1$, $\frac{\omega}{\mathbf{k}} \ll \frac{\omega_1}{\mathbf{k}}$, $\omega \ll \mathbf{k}_1 v_{Ti}$, we find that (25) and (26) take the approximate form

$$d_1 \approx -\frac{\omega_{pe}^4}{n_0^2 m_e} \int \frac{d\mathbf{k}_1}{(\omega - \mathbf{kv}_g)} \left(\mathbf{k}\frac{\partial}{\partial \mathbf{k}_1}\right) \frac{W_{\mathbf{k}_1}}{\omega_{\mathbf{k}_1}} \left(\frac{\partial}{\partial\omega_1}\omega_1^2\tilde{\varepsilon}(k_1)\right)^{-2}_{\omega_1=\omega_{\mathbf{k}_1}}, \quad (27)$$

$$d_2 \approx -\frac{\omega_{pe}^4}{n_0^2 m_e} \int \frac{d\mathbf{k}_1}{(\omega - \mathbf{kv}_g)} \left(\mathbf{k}\frac{\partial}{\partial \mathbf{k}_1}\right) \frac{W_{\mathbf{k}_1}}{\omega_{\mathbf{k}_1}} \left(\frac{\partial}{\partial\omega_1}\omega_1^2\tilde{\varepsilon}(k_1)\right)^{-2}_{\omega_1=\omega_{\mathbf{k}_1}}$$
$$+ \frac{\omega_{pe}^4}{n_0^2 m_e} \int \frac{(\mathbf{kk}_1)}{k_1^2} \frac{W_{\mathbf{k}_1} d\mathbf{k}_1}{(\omega - \mathbf{kv}_g)\,\omega_{\mathbf{k}_1}} \left(\frac{\partial}{\partial\omega_1}\omega_1^2\tilde{\varepsilon}(k_1)\right)^{-2}_{\omega_1=\omega_{\mathbf{k}_1}}, \quad (28)$$

where $\mathbf{v}_g = (\partial\omega_{\mathbf{k}_1}^l)/\partial\mathbf{k}_1$ is the group velocity for the linear spectrum. In deriving Eqs. (27) and (28) we have assumed that $\tilde{\varepsilon}(\mathbf{k}_1) = 0$ and $\tilde{\varepsilon}(\mathbf{k}_1 + \mathbf{k}) \approx (\omega - \mathbf{kv}_g) \left.\frac{\partial\tilde{\varepsilon}}{\partial\omega_1}\right|_{\omega_1=\omega_{\mathbf{k}_1}}$ for the linear spectrum. If we assume $\omega \gg \mathbf{kv}_g$, from (27) and (28) we obtain approximately

$$d_1 \approx \frac{k^2 v_{Te}^2 v_\sim^2}{n_0\omega^2};\quad d_2 \approx \frac{4}{3}\frac{k^2 v_{Te}^2 v_\sim^2}{n_0\omega^2};\quad v_\sim^2 = \frac{3W}{4n_0 m_e}. \quad (29)$$

For the region $\mathbf{k}v_{Ti} \ll \omega \ll \mathbf{k}v_{Te}$, from (24) we obtain

$$\varepsilon(k) \approx -\frac{\omega_{pi}^2}{\omega^2} + \frac{\omega_{pe}^2}{k^2 v_{Te}^2}\left(1 + \frac{4}{3}\frac{k^2 v_\sim^2 T_e}{\omega^2(T_e+T_i)}\right)\left(1 + \frac{k^2 v_\sim^2(7T_e+3T_i)}{3\omega^2(T_e+T_i)}\right)^{-1}. \quad (30)$$

Hence

$$\omega^2 = k^2\tilde{v}_\pm^2,$$

$$\tilde{v}_\pm^2 = \frac{1}{2}\left(v_s^2 - \frac{4}{3}\frac{v_\sim^2 T_e}{(T_e+T_i)}\right)$$
$$\pm\sqrt{\frac{1}{4}\left(v_s^2 - \frac{4v_\sim^2 T_e}{3(T_e+T_i)}\right)^2 + v_s^2 v_\sim^2\frac{(4T_e+3T_i)}{3(T_e+T_i)}}. \quad (31)$$

The minus sign in (31) corresponds to an unstable root. This instability differs quantitatively from the instability obtained in ref. 6 for the one-dimensional case, although the qualitative features remain the same as in ref. 6. In the special case $v_\sim^2 \gg v_s^2$, the square of the growth rate (31) is proportional to W, i.e.,

$$\gamma_k^2 = k^2 v_{Te}^2\frac{W}{n_0(T_e+T_i)}. \quad (32)$$

For $\omega \gg \mathbf{k}v_g$ and $\omega \ll \mathbf{k}v_{Ti}$, $\mathbf{k}v_{Te}$, we obtain

$$\varepsilon(k) = \frac{\omega_{pi}^2}{k^2 v_{Ti}^2} + \frac{\omega_{pe}^2}{k^2 v_{Te}^2}\left(1 + \frac{4}{3}\frac{k^2 v_\sim^2 T_e}{\omega^2(T_e+T_i)}\right)\left(1 + \frac{k^2 v_\sim^2(7T_e+3T_i)}{3\omega^2(T_e+T_i)}\right)^{-1}, \quad (33)$$

$$\omega^2 = -\frac{7}{3}k^2 v_\sim^2\frac{T_e}{T_e+T_i}. \quad (34)$$

Note that in this case too the square of the growth rate of the instability is proportional to W, i.e.,

$$\gamma_k^2 = \frac{7}{4}k^2 v_{Te}^2\frac{W}{n_0(T_e+T_i)}. \quad (35)$$

Note that in the cases investigated here the existing instabilities (31) and (34) differ from the instabilities considered for the one-dimensional case[6] by the numerical coefficient 1/3. Obviously, this is due to the isotropy of the original turbulent state.

Thus, isotropic and one-dimensional turbulence lead to instabilities described by similar expressions, and they differ only by numerical coefficients of order unity. This gives one reason to believe that in the case of arbitrary nonisotropic turbulence the results will be qualitatively similar. One can also write down general relations for the instability of nonisotropic turbulence, since the assumption of isotropy is used only at the end of the calculations to obtain the actual expressions for d_1 and d_2 [see (29)]. It is also easy to generalize the results to the case of an external magnetic field that is not infinitely strong. The present investigation also reveals errors in the results of ref. 8 on the decay of plasmons associated with electron plasma waves.

Excitation of surface electromagnetic waves in a plasma cylinder surrounded by a hollow electron beam

O. V. Dolzhenko, A. V. Zosimov, and A. A. Rukhadze
P. N. Lebedev Physics Institute,
Academy of Sciences of the USSR, Moscow
(Submitted September 7, 1973)
Zh. Tekh. Fiz., 44, 977-984 (May 1974)

The interaction of a hollow relativistic electron beam with the surface oscillations of a plasma cylinder with a free surface is analyzed. It is shown that surface waves can be excited only if the axial magnetic field is relatively weak, so that the plasma electrons are unmagnetized. If, in addition, the beam electrons are unmagnetized as well, then a large number of surface-wave modes are excited. If the beam electrons are magnetized, in a dense plasma many modes are excited; in a rarefied plasma only one axially symmetric surface-wave mode is excited, i.e., the excitation has a single-mode character. The frequencies and linear growth rates are found. Estimates are made of the amplitudes of the steady-state nonlinear waves and of the flux of electromagnetic radiation (Poynting vector) associated with the excited modes.

INTRODUCTION

It is well known that both volume and surface electromagnetic waves can exist in a plasma cylinder with a free surface. The spectrum of characteristic frequencies and the phase velocity along the cylinder axis of volume electromagnetic waves are weak functions of the wave numbers and are of almost the same order for all modes. As a result, when an electron beam interacts with the volume oscillations of a plasma a large number of electromagnetic modes are excited. The situation is different for surface electromagnetic waves in a plasma cylinder, for which the frequency spectrum and the phase velocities are sensitive functions of the wave number. Accordingly, in this case one can always specify conditions in which an electron beam will only excite one surface electromagnetic mode.

In refs. 1-4, the excitation of electromagnetic waves in a plasma cylinder due to the motion of a relativistic electron beam through the plasma is investigated. In this formulation of the problem the beam always excites surface modes and volume modes; as a result the excitation is of a multimode character. With a view to avoiding the excitation of volume waves, in the present paper we examine the interaction of a hollow electron beam with a plasma under conditions such that the beam surrounds the plasma but does not intersect it.

In ref. 4 an expression is obtained in the linear hydrodynamic approximation for the dielectric tensor for a beam–plasma system in cylindrical coordinates; the expression holds for any degree of radial inhomogeneity of the beam and plasma:

$$\varepsilon_{ij}=\begin{pmatrix} \varepsilon_1 & i\varepsilon_2 & \sum\limits_\alpha \alpha_{rz}\left(\frac{\partial}{\partial r}-\frac{l}{r}\frac{\Omega_\alpha}{\omega'_\alpha}\right) \\ -\nu i\varepsilon_2 & \varepsilon_1 & \sum\limits_\alpha i\alpha_{rz}\left(\frac{l}{r}-\frac{\Omega_\alpha}{\omega'_\alpha}\frac{\partial}{\partial r}\right) \\ \sum\limits_\alpha\left(\frac{l}{r}\frac{\Omega_\alpha}{\omega'_\alpha}+\frac{1}{r}\frac{\partial}{\partial r}r\right)\alpha_{rz} & i\sum\limits_\alpha\left(\frac{l}{r}+\frac{\Omega_\alpha}{\omega'_\alpha}\frac{1}{r}\frac{\partial}{\partial r}r\right)\alpha_{rz} & \varepsilon_{\parallel} \end{pmatrix}, \tag{1}$$

where α is the particle species, k and l are the longitudinal and azimuthal wave numbers, u_α is the directed velocity of particles of species α, $\omega'_\alpha=(\omega-ku_\alpha)\gamma_\alpha$, $\gamma_\alpha=(1-u_\alpha^2/c^2)^{-1/2}$, Ω_α is the gyrofrequency and $\omega_{L\alpha}$ is the plasma frequency of particles of species α, and

$$\varepsilon_1=1-\sum_\alpha\frac{\omega_{L\alpha}^2\omega_\alpha'^2\gamma_\alpha^{-1}}{\omega^2(\omega_\alpha'^2-\Omega_\alpha^2)},\quad \varepsilon_2=-\sum_\alpha\frac{\omega_{L\alpha}^2\omega'_\alpha\Omega_\alpha\gamma_\alpha^{-1}}{\omega^2(\omega_\alpha'^2-\Omega_\alpha^2)},$$

$$\varepsilon_3=1-\sum_\alpha\frac{\omega_{L\alpha}^2\gamma_\alpha^{-1}}{\omega_\alpha'^2},\quad \alpha_{rz}=i\frac{\omega_{L\alpha}^2u_\alpha\omega'_\alpha}{\omega^2(\omega_\alpha'^2-\Omega_\alpha^2)},$$

$$\alpha_{zz}=\frac{\omega_{L\alpha}^2u_\alpha^2\gamma_\alpha}{\omega^2(\omega_\alpha'^2-\Omega_\alpha^2)},$$

$$\varepsilon_{\parallel}=\varepsilon_3+\sum_\alpha\frac{1}{r}\frac{\partial}{\partial r}r\alpha_{zz}\frac{\partial}{\partial r}-\frac{l^2}{r^2}\alpha_{zz}+\frac{l}{r}\frac{\Omega_\alpha}{\omega'_\alpha}\left(\alpha_{rz}\frac{\partial}{\partial r}-\frac{\partial}{\partial r}\alpha_{rz}\right).$$

When the tensor (1) is used the field equations

$$\left.\begin{aligned}[\mathrm{curl}\,\mathbf{B}]_i&=-\frac{i\omega}{c}\varepsilon_{ij}E_j,\quad \mathrm{div}\,\mathbf{B}=0,\\ \mathbf{B}&=-i\frac{c}{\omega}\mathrm{curl}\,\mathbf{E},\ \frac{\partial}{\partial r_i}\varepsilon_{ij}E_j=0\end{aligned}\right\} \tag{2}$$

appear in the same form for any degree of inhomogeneity of the density $n_\alpha(r)$.

The following geometry will be considered: A plasma cylinder of radius r_0 is located in a waveguide of radius $R > r_0$; the space between the walls of the waveguide and the plasma cylinder is completely filled by the electron beam; an external magnetic field is directed along the axis of the waveguide; the particle density is constant with a sharp drop to zero at the boundaries r_0 and R.

The boundary conditions have the following form: At the surface of the plasma cylinder

$$\left.\begin{aligned}&\{E_z\}_{r=r_0}=\{E_\varphi\}_{r=r_0}=\{B_z\}_{r=r_0}=0,\\ &\{B_\varphi\}_{r=r_0}=-\frac{i\omega}{c}\Big\{\sum_\alpha\alpha_{rz}E_r+i\sum_\alpha\frac{\Omega_\alpha}{\omega'_\alpha}d_{rz}E_\varphi\\ &\qquad+\sum_\alpha\alpha_{zz}\frac{\partial E_z}{\partial r}+\sum_\alpha\frac{l}{r}\frac{\Omega_\alpha}{\omega'_\alpha}\alpha_{rz}E_z\Big\}_{r=r_0}=0;\end{aligned}\right\} \tag{3}$$

at the surface of the metal waveguide

$$E_z|_{r=R}=E_\varphi|_{r=R}=0. \tag{3$^{\mathrm{I}}$}$$

The dispersion relation proves to be very intractable in the general case of an arbitrary external magnetic field and an arbitrary waveguide radius. Therefore, we assume the waveguide radius to be very large ($R \gg r_0$), and we limit ourselves to three simple limiting cases: a) Neither the plasma nor the beam is magnetized, i.e., $\omega_{L\alpha} \gg \Omega_\alpha$; b) both the plasma and the beam are magnetized, i.e., $\Omega_\alpha \gg \omega_{L\alpha}$; c) the beam is magnetized and the plasma is unmagnetized, i.e., $\omega_{L0} \gg \Omega_e \gg \omega_{L1}$, where ω_{L0} is the electron plasma frequency for the plasma and ω_{L1} is the electron plasma frequency for the beam.

ANALYSIS OF DISPERSION RELATION

The operator ε_{ij} simplifies greatly in the aforementioned limiting cases. In case a) the nonzero components of ε_{ij} are: in the plasma

$$\varepsilon_1 = \varepsilon_3 = \varepsilon_\parallel \equiv \varepsilon_I = 1 - \frac{\omega_{L0}^2}{\omega^2}, \tag{4}$$

in the beam

$$\left.\begin{aligned} \varepsilon_1 = \varepsilon_{II} = 1 - \frac{\omega_{L1}^2}{\gamma\omega^2}, \\ \varepsilon_\parallel = 1 - \frac{\omega_{L1}^2\gamma^{-3}}{(\omega - ku)^2} + \frac{1}{r}\frac{\partial}{\partial r} r\alpha_{zz}\frac{\partial}{\partial r} - \frac{l^2}{r^2}\alpha_{zz}. \end{aligned}\right\} \tag{4^I}$$

The field equations reduce to two equations for E_z and B_z:

$$\begin{aligned} \left(\frac{1}{r}\frac{\partial}{\partial r} r \frac{\partial}{\partial r} - \frac{l^2}{r^2} - \varkappa^2\right) E_z = 0, \\ \left(\frac{1}{r}\frac{\partial}{\partial r} r \frac{\partial}{\partial r} - \frac{l^2}{r^2} - \varkappa^2\right) B_z = 0, \end{aligned} \tag{5}$$

where

$$\varkappa_{I,\,II}^2 = k^2 - \frac{\omega^2}{c^2}\varepsilon_{I,\,II}.$$

The index I refers to the plasma and II to the beam. The other field components are expressed in terms of E_z and B_z through the relationships[3]

$$\begin{aligned} E_\varphi &= \frac{1}{\varkappa^2}\left[\frac{i\omega}{c}\frac{\partial B_z}{\partial r} + \frac{l}{r}\left(k + i\frac{\omega^2}{c^2}\alpha_{rz}\right)E_z\right], \\ E_r &= \frac{1}{\varkappa^2}\left[\frac{\omega}{c}\frac{l}{r}B_z + \left(\frac{\omega^2}{c^2}\alpha_{rz} - ik\right)\frac{\partial E_z}{\partial r}\right], \\ B_\varphi &= \frac{1}{\varkappa^2}\left[k\frac{l}{r}B_z + \frac{\omega}{c}(k\alpha_{rz} - i\varepsilon_1)\frac{\partial E_z}{\partial r}\right], \\ B_r &= \frac{1}{\varkappa^2}\left[-ik\frac{\partial B_z}{\partial r} - \frac{l}{r}\frac{\omega}{c}(\varepsilon_1 + ik\alpha_{rz})E_z\right]. \end{aligned} \tag{6}$$

Boundary condition (3) for B_φ now assumes the form

$$(B_\varphi)_{r=r_0} = -\frac{i\omega}{c}\left\{\alpha_{rz}E_z + \alpha_{zz}\frac{\partial E_z}{\partial r}\right\}_{r=r_0}.$$

Utilizing the requirement that the field be bounded, the solution of Eqs. (5) can be written in the form

$$\left.\begin{aligned} E_{zI} = C_{II}I_l(\varkappa_I r), \quad B_{zI} = D_{II}I_l(\varkappa_I r), \\ E_{zII} = C_{III}K_l(\varkappa_{II} r), \quad B_{zII} = D_{III}K_l(\varkappa_{II} s), \end{aligned}\right\} \tag{7}$$

where $I_l(x)$, $K_l(x)$ are the cylindrical functions of imaginary argument. Inserting these solutions into the boundary conditions yields the dispersion relation

$$\begin{aligned} &\left[\frac{\varepsilon_I}{\varkappa_I}I_l'(\varkappa_I r_0)K_l(\varkappa_{II} r_0) - \frac{\varepsilon_{3II}}{\varkappa_{II}}I_l(\varkappa_I r_0)K_l'(\varkappa_{II} r_0)\right] \\ &\times\left[\frac{1}{\varkappa_I}I_l'(\varkappa_I r_0)K_l(\varkappa_{II} r_0) - \frac{1}{\varkappa_{II}}I_l(\varkappa_I r_0)K_l'(\varkappa_{II} r_0)\right] \\ &-\frac{l^2c^2}{\omega^2 r_0^2}\left[\frac{k}{\varkappa_I^2} - \frac{1}{\varkappa_{II}^2}\left(k + i\frac{\omega^2}{c^2}\alpha_{rz}\right)\right]^2 I_l^2(\varkappa_I r_0)K_l^2(\varkappa_{II} r_0) = 0. \end{aligned} \tag{8}$$

For waves with a phase velocity close to the velocity of the beam electrons (Cerenkov excitation mechanism), i.e., for $\omega \simeq ku$, and for low-density beams, when $\omega_{L1} \ll \omega_{L0}$, this equation is readily solved in the two limiting cases: ($\varkappa_{II}r_0 \gg 1$) and ($\varkappa_{II}r_0 \ll 1$).

In the short-wave limit ($\varkappa_{II}r_0 \gg 1$, so that $\varkappa_I r_0 \gg 1$) we obtain

$$\omega = \frac{\omega_{L0}}{\sqrt{1+\gamma^2}}\left[1 + \frac{-1 + i\sqrt{3}}{2}\left(\frac{n_1}{n_0}\frac{\gamma}{\gamma^4 + 1}\right)^{1/3}\right] \tag{9}$$

for all axial modes l.

In the long-wave limit ($\varkappa_{II}r_0 \ll 1$) for the mode with $l = 0$ we have

$$\begin{aligned} \omega = \frac{u\gamma}{r_0}\left\{1 + \frac{-1 + i\sqrt{3}}{2}\left(\frac{\omega_{L1}^2 r_0^2}{2u^2\gamma^7}\exp\left[2\frac{(\gamma^2 - 1)c}{\omega_{L0}r_0}\frac{I_0\left(\frac{\omega_{L0}r_0}{c}\right)}{I_1\left(\frac{\omega_{L0}r_0}{c}\right)}\right]\right)^{1/3}\right\} \\ \times\exp\left[-\frac{(\gamma^2 - 1)c}{\omega_{L0}r_0}\frac{I_0\left(\frac{\omega_{L0}r_0}{c}\right)}{I_1\left(\frac{\omega_{L0}r_0}{c}\right)}\right], \end{aligned} \tag{10}$$

and for modes with $l \geq 1$

$$\omega = \frac{\omega_{L0}}{\sqrt{2}}\left\{1 + \frac{-1 + i\sqrt{3}}{2}\left[\frac{n_1}{2n_0}\frac{1}{\gamma}\right]^{1/3}\right\}, \tag{11}$$

where n_1 and n_0 are the densities of beam and plasma electrons.

Short-wave modes are possible only in a dense plasma when $\omega_{L0}^2 r_0^3 \gg 2u^2\gamma^2$, while long-wave modes are only excited in a rarefied plasma when

$$\frac{(\gamma^2 - 1)c}{\omega_{L0}r_0} \gg \frac{I_0\left(\frac{\omega_{L0}r_0}{c}\right)}{I_1\left(\frac{\omega_{L0}r_0}{c}\right)}.$$

It follows from a comparison of Eq. (8) with the dispersion relation for a waveguide of finite radius that Eq. (9) (short-wave limit or a dense plasma) holds effectively for any $R > r_0$, while expressions (10) and (11) (long-wave limit or rarefied plasma) are valid for

$$\frac{R}{r_0} > \exp\left[(\gamma^2 - 1)\frac{c}{\omega_{L0}r_0}\frac{I_0\left(\frac{\omega_{L0}r_0}{c}\right)}{I_1\left(\frac{\omega_{L0}r_0}{c}\right)}\right] \gg 1.$$

The growth rates $\delta = \mathrm{Im}\,\omega$ are independent of the mode index l in the short-wave limit ($\varkappa_{II}r_0 \gg 1$); while in the long-wave limit ($\varkappa_{II}r_0 \ll 1$) the growth rates of modes with $l \geq 1$ are much greater than the growth rate of the mode with $l = 0$ and are also independent of l, i.e., in both cases many modes are excited simultaneously. However, as will be shown below, the flux of microwave energy is determined mainly by a single mode. The flux of microwave energy is small in the case of nonrelativistic beams ($u \ll c$, $\gamma \gg 1$), since the excited field is almost electrostatic in character; in the case of ultrarelativistic beams ($\gamma \gg$

1) the waves excited by the beam are almost transverse and the flux of radiation energy is significant.

Let us consider case b), when both the plasma and the beam are magnetized (ω_{L0}, $\omega_{L1} \ll \Omega_e$) and case c), when the beam is magnetized and the plasma is not ($\omega_{L0} \gg \Omega_e \gg \omega_{L1}$). The operator $\hat{\varepsilon}_{ij}$ has the following nonzero components. For case b): in the plasma

$$\varepsilon_1 = 1,\quad \varepsilon_2 = \frac{\omega_{L0}^2}{\omega\Omega_e},\quad \varepsilon_3 = 1 - \frac{\omega_{L0}^2}{\omega^2},$$

in the beam

$$\varepsilon_1 = 1,\quad \varepsilon_3 = 1 - \frac{\omega_{L1}^2\gamma^{-3}}{(\omega - ku)^2}.$$

For case c): in the plasma

$$\varepsilon_1 = \varepsilon_3 = 1 - \frac{\omega_{L0}^2}{\omega^2},\quad \varepsilon_2 = -\frac{\omega_{L0}^2\Omega_e}{\omega^3},$$

in the beam

$$\varepsilon_1 = 1,\quad \varepsilon_3 = 1 - \frac{\omega_{L1}^2\gamma^{-3}}{(\omega - ku)^2}.$$

The boundary conditions for B_φ now assume the form $\{B_\varphi\}_{r=r_0} = 0$, and the field equations reduce to two equations for E_z and B_z:

$$\left.\begin{aligned} &\left(\varkappa^2 + \frac{\omega^2}{c^2}\frac{\varepsilon_2^2}{\varepsilon_1}\right)\Delta_\perp E_z + \frac{\varepsilon_3}{\varepsilon_1}\left(\frac{\omega^4}{c^4}\varepsilon_2^2 - \varkappa^4\right)E_z = i\frac{\varepsilon_2}{\varepsilon_1}\frac{\omega k}{c}\Delta_\perp B_z, \\ &\varkappa^2\Delta_\perp B_z + \left(\frac{\omega^4}{c^4}\varepsilon_2^2 - \varkappa^4\right)B_z = -i\frac{\omega k}{c}\varepsilon_2\Delta_\perp E_z, \end{aligned}\right\} \tag{12}$$

where

$$\Delta_\perp = \frac{1}{r}\frac{\partial}{\partial r} r \frac{\partial}{\partial r} - \frac{l^2}{r^2},$$

$$\varkappa^2 = k^2 - \frac{\omega^2}{c^2}\varepsilon_1.$$

The remaining field components are connected with E_z and B_z by the relationships[4]

$$\begin{aligned} E_r &= \left(\varkappa^4 - \varepsilon_2^2\frac{\omega^4}{c^4}\right)^{-1}\left(-ik\varkappa^2\frac{\partial E_z}{\partial r} + \frac{l}{r}\frac{\omega}{c}\varkappa^2 B_z - \frac{\omega^3}{c^3}\varepsilon_2\frac{\partial B_z}{\partial r} + ik\frac{l}{r}\frac{\omega^2}{c^2}\varepsilon_2 E_z\right), \\ E_\varphi &= \left(\varkappa^4 - \varepsilon_2^2\frac{\omega^4}{c^4}\right)^{-1}\left(i\frac{\omega}{c}\varkappa^2\frac{\partial B_z}{\partial r} + \frac{l}{r}k\varkappa^2 E_z - k\varepsilon_2\frac{\omega^2}{c^2}\frac{\partial E_z}{\partial r} - i\frac{l}{r}\frac{\omega^3}{c^3}\varepsilon_2 B_z\right), \\ B_r &= \left(\varkappa^4 - \varepsilon_2^2\frac{\omega^4}{c^4}\right)^{-1}\Big[-ik\varkappa^2\frac{\partial B_z}{\partial r} - \frac{\omega}{c}\varepsilon_1\left(\varkappa^2 + \frac{\omega^2}{c^2}\frac{\varepsilon_2^2}{\varepsilon_1}\right)E_z \\ &\quad + k\frac{\omega}{c}\varepsilon_2\frac{\partial E_z}{\partial r} + i\frac{l}{r}\frac{\omega^2}{c^2}k\varepsilon_2 B_z\Big], \\ B_\varphi &= \left(\varkappa^4 - \varepsilon_2^2\frac{\omega^4}{c^4}\right)^{-1}\Big[-i\frac{\omega}{c}\varepsilon_1\left(\varkappa^2 + \frac{\omega^2}{c^2}\frac{\varepsilon_2^2}{\varepsilon_1}\right)\frac{\partial E_z}{\partial r} \\ &\quad + \frac{l}{r}k\varkappa^2 B_z - k^2\frac{\omega^2}{c^2}\varepsilon_2\frac{\partial B_z}{\partial r} + i\frac{l}{r}\frac{\omega}{c}k^2\varepsilon_2 E_z\Big]. \end{aligned} \tag{13}$$

In the beam region Eqs. (12) decouple and reduce to set (5), the solution of which can be written in the form

$$E_{zII} = A_{IIl}K_l\left(\sqrt{\frac{\varepsilon_{3II}}{\varepsilon_{1II}}}\varkappa_{II}r\right),\quad B_{zII} = B_{IIl}K_l(\varkappa_{II}r). \tag{14}$$

In the plasma region the solution of set (12) will be

$$E_{zI} = A_{Il}I_l(k_1r) + B_{Il}K_l(k_1r),$$

$$B_{zI} = i\frac{c}{\omega k}\left[\left(\frac{\varepsilon_3\varkappa^2}{\varepsilon_2} - k_1^2\frac{\varepsilon_1}{\varepsilon_2}\right)A_{Il}I_l(k_1r) + \left(\frac{\varepsilon_3\varkappa^2}{\varepsilon_2} - k_2^2\frac{\varepsilon_1}{\varepsilon_2}\right)B_{Il}K_l(k_1r)\right], \tag{15}$$

where

$$\left.\begin{aligned} &k_{1,2}^2 = \frac{\varepsilon_1 + \varepsilon_3}{2\varepsilon_1}\varkappa^2 + \frac{\omega^2}{2c^2}\frac{\varepsilon_2^2}{\varepsilon_1} \pm \frac{1}{2}\sqrt{\left[\left(1 - \frac{\varepsilon_3}{\varepsilon_1}\right)\varkappa^2 + \frac{\omega^2}{c^2}\frac{\varepsilon_2}{\varepsilon_1}\right]^2 + 4k^2\frac{\omega^2}{c^2}\frac{\varepsilon_3\varepsilon_2^2}{\varepsilon_1^2}}, \\ &\varkappa_{II}^2 = k^2 - \frac{\omega^2}{c^2}\varepsilon_{1II}. \end{aligned}\right\} \tag{16}$$

The dispersion relation obtained by inserting these solutions into the boundary conditions proves to be very cumbersome. It is readily shown, however, that in case b), when $\omega_{L0} \ll \Omega_e$, the dispersion relation has no solutions, i.e., the beam excites no waves in a magnetized plasma. In case c), however, when the beam is magnetized and the plasma is not ($\omega_{L0} \gg \Omega_e \gg \omega_{L1}$), $\varepsilon_{1I} = \varepsilon_{3I}$ and the roots $k_{1,2}$ become almost degenerate, i.e.,

$$k_{1,2} = \frac{\varepsilon_1 + \varepsilon_3}{2\varepsilon_1}\varkappa^2 \pm \sqrt{k^2\frac{\omega^2}{c^2}\varepsilon_3\frac{\varepsilon_2^2}{\varepsilon_1^2}},$$

where the second term is negligibly small. The dispersion relation in this case reduces to the form

$$\begin{aligned} &\left[\frac{\varepsilon_{1I}}{\varkappa_I}I_l'(\varkappa_Ir_0)K_l(\sqrt{\varepsilon_{3II}}\varkappa_{II}r_0) - \frac{\sqrt{\varepsilon_{3II}}}{\varkappa_{II}}I_l(\varkappa_Ir_0)K_l'(\sqrt{\varepsilon_{3II}}\varkappa_{II}r_0)\right] \\ &\quad \times\left[\frac{1}{\varkappa_I}I_l'(\varkappa_Ir_0)K_l(\varkappa_{II}r_0) - \frac{1}{\varkappa_{II}}I_l(\varkappa_Ir_0)K_l'(\varkappa_{II}r_0)\right] \\ &\quad - \frac{l^2k^2c^2}{\omega^2r_0^2}\left(\frac{1}{\varkappa_I^2} - \frac{1}{\varkappa_{II}^2}\right)^2 I_l^2(\varkappa_Ir_0)K_l(\varkappa_{II}r_0)K_l(\sqrt{\varepsilon_{3II}}\varkappa_{II}r_0) = 0. \end{aligned} \tag{19}$$

In the absence of a beam Eq. (19)* coincides with Eq. (8), i.e., the characteristic frequencies in this case can differ from case a) only in imaginary parts (in the growth rates of the oscillations). The conditions on the plasma density for the excitation of short-wave and long-wave modes are maintained, as is the condition on the ratio of the waveguide radius R to the plasma cylinder radius r_0 for which the long-wave and short-wave approximations are valid. However, the difference in the growth rates for cases a) and c) introduces changes in case c) in the manner in which the oscillations grow and in the character of the nonlinear saturation of the generated waves.

In the short-wave limit ($\varkappa_{II}r_0 \gg 1$) the growth rates are independent of the mode index l:

$$\delta = \operatorname{Im}\omega = \frac{\sqrt{3}}{2}\left(\frac{n_1}{2n_0}\frac{\gamma}{\gamma^4 + 1}\right)^{1/3}\frac{\omega_{L0}}{\sqrt{1 + \gamma^2}},$$

i.e., they are smaller than the growth rates in case a) by a factor of $2^{1/3}$.

In the long-wave limit ($\varkappa_{II}r_0 \ll 1$) axially nonsymmetric modes are not excited by a magnetized beam since the growth rate is positive only for the symmetric mode with $l = 0$:

$$\delta = \frac{\sqrt{3}}{2}\left\{\frac{\omega_{L1}^2\omega_{L0}c}{4\gamma^6u}\frac{I_1\left(\frac{\omega_{L0}r_0}{c}\right)}{I_0\left(\frac{\omega_{L0}r_0}{c}\right)}\exp\left[-\frac{(\gamma^2 - 1)c}{\omega_{L0}r_0}\frac{I_0\left(\frac{\omega_{L0}r_0}{c}\right)}{I_1\left(\frac{\omega_{L0}r_0}{c}\right)}\right]\right\}^{1/3}.$$

RADIATION EFFICIENCY AND DISCUSSION

Having analyzed the excitation of surface waves, we are now faced with the problem of the output of this radiation from the waveguide. An output of radiation is possible if the axial component of the Poynting vector

$$P_z = \frac{c}{4\pi}\int_0^R r\,dr\int_0^{2\pi} d\varphi\,[\overline{\mathbf{E}\times\mathbf{B}}],$$

is nonzero.

Utilizing (6) and (13) we can calculate the electromagnetic energy flux P_z correct to the constants $A_{II l}$, indeterminate in the linear theory, entering into the amplitude of the axial component of the electric field E_z in the beam region $[E_{z}\text{II} = A_{IIl}(\varkappa_{II}r),\ E_z\text{II} = A_{IIl}K_l(\varepsilon_{3II}\varkappa_{II}r)^{1/2}]$. In order to determine the maximum value of these constants recourse must be made to a model for the nonlinear saturation of the wave.

It can be shown from (6) and (13) that the short waves excited in a dense plasma will be almost electrostatic at small velocities of the beam electrons ($u \ll c$) and will be almost transverse for ultrarelativistic beams ($\gamma \gg 1$); the long-wave modes in a rarefied plasma are, however, always almost transverse.

An upper limit on the growth of the amplitude of potential waves can be established in terms of the capture of the beam electrons by the potential field of the wave. A condition of such capture, when relative motion between the wave and the beam electrons ceases, is given by[5]

$$e\Phi = \frac{m}{2}\gamma^3\,\mathrm{Re}\left(\frac{\omega}{k}-u\right)^2,$$

where Φ is the wave potential ($E_z = -ik\Phi$).

In the case of transverse waves the results of Kovtun and Rukhadze[6] can be used to estimate the nonlinear conversion of a transverse field into electrostatic waves, and the maximum amplitude of the latter estimated through the capture of beam electrons.

The ratio of the maximum flux of electromagnetic energy determined in this manner to the flux of kinetic energy of the beam electrons $\pi(R^2-r_0^2)mn_1c^2u(\gamma-1)$ gives a measure of the efficiency of a radiator (generator) based on the investigated beam–plasma interaction.

In the short-wave limit the energy flux is removed mainly by the mode $l = 0$ (the flux removed by the remaining modes is smaller by a factor of $\omega^2_{L0}r_0^2/2u^2\gamma^2$), and we have for the efficiency in the case of an unmagnetized beam

$$\eta = \frac{r_0u\gamma^2(\gamma+1)(\gamma^6-1)}{16\omega_{L0}(R^2-r_0^2)\sqrt{\gamma^2+1}}\left(\frac{\gamma}{\gamma^4+1}\right)^{1/3}\left(\frac{n_1}{n_0}\right)^{1/3}.$$

The efficiency for a magnetized beam is smaller by a factor $2^{4/3}$.

In the long-wave limit in the case of an unmagnetized beam the flux of electromagnetic energy is removed mainly by the mode $l = 1$ (the contribution from the other modes is smaller by a factor of $2u^2\gamma^2/\omega^2_{L0}r_0^2$), and the generator efficiency is

$$\eta = \frac{u^3}{6uc^2}\left(\frac{n_1}{2n_0\gamma}\right)^{1/3}\frac{\gamma^5(2\gamma^2-1)}{(\gamma-1)}\frac{r_0^2}{R^2-r_0^2}.$$

If, however, the beam is magnetized and only the mode with $l = 0$ is excited, then the generator efficiency is given by the expression

$$\eta = \frac{1}{4\gamma^2(\gamma-1)}\left[\frac{2I_1^2\left(\frac{\omega_{L0}r_0}{c}\right)}{I_0^2\left(\frac{\omega_{L0}r_0}{c}\right)}\right].$$

The following conclusions can be drawn from our analysis.

1. In a magnetized plasma oscillations are not generally excited. In an unmagnetized dense plasma the beam excites a large number of short-wave modes with the same frequency $\omega = \omega_{L0}(\gamma^2+1)^{1/2}$, but electromagnetic energy is removed mainly by the axially symmetric mode. The cases of a magnetized and an unmagnetized beam differ only in the growth rates and in the radiation efficiency. For ultrarelativistic beams the excited waves are almost transverse and the radiation efficiency is appreciably greater than for slow beams.

2. In a rarefied unmagnetized plasma an unmagnetized beam excites a large number of nonsymmetric modes with $l \geq 1$ and the same frequency $\omega = \omega_{L0}/\sqrt{2}$. The oscillations are almost transverse, and in the case of many modes electromagnetic energy is removed mainly by the mode with $l = 1$. A magnetized beam, on the other hand, excites only one axially symmetric mode with frequency

$$\omega = \frac{u\gamma}{r_0}\exp\left[-\frac{(\gamma^2-1)c}{\omega_{L0}r_0}\frac{I_0\left(\frac{\omega_{L0}r_0}{c}\right)}{I_1\left(\frac{\omega_{L0}r_0}{c}\right)}\right].$$

3. Excitation of waves in a rarefied plasma by a magnetized beam is advantageous not only because just one mode of oscillation is excited. In this regime the frequency depends very strongly (exponentially) on the velocity of the beam electrons and can readily be varied over a wide range by varying the latter. The limitations on the plasma density may, however, be an obstacle to obtaining a high radiation power.

The authors are grateful to B. I. Aronov for a number of remarks.

Hydrodynamic theory is derived for the launching and propagation of regular periodic waves of finite amplitude propagating along the axis of a cylindrical plasma-filled waveguide in a strong external magnetic field. It is shown that the problem of seeking the field configuration dispersion of such waves reduces to the solution of a quasilinear equation of the elliptic type for the high-frequency potential. The slightly nonlinear solutions of this equation are classified. The conditions under which periodic waves of finite amplitude exist are determined. Analytic expressions are found for the dispersion and wave configuration at Mach numbers near unity. The Cerenkov excitation of a nonlinear plasma-filled waveguide by a train of charged disks is analyzed. The plasma nonlinearity stabilizes the Budker and Cerenkov instabilities of a relativistic beam injected into a bounded plasma.

The launching and propagation of regular waves of finite amplitude in a bounded plasma are of interest in connection with the development of collective acceleration methods[1-3] and beam methods for producing and controlling the spectra of microwaves.[4,5] In the present paper we analyze the dispersion, field configuration, and launching efficiency for regular nonlinear waves in an anisotropic cylindrical plasma waveguide.

1. STATEMENT OF THE PROBLEM

We consider a cylindrical waveguide having conducting walls of radius a and filled with a magnetized plasma ($\omega_p^2 \ll \omega_H^2$). The self-consistent system of equations describing the propagation of high-frequency electromagnetic waves in such a waveguide consists of the equation of longitudinal motion, the continuity equation for the plasma electrons, and the Maxwell equations for the field. In the simplest case of axisymmetric TM waves these equations are

$$\left.\begin{gathered}\frac{dp_z}{dt}=eE_z,\quad \frac{\partial\rho}{\partial t}+\frac{\partial}{\partial z}(\rho v_z)=0,\\ \frac{\partial H_\perp}{\partial z}+\frac{1}{c}\frac{\partial E_\perp}{\partial t}=0,\quad \frac{1}{c}\frac{\partial H_\perp}{\partial t}+\frac{\partial E_\perp}{\partial z}-\frac{\partial E_z}{\partial r}=0,\\ \frac{1}{r}\frac{\partial}{\partial r}rH_\perp-\frac{1}{c}\frac{\partial E_z}{\partial t}=\frac{4\pi e}{c}\rho v_\parallel.\end{gathered}\right\}\qquad(1)$$

We seek solutions of these equations in the form of waves propagating along the waveguide axis at a constant phase velocity V. In this case, introducing the high-frequency wave potential $\varphi(r, z-Vt)$, we can reduce the order of system (1) by using its first integrals

$$\left.\begin{gathered}\rho(r,z')[u(r,z')-\beta]=I_1(r),\\ \frac{1-\beta u}{(1-u^2)^{1/2}}+\frac{e\varphi}{m_0c^2}=\frac{eI_2(r)}{m_0c^2},\quad \beta\equiv\frac{V}{c},\\ H_\perp(r,z')-\beta E_\perp(r,z')=\beta I_3(r),\quad \gamma\equiv(1-\beta^2)^{-1/2},\\ E_\perp\equiv-\gamma^2\frac{\partial\varphi}{\partial r},\quad E_z\equiv-\frac{\partial\varphi}{\partial z'},\quad z'\equiv z-Vt,\ u\equiv\frac{v_z}{c}.\end{gathered}\right\}\qquad(2)$$

The functions $I_s(r)$, which are not functions of z', must be found from the boundary conditions on z'. The first is unambiguously determined by the known value of ρ_+V for the total flow at the points z' where the electron velocity vanishes:

$$\rho(r,z')u(r,z')=\beta[\rho(r,z')-\rho_+].\qquad(2a)$$

The other two first integrals appear in the final equation for the high-frequency potential, $\Phi(\eta,\xi)\equiv e/(m_0V^2)\cdot[\varphi(r,z')-I_2(r)]$ (cf. ref. 6),

$$\left.\begin{gathered}M_0^2\frac{1}{\eta}\frac{\partial}{\partial\eta}\eta\frac{\partial\Phi}{\partial\eta}+\frac{\partial^2\Phi}{\partial\xi^2}+R(\Phi)=0,\quad \Phi<\Phi_{\max}\equiv\frac{\gamma}{\gamma+1};\\ R(\Phi)\equiv\frac{w(\Phi)}{1-w(\Phi)}+G(\eta),\\ w(\Phi)\equiv\frac{u}{\beta}=\frac{1-(1-\beta^2\Phi)\sqrt{1-2\Phi+\beta^2\Phi^2}}{(1-\beta^2\Phi)^2+\beta^2},\\ \eta\equiv\frac{r}{a}\leqslant1,\ \xi\equiv\frac{\omega_p}{V}z',\ M_0^2\equiv\frac{V^2\gamma^2}{\omega_p^2a^2},\ \omega_p^2\equiv\frac{4\pi e^2n_p}{m_0}\end{gathered}\right\}\qquad(3)$$

as the linear superposition

$$G(\eta)\equiv M_0^2\frac{1}{\eta}\frac{d}{d\eta}\left\{\eta\left[\frac{e}{m_0V^2}\left(\frac{\partial I_2}{\partial r}-I_3\right)\right]\right\}.$$

Physically, this latter function represents the perturbation of the average charge density in the plasma due to the finite amplitude of the potential. In our case of periodic waves in a current-free plasma, the average value of the total charge density over a period along z is $R(\Phi)\sim\rho_- - \rho_+$, and the current ρu [see (2a)] vanishes.[2] According to (3), this condition is equivalent to the equation

$$\bar{R}(\Phi)\equiv\int_{-L/2}^{+L/2}d\xi R[\Phi(\eta,\xi)]=-\frac{M_0^2}{\eta}\frac{d}{d\eta}\left(\eta\frac{d}{d\eta}\bar{\Phi}\right)=0,\qquad(3a)$$

which holds automatically in the one-dimensional case and which gives the unknown function $G(\eta)$ in the two-dimensional case (see below).

To determine unambiguously the potential $\Phi(\eta,\xi)$ we must also specify the boundary conditions with respect to the transverse coordinate. For purposes of acceleration, e.g., the most interesting solutions (3) are those corresponding to the maximum longitudinal field at the axis. The longitudinal field and the potential vanish at the conducting walls. The boundary conditions with respect to η are thus

$$\Phi(1, \xi) = \frac{\partial \Phi}{\partial \eta}(0, \xi) = 0. \tag{3b}$$

2. LINEAR THEORY

Before we turn to the nonlinear solutions of Eq. (2) we will briefly discuss those results of the corresponding linear theory which we will need below.

In the linear approximation we have $R(\Phi) = \Phi$, $G = 0$, so that periodic natural modes of this waveguide can be analyzed through separation of variables. Substituting into (3) the potential Φ in the form

$$\Phi(\eta, \xi) = AP(\eta)\exp(ik\xi) \tag{4a}$$

we find Bessel's equation for the radial function $P(\eta)$:

$$\left[M_0^2 \frac{1}{\eta}\frac{d}{d\eta}\eta\frac{d}{d\eta} + 1 - k^2\right]P(\eta) = 0. \tag{4b}$$

Using this equation and the boundary conditions at the walls and the waveguide axis, we find the field configuration and dispersion relation for these waves:

$$\begin{gathered} P_s(\eta) = J_0(\lambda_s \eta), \quad J_0(\lambda_s) = 0, \\ k_s^2 \equiv 1 - M_s^2, \quad M_s^2 \equiv M_0^2 \lambda_s^2, \end{gathered} \tag{4c}$$

where $s = 1, 2, 3, \ldots$ is the wave index ($\lambda_1 = 2.405$).

For the analysis below it is important to note that the phase velocity of the wave of index s,

$$V_s(\omega) \equiv \frac{c}{\left[1 + \frac{\lambda_s^2 c^2}{(\omega_p^2 - \omega^2)a^2}\right]^{1/2}}\,, \tag{4d}$$

falls off with increasing frequency, from the constant value $V_s(0) \equiv c[1 + \lambda_s^2/\nu]^{-1/2}$ at $\omega \to 0$ [$\nu \equiv (\omega_p^2 a^2)/c^2$ is the Budker "instantaneous electron"], to zero at $\omega \to \omega p$. Phase velocities on the order of the velocity of light can be obtained in the low-frequency range ($\omega_p^2 \gg \omega^2 \gg \omega_{ce}\omega_{ci}$) only with a sufficiently large instantaneous plasma density ($\nu \gg \lambda_s^2$).

3. SLIGHTLY NONLINEAR PERIODIC WAVES

In general, the Mach number M_s for wave s is on the order of unity ($M_s \sim 1$), so that Eq. (3) contains no small parameter. We can thus find analytic solutions of (3) only for potential amplitudes which are not too large, in which case the solutions can be obtained by an appropriate modification of the Bogolyubov method (see also ref. 7). We expand the potential $\Phi(\xi, \eta)$ in a series in radial harmonics of the linear theory satisfying the boundary conditions at the axis and walls of the waveguide:

$$\Phi(\eta, \xi) = \sum_s P_s(\eta) Z_s(\xi), \tag{5}$$

where $Z_s(\xi)$ are the unknown amplitudes of these harmonics. Substituting (5) into (3), and integrating over η, we find for $Z_s(\xi)$ a complete system of coupled nonlinear differential equations:

$$\left(\frac{d^2}{d\xi^2} + k_s^2\right)Z_s(\xi) = f_s(\xi) \equiv \frac{1}{N_s}\int_0^1 \eta d\eta P_s(\eta) f(\xi, \eta), \tag{6}$$

$$f(\xi, \eta) \equiv \Phi(\xi, \eta) - R[\Phi(\eta, \xi)],$$

$$N_s \equiv \int_0^1 \eta d\eta P_s^2(\eta) = \frac{1}{2} J_1^2(\lambda_s).$$

Analysis of these equations shows that under the condition $|\Phi| \ll 1$ we can associate with each linear traveling wave of type (4) a slightly nonlinear wave

$$Z_s(\xi) = A_s \cos[K_s \xi + \psi_s] + \delta_s(\xi) A_s^2, \tag{7a}$$

whose spatial period $L_s \equiv 2\pi/K_s$ is governed unambiguously by the requirement that there be no secular terms in the driving force $f_s(\xi)$ of Eq. (6) for the amplitude of this wave. The amplitudes of the other radial harmonics of the field of this wave ($m \neq s$) are also unambiguously determined from the condition that there be no homogeneous (undriven) solutions of Eqs. (6) for their amplitudes $Z_m(\xi)$. Within terms quadratic in the amplitude A_s we can write the dispersion and field configuration for the wave of index s as

$$K_s^2 = k_s^2 + \mu_s A_s^2, \tag{7b}$$

$$\left.\begin{gathered} \delta_s(\xi) = \frac{3}{4}\frac{Q_{ss}^{(s)}}{4K_s^2 - k_s^2}\cos[2(K_s\xi + \psi_s)], \\ \mu_s \equiv -\frac{9}{8}\sum_{m=1}^{\infty} Q_{ss}^{(m)} Q_{ms}^{(s)} \frac{1}{k_m^2 - 4K_s^2} + \frac{3}{4}\frac{4\gamma^2+1}{\gamma^2} T_s < 0, \\ N_\gamma Q_{\alpha\beta}^{(\gamma)} \equiv \int_0^1 \eta d\eta P_\alpha(\eta) P_\beta(\eta) P_\gamma(\eta), \quad T_\alpha N_\alpha \equiv \int_0^1 P_\alpha^4(\eta)\eta d\eta, \end{gathered}\right\} \tag{7c}$$

where the constant component of the potential has been eliminated by means of quasineutrality condition (3a).

We see from (7b) that the phase velocity of the wave increases with increasing amplitude of the potential; this result, first found in ref. 2, has recently been verified experimentally.[8]

4. PERIODIC WAVES OF FINITE AMPLITUDE

It follows from Eqs. (7) that the nonlinear wave index s in general contains contributions from all the radial harmonics having different roots of the Bessel function. However, the condition for the applicability of these equations, $A_s^2 \ll k_s^2$, does not hold at low frequencies ($\omega \ll \omega_p$), where the phase velocity for wave s is approximately equal to $V_s(0)$. Here we have $k_s^2 \equiv 1 - M_s^2 \ll 1$, so that the iteration procedure used in the derivation of (7) turns out to be inapplicable even at $A_s \sim 1 - M_s^2 \ll 1$. Nevertheless, even in this case we can find an approximate analytic solution of system (6) by exploiting the smallness of the parameter $(1 - M_s^2)$.

We see from (7a) and (7b) that with $k_s^2 \ll 1$ the most important contribution to the right-hand sides of these equations comes from the terms corresponding to the field of the given radial harmonic. This means that under these conditions the dispersion and the field configuration for nonlinear wave s can be found directly from the nonlinear equation of system (6) for the amplitude of this harmonic, $Z_s(\xi)$:

$$Z_s'' - M_s^2 Z_s = \frac{1}{N_s}\int_0^1 \eta d\eta J_0(\lambda_s\eta)$$

$$\times\left\{1-\left[1-2\sum_{m=1}^{\infty} Z_m(\xi) J_0(\lambda_m\eta)\right]^{-1/2}\right\} - g_s; \qquad (8a)$$

$$g_s \equiv \frac{1}{N_s}\int_0^1 \eta d\eta G(\eta) J_0(\lambda_s\eta), \quad \beta^2 \ll 1,$$

where the amplitudes $Z_m(\xi)$ of the other radial field harmonics ($m \neq s$) are found from

$$-M_m^2 Z_m^{(s)}(\xi) = \frac{1}{N_m}\int_0^1 \eta d\eta J_0(\lambda_m\eta)\,\{1-[1-2J_0(\lambda_s\eta)\,Z_s(\xi)]^{-1/2}\} - g_m.$$

The Fourier amplitudes for the function $G(\eta)$, and thus the entire function, are determined unambiguously from quasineutrality condition (3a), which in this case becomes

$$\bar{Z}_m^{(s)} \equiv \int_{-L_s/2}^{+L_s/2} d\xi Z_m^{(s)}(\xi) = 0. \qquad (8b)$$

We have thus shown that in the case $1 - M_s^2 \ll 1$ we can use (8) to reduce the problem of finding the potential for wave s to the solution of the equation of motion for a particle having a coordinate $Z_s(\xi)$ in the field of the nonlinear electrostatic force:

$$F(Z_s) \equiv +M_s^2 Z_s + \frac{1}{N_s}\int_0^1 \eta d\eta J_0(\lambda_s\eta)$$

$$\times\left\{1-\left[1-2\sum_{m=1}^{\infty} Z_m(\xi) J_0(\lambda_m\xi)\right]^{-1/2}\right\} - g_s. \qquad (8c)$$

If the amplitude of this wave, A_s, is not too close to the maximum possible amplitude ($\Phi_{max} = 0.5$, $\beta^2 \ll 1$), then we can neglect the terms with $m \neq s$ in (8a) and (8c), according to (8b). We can then find an analytic expression for first integral (8a):

$$Z_s'^2 - M_s^2 Z_s^2 - \frac{2}{N_s}\int_0^1 \eta d\eta\,[\sqrt{1-2Z_s J_0(\lambda_s\eta)})$$

$$+ Z_s J_0(\lambda_s\eta)] + 2g_s Z_s = G_s \qquad (9)$$

We can thus find the function $Z_s(\xi)$ explicitly. Furthermore, from the known amplitude of this wave, $A_s \equiv \max \Phi(0, \xi)$, and its phase velocity $V_s \equiv (\omega_p a/\lambda_s) M_s$ we can calculate its frequency:

$$\left.\begin{aligned} \Omega_s(A_s) &\equiv K_s = \frac{2\pi}{L_s(A_s)}, \\ L_s(A_s) &\equiv 2\int_{a_s}^{A_s} dZ_s\,[Z_s'^2]^{-1/2}, \end{aligned}\right\} \qquad (10)$$

where $a_s(A_s)$ is the minimum potential in the given wave, determined from the condition $Z'_s(a_s) = 0$, where the constant g_s is eliminated by means of quasineutrality condition (3a).

These equations hold for arbitrary s, provided that the condition $1 - M_s^2 \ll 1$ is satisfied. We turn now to a more detailed analysis of the case of most applied interest – that of the first radial harmonic (s = 1). In this case, as we see from (8b), our neglect of the higher radial harmonics ($m \geq 2$) in (9) and (10) causes an error no larger than 10%, even for the case in which the amplitude of the potential is comparable to the maximum possible value [$A_1 \lessapprox (0.7\text{–}0.8)\Phi_{max}$]. If, on the other hand, this amplitude is slightly lower [$A_1 \lessapprox (0.5\text{–}0.6)\Phi_{max}$], the functions $Z_1'(\xi)$ and $\Omega_{NL}(A_1)$ can be found analytically. Expanding the integrand in (9) in a series in Z_1 and retaining the first nonlinear term, we find the function $(Z_1')^2(Z_1)$:

$$Z_1'^2 = (A_1 - Z_1)(Z_1 - a_1)[1 - M_1^2 + Q_{11}^{(1)}(Z_1 + A_1 + a_1)],$$

$$+ \quad Q_{11}^{(1)} \simeq 0.72, \qquad (11)$$

where the constants C_1 and g_1 are expressed in terms of the maximum and minimum wave potentials, A_1 and a_1, respectively.

Using Eq. (11a) and the quasineutrality condition

$$\int_{a_1}^{A_1} x dx\,\{(A_1 - x)(x - a_1)[1 - M_1^2 + Q_{11}^{(1)}(A_1 + a_1 + x)]\}^{-1/2} = 0, \qquad (11b)$$

which determines the function $a_1(A_1)$, we can also use analytic methods to analyze the behavior of the dispersion and field configuration of the period wave. In particular, at small amplitudes ($A_1 \ll 1 - M_1^2$) we find from these equations explicit equations for the minimum potential a_1 and the wave period Z_1:

$$a_1(A_1) = -A_1\left[1 - \frac{1}{2}\frac{Q_{11}^{(1)} A_1}{1 - M_1^2}\right], \qquad (12a)$$

$$L_1(A_1) = \frac{2\pi}{(1 - M_1^2)^{1/2}}\left[1 - \frac{3}{L\pi}\frac{(Q_{11}^{(1)} A_1)^2}{(1 - M_1^2)^2}\right]. \qquad (12b)$$

Accordingly, at small amplitudes of the potential and for a fixed wave phase velocity (M_1 = const), the spatial period of the wave decreases (the frequency increases) with increasing amplitude. If, on the other hand, the wave frequency is held constant (L_1 = const), an increase in the potential amplitude is accompanied by an increase in the velocity. With $A_1 \sim (1 - M_1^2)$, Eqs. (12) do not hold, so we must use numerical methods to calculate the shape of the wave potential and its phase velocity under these conditions. Figure 1 shows the frequency of the first radial harmonic (s = 1) as a function of the potential amplitude as calculated from Eqs. (9)–(11) and (3a). We see that the phase velocity continues to increase with increasing potential amplitude even at high potential amplitudes – but not so high that the condition allowing us to neglect the

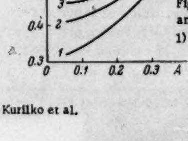

Fig. 1. Frequency as a function of the amplitude of the first harmonic M_1: 1) 0.95; 2) 0.9; 3) 0.85; 4) 0.8.

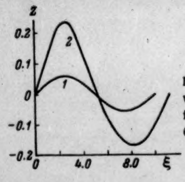

Fig. 2. Longitudinal profile of the wave potential at the waveguide axis for a fixed frequency, $\Omega = 0.5$. A_1: 1) $6 \cdot 10^{-2}$; 2) 0.24.

higher radial harmonics [$A_1 < (0.5\text{-}0.6)\Phi_{\max}$] breaks down. Furthermore, as the phase velocity decreases (or the Mach number M_1 decreases), and the potential amplitude increases, there is an increase in the nonlinearity of the dispersion (the derivative of the phase velocity with respect to amplitude at fixed frequency). The curves in Fig. 2 show the shape of the wave potential at the waveguide axis as a function of the wave amplitude at a fixed frequency.

5. CERENKOV EXCITATION OF A NONLINEAR PLASMA-FILLED WAVEGUIDE BY A PERIOD TRAIN OF CHARGED DISKS

The functional dependence of the phase velocity of the period wave on its amplitude, analyzed above, turns out to be important in the Cerenkov excitation of this wave by specified sources.[1)] Let us assume, for example, that a periodic train of thin charged disks carrying a charge density

$$\rho(r, z, t) = \sigma_0 J_0\left(\lambda_1 \frac{r}{a}\right) \sum_{s=1}^{N} \delta[z - V_0 t + (s-1) l] \tag{13}$$

is moving along the axis of a waveguide of the type considered here; here σ_0 is the amplitude of the surface charge density on each disk, $J_0(\lambda_1 \eta)$ is its functional dependence on the radius, and l is the repetition period of the disks.

The field configuration excited in the waveguide by such disks can be found from Eqs. (6)-(10) by setting $V = V_0$ ($1 - M_1^2 \ll 1$) and determining the integration constants from the boundary conditions at the disk surfaces:

$$\begin{gathered} Z_1[z = V_0 t - (s-1) l + 0] - Z_1[z = V_0 t - (s-1) l - 0] = 0; \\ Z_1'[z = V_0 t - (s-1) l + 0] - Z_1'[z = V_0 t - (s-1) l - 0] \\ = \varepsilon \equiv \frac{4\pi\sigma_0 |e|}{m_0 \omega_p V_0},\ Z_1(+\infty) = Z_1'(+\infty) = 0. \end{gathered} \tag{14}$$

If the charge on a disk is small ($\varepsilon \to 0$) and the functional dependence of the period of the excited wave on its amplitude can be neglected, each disk excited a wave at frequency Ω given by the dispersion relation $V^{(1)}(\Omega) = V_0$. If the repetition period of the disks, l, is equal to the wavelength of this wave, the Cerenkov fields of the disks combine coherently, so that the amplitude of the total field increases linearly with the disk index. It has been shown experimentally[11,12] and theoretically[4,12,13] that this effect is the basis of the collective Cerenkov interaction between charged-particle beams and plasmas. However, as the number of disks N increases, or the charge on each disk σ_0 increases, the condition for the applicability of the linear theory [$\varepsilon N \ll 1 - M_1^2(V_0) \ll 1$] is violated.

Because of the increase in the wavelength of the excited wave with increasing potential amplitude, the later disks begin to lag behind the maximum of the field excited by the earlier disks. As a result, the coherence of their radiation is disrupted, and the increase in the resultant field amplitude ends. The maximum number of coherently radiating disks, $N_{\max}$, can be evaluated from Eqs. (11)-(12). From the requirement that the nonlinear change in the wave period be small in comparison with the bunch repetition period $l = 2\pi(1 - M_1^2)^{1/2}$ we find

$$\left.\begin{aligned} N_{\max} &\sim \frac{1}{\varepsilon}(1 - M_1^2)^{3/2}, \\ E_{\max} &\simeq \sqrt{4\pi n_p m_0 V_0^2}\left(1 - \frac{\lambda_1^2 V_0^2}{\omega_p^2 a^2}\right)^{3/4} \ll 1. \end{aligned}\right\} \tag{15}$$

6. CERENKOV EXCITATION OF A NONLINEAR PLASMA (SELF-CONSISTENT APPROXIMATION)

The functional dependence of the dispersion characteristics of a plasma on the field amplitude can lead to a stabilization of two-stream instabilities, as a result of the violation of the condition for the efficient interaction of the wave with the beam particles, $\omega = kV_0$ (ref. 4). However, at relatively low beam energy densities this effect turns out to be weaker than the inverse effect of the field on the beam, which leads to a violation of this condition because of the change in the velocity of the beam particles. Accordingly, the plasma dispersion can be nonlinear only if the inverse effect of the field on the beam is negligible, as in the case of the Budker instability.[14,15] To see that this is so, we transform to the reference frame in which the beam electrons are at rest and in which the ions move, exciting longitudinal waves in the electronic background. In the simplest case of an unbounded beam the dispersion relation for these waves,

$$1 - \frac{\omega_-'^2}{\omega^2} - \frac{\omega_+'^2}{(\omega - kV_0')^2} = 0,\quad \omega_\pm'^2 \equiv \frac{4\pi^2 n_\pm'}{m_\pm'} \tag{16}$$

(the primes denote quantities referring to the rest system of the electrons), has growing solutions, for which the growth rate is

$$\delta' \equiv \omega_-'\left(\frac{n_+' m_-'}{n_-' m_+'}\right)^{1/3} \frac{\sqrt{3}}{2^{4/3}}.$$

The plasma nonlinearity becomes important at the field amplitude E_- at which the nonlinear frequency shift $\Delta\omega_- \sim \omega_-'(v_E^2/c^2)$ becomes comparable to the growth rate δ'. The inverse effect of the field on the ion beam becomes appreciable at the field amplitude E_+ at which the displacement of an ion during the characteristic time of the instability growth is comparable to the wavelength $\lambda_g' = V_0'/\omega_-'$. Comparing E_- and E_+, we find

$$\frac{E_+^2}{E_-^2} \simeq \frac{n_+' m_+' V_0'^2}{n_-' m_-' c^2}. \tag{17}$$

Accordingly, because of the large ratio of the ion mass to the electron mass, the nonlinearity of the dis-

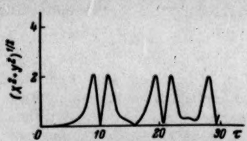

Fig. 3. Electron oscillation amplitude for the Budker instability as a function of the dimensionless time τ.

persion properties of the plasma becomes apparent much earlier than the inverse effect of the field on the beam, even for relatively low beam energies.

For a quantitative evaluation of the maximum amplitude of the field excited in this system it is convenient to use the method in which the kinetic equation is integrated in terms of Lagrange variables.[10,11,16] Since the instability is stabilized before the electron trajectories intersect, we find the following system of coupled nonlinear equations for the deviations $\Delta_{\pm}(t, z_0) \equiv Z_{\pm}(t, z_0) - V_{\pm}t - z_0$ of electrons and ions from the trajectories $Z_{\pm}^{(0)} \equiv z_0 + V_{\pm}t$ in the case of a monoenergetic beam without an interaction:

$$\left.\begin{aligned}\left\{\left(1-\frac{\Delta_-^2}{c^2}\right)^{-3/2}\frac{\partial^2}{\partial t^2}+\omega_-'^2\right\}\Delta_-(t,\ z_0)=\frac{n_+'}{n_-'}\Delta_+(t,\ z_0-V_0't),\\ \frac{\partial^2}{\partial t^2}\Delta_+(t,\ Z_0)=\frac{m_-'}{m_+'}\Delta_-(t,\ z_0+V_0t).\end{aligned}\right\}\quad(18)$$

In the linear approximation we find from this equation a complete system of coupled differential equations for the Fourier amplitudes $a_{\pm}(t) \equiv \Delta_{\pm}(t, z_0)\exp(-ikz_0)$ of the unknown displacements; the condition that there be no trivial solutions of this system yields dispersion relation (16) for the corresponding natural frequencies $[a_+(t) = a_-(t)\exp(-ikV_0t)]$. Exploiting the smallness of the growth rate ($\delta' \ll \omega_-'$), we can seek nonlinear solutions of system (18) by the Bogolyubov method:

$$\left.\begin{aligned}\Delta_-(t,\ z_0)=\mu\,[(x+iy)(\tau)]\exp[i(kz_0-\omega_0t)]+\text{c.c.},\\ \mu\equiv\left[\frac{2}{3}\left(\frac{n_+'m_-'}{2n_-'m_+'}\right)^{1/3}\right]^{1/2},\quad \tau\equiv\delta't,\ kV_0'\simeq\omega_0\simeq\omega_-'.\end{aligned}\right\}\quad(18a)$$

Then for the functions $x(\tau)$ and $y(\tau)$, which vary slowly with the time, we find a system of coupled, nonlinear, third-order equations not containing a small parameter:

$$\left.\begin{aligned}\dot{\bar{x}}+y=\frac{d^2}{d\tau^2}[(x^2+y^2)y],\\ \dot{\bar{y}}-x=\frac{d^2}{d\tau^2}[(x^2+y^2)x].\end{aligned}\right\}\quad(19)$$

Numerical solution of these equations shows that the change in amplitude which they describe is a periodic function of the time τ with a maximum amplitude on the order of two, and a characteristic period on the order of ten, times the reciprocal growth rate (Fig. 3). Hence we find the following expressions for the maximum oscillatory velocity of the electrons and for the field intensity:

$$\left.\begin{aligned}\left(\frac{v_E'^2}{c^2}\right)_{\max}\simeq\frac{8}{3}\left(\frac{\delta'}{\omega_-'}\right)\ll 1,\\ E_{\max}^2\simeq\frac{2^{5/3}}{3}16\pi\left(n_-'^2n_+'^2\frac{m_-'}{m_+'}\right)^{1/3}m_-'c^2.\end{aligned}\right.\quad(20)$$

The nonlinearity of the dispersion characteristics of the plasma can lead to a stabilization of the amplitude of the field excited by the beam, even in the case of an electron beam, provided that the beam energy is sufficiently high. For example, in an experiment involving the injection of a periodic train of electron bunches into a plasma resonator having a fixed spatial field configuration[12] (z = const), the increase in the field amplitude leads to a change in the natural frequency of the resonator, according to (12b). Accordingly, as the injection energy is raised, and the inverse effect of the field on the motion of the beam particles is weakened, the growth of the field amplitude reaches saturation as a result of the nonlinear phase drift of the field as time elapses. Figure 4 shows the energy of the periodic train of electron bunches at the exit from the resonator as a function of the bunch index N calculated for various injection energies and taking into account the nonlinear frequency shift $\Delta\Omega \equiv -\sigma A^2$ in Eqs. (6b) of ref. 12. We see that as the injection energy is raised the role of the nonlinear frequency shift in stabilizing the amplitude growth becomes more important.

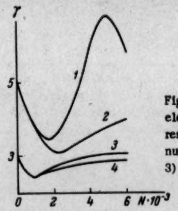

Fig. 4. Energy of the periodic train of electron bunches at the exit from the resonator as a function of the bunch number N. γ: 1, 2) 5; 3, 4) 3. α: 1, 3) 0.3; 2, 4) 0.

We can summarize the basic results of this analysis as follows:

1. We have analyzed the dispersion and field configuration of regular periodic waves of finite amplitude propagating along the axis of an anisotropic plasma-filled waveguide having conducting walls. We have shown that at low frequencies ($\omega < \omega_{pe}$) the field configuration and dispersion of these waves are governed primarily by only a single radial field harmonic – that describing that radial potential profile in the corresponding linear wave. The phase velocities of these waves and the nonlinearity of the dispersion increase monotonically with increasing amplitude of the potential.

2. We have analyzed the problem of the Cerenkov excitation of a nonlinear plasma-filled waveguide by a periodic train of charged disks, finding that the disruption of the coherence of the disk radiation due to the increase in the wavelength with increasing amplitude limits the role of this amplitude.

3. We have studied the effect of a nonlinearity of the plasma dispersion characteristics on the stabilization of the two-stream instabilities, finding that this mechanism limits the growth of the Budker instability. We have calculated the maximum amplitude of the Budker-instability field and the characteristic time required for its establishment. We have also shown that an analogous effect can have a decisive influence on the interaction of a modulated relativistic beam with a plasma resonator, especially at high energies of the injected beam.

We note in conclusion that we have restricted this analysis to the steady-state solutions of the original equations, (1)-(3), and we have not taken up the stability of these solutions.[17–19] Recent experiments at a high microwave power level[8] have shown that under certain conditions these regular waves are stable.

The authors thank M. A. Leontovich and B. B. Kadomtsev for discussion of these results.

Kinetic plasma instabilities excited by a monoenergetic beam

A. I. Ranyuk and V. L. Sizonenko

Physicotechnical Institute,
Academy of Sciences of the Ukrainian SSR, Khar'kov

(Submitted September 12, 1973)
Zh. Tekh. Fiz., 44, 995-997 (May 1974)

The solutions of the dispersion equation describing the excitation of kinetic branches in a beam–plasma system with a monoenergetic beam are investigated by numerical methods. Solutions for a wide range of wavelengths and plasma parameters are obtained.

It has been found in refs. 1-3 that, along with the well-known hydrodynamic instabilities, kinetic oscillation branches are also excited in a beam–plasma system in spite of the fact that the energy homogeneity condition for the beam is satisfied: $u/v_b \gg (n_p/n_b)^{1/3}$; where u is the directed velocity of the beam, v_b is the beam thermal velocity, and n_b and n_p are the densities of the beam and the plasma, respectively. These instabilities have a growth rate γ, whose magnitude is comparable to the maximum growth rate of the hydrodynamic modes. These are excited with either relativistic or nonrelativistic beams.

According to refs. 1-3, the pertinent dispersion equation is

$$z_0 - z + \eta\left[1 + i\sqrt{\pi}\, z w(z)\right] = 0, \tag{1}$$

where, in the case of a nonrelativistic beam.

$$z = \frac{\omega - \mathbf{k}\mathbf{u}}{\sqrt{2}\, k v_b}, \quad z_0 = \frac{-(\mathbf{k}\mathbf{u})}{2\sqrt{2}\, k v_b}\left[\frac{\omega_p^2}{(\mathbf{k}\mathbf{u})^2} - 1\right],$$

$$\eta = -\frac{\omega_b^2(\mathbf{k}\mathbf{u})}{(\sqrt{2}\, k v_b)^3}, \quad w(z) = e^{-z^2}\left(1 + \frac{2i}{\sqrt{\pi}}\int\limits_0^z e^{t^2} dt\right),$$

while, for a relativistic beam (and $z_0 = 0$),

$$z = \frac{\omega - \mathbf{k}\mathbf{u}}{\sqrt{2}\,\Gamma k' v_b}, \quad \eta = -\frac{\omega_b'^2(\mathbf{k}\mathbf{u})}{(\sqrt{2}\,\Gamma k v_b)^3}, \quad \Gamma = \sqrt{1 - \frac{u^2}{c^2}}.$$

Here, ω_p and ω_b are the plasma frequencies of the plasma and the beam, respectively, and ω and $\mathbf{k}$ are the frequency and the wave vector, respectively; the primed quantities pertain to the reference system in which the relativistic beam is at rest.

In addition to the beam–plasma instabilities, the dispersion equation (1) also holds for certain current-driven instabilities, where electrons move relative to ions with the velocity **u** (see ref. 4). In this case, as shown in ref. 4, for a nonmagnetized plasma

$$z_0 = -\frac{\mathbf{k}\mathbf{u}}{2\sqrt{2}\, k v_{Ti}}\left(\frac{\omega_{pe}^2}{(\mathbf{k}\mathbf{u})^2} - 1\right), \quad z = \frac{\omega}{\sqrt{2}\, k v_{Ti}}, \quad \eta = \frac{(\mathbf{k}\mathbf{u})\omega_{pi}^2}{(\sqrt{2}\, k v_{Ti})^3};$$

for a magnetoactive plasma with the current in the direction of the magnetic field the expressions for z and η are more cumbersome and are, therefore, not given here. Here, $\omega_{p\alpha}$ is the plasma frequency for species α (e, i), and v_{Ti} is the ion thermal velocity.

The dispersion equation (1) has been investigated analytically in refs. 1-4 for large and small values of η. It is also interesting to solve this equation for arbitrary values $\eta \sim 1$ and $z_0 \sim 1$, since the phase velocities of unstable modes are then comparable to the thermal velocities of particles ($z \sim 1$).

We have determined the roots of Eq. (1) numerically, using the M-220 and M-222 computers and the calculation method described in refs. 5 and 6.

The transient solutions of Eq. (1) are given in Figs. 1-3 as curves of the functions x and y, where $x \equiv \mathrm{Re}\, z$ and $y \equiv \mathrm{Im}\, z$.

Equation (1) has also damped solutions, which are shown in Fig. 4. Figure 5 shows both the growing and damped solutions for $\eta = 0.7$.

The numerical results are checked by using the analytical solutions x and y for small and large values of η.

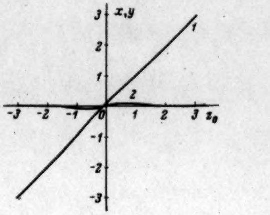

Fig. 1. Dependences of x (curve 1) and y (curve 2) on z_0 for $\eta = 0.1$.

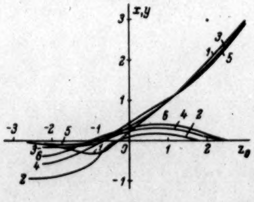

Fig. 2. 1, 3, and 5) x; 2, 4, and 6) y. 1 and 2) $\eta = 0.3$; 3 and 4) $\eta = 0.7$; 5 and 6) $\eta = 1$.

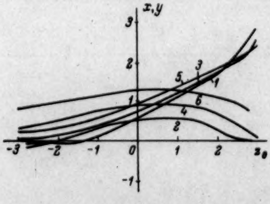

Fig. 3. 1, 3, and 5) x; 2, 4, and 6) y. 1 and 2) $\eta = 2$; 3 and 4) $\eta = 5$; 5 and 6) $\eta = 10$.

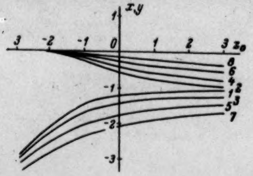

Fig. 4. 1, 3, 5, and 7) x; 2, 4, 6, and 8) y. 1 and 2) $\eta = 1$; 3 and 4) $\eta = 2$; 5 and 6) $\eta = 5$; 7 and 8) $\eta = 10$.

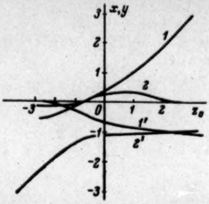

Fig. 5. Solutions for $\eta = 0.7$. 1) x; 2) y (increasing solution); 1', and 2') x and y, respectively (damped solution).

Putting $z_0 = 0$ and $\eta \ll 1$, we obtain

$$z = \eta + i\sqrt{\pi}\,\eta^2.$$

This expression describes the solutions obtained numerically for $\eta = 0.1$ and $\eta = 0.3$.

Assuming that $\eta \gg 1$, $|z_0| = 0$, and $|z| \gg 1$, we obtain the following equation instead of (1):

$$z^3 + \frac{\eta}{2} = 0, \tag{2}$$

which yields the transient solution

$$z = \frac{1 + i\sqrt{3}}{2}\left(\frac{\eta}{2}\right)^{1/3}. \tag{3}$$

For $\eta = 10$, we obtain $x \simeq 0.86$ and $y \simeq 1.46$. It should be noted that solution (3) for $\eta = 10$ is in good agreement with the data given in Fig. 4, although, strictly speaking, the asymptotic behavior of $|z| \gg 1$, for $\eta = 10$ cannot be utilized.

Thus it has been shown that, for $z_0 \sim 1$ and $\eta \sim 1$, Eq. (1) does have transient solutions with Re z ~ Im z ~ 1.

Quasilinear theory of beam-generated surface waves in a plasma

V. I. Pakhomov and V. L. Sizonenko

(Submitted May 16, 1973; resubmitted August 13, 1973)
Zh. Tekh. Fiz., 44, 998-1005 (May 1974)

A system of quasilinear equations is obtained that describes the interaction of a beam of charged particles with electrostatic surface waves in a semiinfinite magnetoactive plasma. The quasilinear integral and the spectrum in the final stage are found.

1. INTRODUCTION

Investigations of the interaction of beams of charged particles with surface waves in the linear approximation have been reported in many papers.[1,2] If the beam density is low and the velocity spread of the beam particles is large the quasilinear approximation,[3] which takes account of the reaction of the waves on the distribution function of the beam particles, can be used to investigate the nonlinear stage of the interaction of the beam with the surface waves.

In this case the quasilinear relaxation of the beam has certain distinctive features due to the exponential reduction of the amplitude of the surface wave as a function of distance from the boundary. Thus the diffusion coefficient of particles in velocity space, which is proportional to the wave energy, will also decrease exponentially with the distance from the boundary. Consequently in the quasilinear relaxation process a beam which is initially homogeneous in ordinary space becomes inhomogeneous. This feature must be taken into account even in the linear theory, i.e., an inhomogeneous beam must be considered in obtaining the expression for the linear growth rate of surface waves.

In general the quasilinear relaxation of a beam interacting with surface waves is a very complex process. A beam moving parallel to the boundary excites waves with a large range of phase velocities. This feature and the inhomogeneity of the beam and the nonuniformity of the field of the excited waves are attributable essentially to the multidimensional character of the quasilinear relaxation process. The relaxation of the beam is accompanied by the diffusion of particles in velocity space and in ordinary space. It is known[4] that in the simpler case of an unbounded homogeneous beam moving in an isotropic plasma, the three-dimensional quasilinear relaxation of the beam cannot be described analytically.

We treat here the simplest one-dimensional quasilinear relaxation of a beam interacting with high-frequency electrostatic surface waves in a semiinfinite plasma ($y < 0$). The beam moves outside the plasma ($y > 0$) along the z axis, which is directed along a uniform external magnetic field $\mathbf{H}_0$ which fills all space. The beam density n_0 and the beam velocity v_0 are assumed to be arbitrary functions of the y coordinate. The beam particles have a certain spread in longitudinal velocity.1) The value of the spread can also depend on the distance from the boundary. We consider surface waves that propagate along the magnetic field and the reaction of the waves on the average distribution function of the beam particles. The fact that these waves are most strongly excited by the beam justifies the use of a "one-dimensional" model.

We derive a set of quasilinear equations, find the "quasilinear" integral, and determine the intensity of the surface waves in the final stage.

2. LINEAR GROWTH RATE OF EXCITED SURFACE WAVES

The initial equations of the problem are the kinetic equation

$$\frac{\partial F}{\partial t}+\mathbf{v}\frac{\partial F}{\partial \mathbf{r}}+\frac{e}{m}\left(\nabla\psi-\frac{[\mathbf{v}\mathbf{H}_0]}{c}\right)\frac{\partial F}{\partial \mathbf{v}}=0 \tag{1}$$

and Poisson's equation

$$\Delta\psi=4\pi e\left(\int F d\mathbf{v}-n\right). \tag{2}$$

Equations (1) and (2) describe both the plasma ($y < 0$) and the beam ($y > 0$). We consider high-frequency waves and neglect the effect of beam and plasma ions.

We assume that in the initial state the particles have only a longitudinal velocity component [$\mathbf{v} = (0, 0, v)$] and that the beam and plasma are inhomogeneous in the direction of the normal to the boundary (the y axis).

Assuming that the perturbations are small,

$$F=F_0+F', \quad |F'|\ll F_0,$$

linearizing the kinetic equation, and considering plane waves $\exp i(kz - \omega t)$ propagating in the direction of the external magnetic field $\mathbf{H}_0$, we find the correction to the distribution function

$$f=\int F' v_\perp dv_\perp d\varphi$$
$$=\frac{e}{m}\left\{\frac{k\psi}{\omega-kv}\frac{\partial f_0}{\partial v}-\frac{1}{2\omega_H}\frac{\partial}{\partial y}\left[\left(\frac{1}{\omega-kv+\omega_H}-\frac{1}{\omega-kv-\omega_H}\right)f_0\frac{\partial\psi}{\partial y}\right]\right\}, \tag{3}$$

where $f_0 = f_0(y, v)$, $\omega_H = e\mathbf{H}_0/mc > 0$ is the electron cyclotron frequency, and φ is the azimuthal angle in velocity space.

Using (3) we write Poisson's equation in the form

$$\frac{d}{dy}\left(\varepsilon_1\frac{d\psi}{dy}\right)-k^2\varepsilon_3\psi=0, \tag{4}$$

where

$$\varepsilon_1=1+A_1(y), \quad A_1=\frac{2\pi e^2}{m\omega_H}(I_+-I_-), \quad I_\pm=\int_{-\infty}^{\infty}\frac{f_0 dv}{\omega-kv\pm\omega_H},$$

$$\varepsilon_3=1+A_2(y)\equiv 1+\frac{4\pi e^2}{mk}\int_{-\infty}^{\infty}\frac{\frac{\partial f_0}{\partial v}}{\omega-kv}dv. \tag{5}$$

We obtain the dispersion equation from the matching condition for the solutions of Eq. (4) and $\varepsilon_1(d\psi/dy)$ for the beam and plasma at the boundary y = 0.

Assuming that the plasma is cold and uniform, from (5) we have

$$\varepsilon_1 = 1 - \frac{\omega_p^2}{\omega^2 - \omega_H^2}, \quad \varepsilon_3 = 1 - \frac{\omega_p^2}{\omega^2}, \quad \left(\omega_p^2 = \frac{4\pi e^2 n_p}{m}\right); \tag{6}$$

consequently the solution of Eq. (4) for a surface wave in the region occupied by the plasma (y < 0) has the form

$$\psi = C_- e^{\varkappa y}, \quad \left(\varkappa = k\sqrt{\frac{\varepsilon_3}{\varepsilon_1}} > 0\right). \tag{7}$$

It follows from (7) that the condition for the existence of a surface wave in the plasma is $\varepsilon_3/\varepsilon_1 > 0$.

It is impossible to obtain an analytic solution of Eq. (4) in the region of the inhomogeneous beam (y > 0) in the general case. However, when the beam density n_b is small in comparison with the plasma density n_p the method of successive approximations[1,7] can be used to solve Eq. (4). In our problem the assumption $n_b \ll n_p$ is unavoidable since the quasilinear approximation can only be used to investigate a system with a small growth rate. For $n_b \ll n_p$ the field of a surface wave in the region y > 0 will differ only slightly from the vacuum field described by the function exp(− ky). Without going into the calculations we present the dispersion relation for surface waves on the plane boundary between the uniform cold plasma and an inhomogeneous hot beam of low density

$$\varepsilon_1\varkappa + k = -k\int_0^\infty (A_1 + A_2)\, e^{-2ky}dy, \tag{8}$$

where A_1 and A_2 are given by (5) and refer to the beam.

In the absence of a beam ($A_1 = A_2 = 0$) Eq. (8) takes the form

$$\varepsilon_1\varkappa + k = 0. \tag{9}$$

From (9) we find the frequency of the electrostatic surface waves on the plane plasma−vacuum boundary:

$$\omega_0 = \sqrt{\frac{\omega_p^2 + \omega_H^2}{2}}. \tag{10}$$

The solution (10) exists for $\omega_p > \omega_H$.

An inhomogeneous low-density beam excites surface waves with the frequency (10). For a sufficiently large thermal spread of the longitudinal velocities of the beam particles, we find the following expression for the growth rate $\gamma(\omega = \omega_0 + i\gamma)$ from (18):

$$\gamma = \frac{\pi\omega_0(\omega_p^2 - \omega_H^2)}{4kn_p\omega_H}\left\{\frac{\omega_H}{k}\left\langle\frac{\partial f_0}{\partial v}\right\rangle\Big|_{v=\frac{\omega_0}{k}} + \frac{1}{2}\left(\langle f_0\rangle\Big|_{v=\frac{\omega_0+\omega_H}{k}} - \langle f_0\rangle\Big|_{v=\frac{\omega_0-\omega_H}{k}}\right)\right\}, \tag{11}$$

where

$$\langle f_0\rangle = 2k\int_0^\infty f_0 e^{-2ky}dy. \tag{12}$$

Three groups of resonance particles of the beam contribute to the growth (or damping) rate (11) of surface waves with a given wave vector k, or a given phase velocity ω_0/k: 1) particles in Cerenkov resonance with the wave; their velocity coincides with the phase velocity of the wave; 2) particles in cyclotron resonance with the wave under conditions of the anomalous Doppler effect; their velocity is higher than the phase velocity of the wave; 3) particles in cyclotron resonance with the wave under conditions of the normal Doppler effect; their velocity is lower than the phase velocity of the wave.

We consider a beam with a small velocity spread v_T ($v_T \ll v_0$). Through the Cerenkov mechanism such a beam will excite waves with a range of phase velocities $\Delta v_p \sim v_T$ immediately below the value of $v_0 (v_p < v_0)$. If $\omega_p \gg \omega_H$, $\omega_0 \sim \omega_p \sim \omega_H$. In this case beam particles from the tail of the distribution, whose velocities differ from v_0 by amounts of the order of $v_0 \gg v_T$, will be in cyclotron resonance with waves having phase velocities in the range Δv_p. Their contribution can be neglected.

Through the cyclotron mechanism the bulk of the beam particles will excite waves in the range $\Delta v_p' \sim v_T$ lying to the left of v_0 by an amount of the order of v_0; the beam particles must be "superluminal". Also through the cyclotron mechanism, under conditions of the normal Doppler effect, the beam particles with thermal velocities will damp out waves from the range of phase velocities $\Delta v_p'' \sim v_T$ lying to the right of v_0 by an amount of the order of v_0. The growth (or damping) rate due to the cyclotron mechanism is of the order of magnitude of v_0/v_T times smaller than that due to the Cerenkov mechanism.

The preceding discussion shows that when the velocity spread of the beam particles is small ($v_T \ll v_0$) and the relation $\omega_p \gg \omega_H$ holds for the plasma, all three particle−wave interaction mechanisms can be considered separately, with the Cerenkov interaction playing the leading role. We consider this case in the investigation of the quasilinear relaxation of the beam presented below.

For an increase in the plasma density or a decrease in the external magnetic field the intervals between Δv_p, $\Delta v_p'$, and $\Delta v_p''$ are decreased, and for $\omega_p/\omega_H \sim v_0/v_T \gg 1$ these intervals are of order v_T and the spectra overlap. In this case all three mechanisms can make approximately equal contributions to the growth rate.

When the velocity spread of the beam particles is large ($v_T \sim v_0$) it is necessary to take account of all three interaction mechanisms.

We note that the expression for γ does not contain spatial derivatives of the distribution function of the beam particles since the waves propagate along the beam velocity v_0. These derivatives appear for oblique wave propagation.

The contributions of the separate parts of the beam to the growth rate (11) depend on how far these particles are from the boundary. This fact appears explicitly in the averaging with an appropriate weight in (12). The fact that the growth rate is a spatial integral of a quantity is a characteristic feature of the problem under consideration.

3. QUASILINEAR RELAXATION OF THE BEAM

We continue the investigation of the problem posed in the quasilinear approximation, i.e., we take account of the effect of the excited waves on the distribution function of the beam particles in the first nonvanishing approximation in the wave energy.

It is known[3] that the quasilinear approximation can be used to investigate the instabilities of beam systems when the growth rate γ is appreciably smaller than kv_T and the frequency ω. From Eq. (11) we obtain the condition

$$\left(\frac{v_T}{v_0}\right)^3 \gg \frac{n_b}{n_p}. \tag{13}$$

We assume that the conditions $v_T \ll v_0$ and $\omega_p \gg \omega_H$ are satisfied. Then, as noted above, we need take account only of the Cerenkov interaction of the particles with the waves, i.e., in Eq. (11) for the growth rate we take account only of the first term on the right-hand side.

In the usual way we represent the rapidly oscillating part of the distribution function and the field of the excited waves by a superposition of plane waves $\exp i(kz - \omega_k t)$ with random phases. The amplitudes of these waves are related by the linear theory, equation (3). In the case under consideration only the first term on the right-hand side of (3) need be taken into account. We obtain the equation for the slowly varying distribution function of the beam particles by averaging the kinetic equation over the fast oscillations. Since only the Cerenkov interaction is taken into account the particle velocity v is uniquely determined by the wave vector $k = \omega_0/v$.

As a result we obtain the one-dimensional diffusion equation

$$\frac{\partial f_0(y,\ v,\ t)}{\partial t} = \frac{\partial}{\partial v} D \frac{\partial f_0(y,\ v,\ t)}{\partial v}, \tag{14}$$

where the diffusion coefficient D is given by

$$D = \frac{8\pi^2 e^2}{m^2} \frac{W(y,\ v,\ t)}{v}. \tag{15}$$

If f_0 varies slowly with the time, the spectral energy density of the electrostatic surface oscillations $W = k^2|\psi|^2 \cdot (4\pi)^{-1}$ varies according to the equation

$$\frac{\partial W(y,\ v,\ t)}{\partial t} = 2\gamma(v,\ t)\, W(y,\ v,\ t), \tag{16}$$

where γ is given by the linear theory equation

$$\gamma(v,\ t) = \frac{\pi}{4} \frac{\omega_p^2 - \omega_H^2}{\omega_0} \frac{v^2}{n_p} \left\langle \frac{\partial f_0(y,\ v,\ t)}{\partial v} \right\rangle, \tag{17}$$

in which the distribution function averaged over the fast waves must appear instead of the initial distribution function.

The quantity $W(y,\ k,\ t)dk = W(y,\ v,\ t)(\omega_0/v^2)dv$ is the energy density of the electrostatic surface waves whose phase velocity lies between v and v + dv at a distance y from the boundary on the beam side. Integrating over all v we obtain the volume energy density of the oscillations. The dependence of W on y is given by

$$W(y,\ v,\ t) = W(y=0,\ v,\ t)\, e^{-2\frac{\omega_0}{v}y}. \tag{18}$$

The system of equations (14)-(17) describes the quasilinear relaxation of the beam interacting with the surface waves. The distribution function of the beam particles is "eroded" on the low velocity side. Since collisions are not taken into account the beam must relax to a plateau state.

A characteristic feature of the quasilinear relaxation of a beam exciting surface waves is the spatial nonuniformity of the relaxation process. Clearly at a certain instant in the quasilinear relaxation process the degree of "erosion" of the beam particle distribution function will decrease with the distance from the boundary. For example, an initially spatially homogeneous beam develops a certain profile of the average velocity during the relaxation process, with v_0 increasing with the distance from the boundary. Subsequently, as the plateau state is established, the directed velocity profile disappears, starting from the boundary.

Equations (14)-(17) describe the simplest form of the quasilinear relaxation of a beam exciting surface waves. In the case considered there is neither heating of the beam in the transverse direction, nor diffusion of particles in ordinary space. The interdependence of the relaxation of layers of the beam at various distances from the boundary is contained only in the averaging of γ over y (Eq. 12).

The system of quasilinear equations (14)-(17) has a time integral. From these equations there follows the relation

$$\frac{\partial f_0}{\partial t} = \frac{16\pi e^2 n_p}{m^2} \frac{\omega_0}{\omega_p^2 - \omega_H^2} \frac{\partial}{\partial v}\left[\frac{1}{v^3} \frac{\partial W(y,\ v,\ t)}{\partial t} \frac{\dfrac{\partial f_0}{\partial v}}{\left\langle \dfrac{\partial t_0}{\partial v} \right\rangle}\right]. \tag{19}$$

Integrating (19) with respect to y from zero to infinity and using (18) we obtain

$$\frac{\partial}{\partial t}\left\{\int_0^\infty f_0 dy - \frac{2\omega_p^2}{m(\omega_p^2 - \omega_H^2)} \frac{\partial}{\partial v}\left[\frac{W(y=0,\ v,\ t)}{v^2}\right]\right\} = 0. \tag{20}$$

Thus the quantity in braces in (20) is conserved in the quasilinear relaxation of the beam.

We make the usual assumption that at zero time the fluctuations of the surface oscillations are thermal and that their energy can be neglected in comparison with the beam energy, i.e., we assume that W(y = 0, v, t = 0) = 0. Then, from (20)

$$\frac{\partial}{\partial v}\left[\frac{W(y=0,\ v,\ t)}{v^2}\right] = \frac{m(\omega_p^2 - \omega_H^2)}{4\omega_p^2} \int_0^\infty [f_0(y,\ v,\ t) - f_0(y,\ v,\ t=0)]\, dy. \tag{21}$$

Since $v_T \ll v_0$ we can set

$$f_0(y, v, t=0) = n_b(y)\,\delta(v - v_0). \tag{22}$$

Assume that the quasilinear relaxation is terminated in time $t = t_R$, i.e., the plateau on the distribution function has been established for any y. Then

$$f_0(y, v, t_R) = \begin{cases} \dfrac{n_b(y)}{v_0}, & 0 < v < v_0; \\ 0, & v > v_0. \end{cases} \tag{23}$$

For simplicity we assume that v_0 does not depend on y. It is clear that if $n_b(y)$ is finite as $y \to \infty$, $t_R = \infty$.

Substituting (22) and (23) into (21) and integrating with respect to v from 0 to v_0, we find the spectral energy density of the electrostatic waves at the boundary y = 0 in the final state:

$$W(y=0, v, t_R) = \begin{cases} \dfrac{m(\omega_p^2 - \omega_H^2)}{2\omega_p^2}\dfrac{v^3}{v_0}\displaystyle\int_0^\infty n_b(y)\,dy, & 0 < v < v_0; \\ 0 & v > v_0. \end{cases} \tag{24}$$

The quantity $W(y = 0, v, t_R)$ does not change if the beam is at various distances from the boundary; as this distance is increased, only the time t_R to establish a stationary state is increased.

Multiplying (24) by $\exp[-2(\omega_0/v)y](\omega_0/v^2)$ and integrating with respect to v from 0 to v_0 and with respect to y from 0 to ∞, we obtain the total energy U_b of the electrostatic waves in the final state contained in a semiinfinite ($y > 0$) column with unit cross-sectional area:

$$U_b = \frac{1}{6}\frac{\omega_p^2 - \omega_H^2}{\omega_p^2} U_0, \tag{25}$$

where $U_0 = (mv_0^2/2)\int\limits_0^\infty n_b(y)dy$ is the initial kinetic energy of the beam in that column.

It is not difficult to calculate the energy U of the electric field contained in a similar column on the plasma side ($y < 0$). Taking account of the fact that the ratio of the energy density of the field in the plasma (at $y = -0$) to the energy density of the field in the beam (at $y = +0$) is $(\varepsilon_1 + \varepsilon_3)/2\varepsilon_1$, and also the fact that the damping rate of the field of the surface wave in the plasma is $\sqrt{\varepsilon_1/\varepsilon_3} = (\omega_p^2 + \omega_H^2)/(\omega_p^2 - \omega_H^2)$ times larger than in the beam region, we obtain

$$U_p = \frac{1}{6}\frac{\omega_p^4 + \omega_H^4}{\omega_p^2(\omega_p^2 + \omega_H^2)} U_0. \tag{26}$$

The total energy contained in the electric field in the final state is therefore

$$U = U_b + U_p = \frac{1}{3}\frac{\omega_p^2}{\omega_p^2 + \omega_H^2} U_0. \tag{27}$$

In the final state 1/3 of the initial energy remains in the beam and 2/3 has been transformed into waves. Using this fact we find the wave energy U_k of the plasma particles in the final state:

$$U_k = \frac{2}{3}U_0 - \frac{1}{3}\frac{\omega_p^2}{\omega_p^2 + \omega_H^2}U_0 = \frac{1}{3}\frac{\omega_p^2 + 2\omega_H^2}{\omega_p^2 + \omega_H^2}U_0. \tag{28}$$

The value of $(U_p + U_k)$ can be obtained by using the familiar expression for the average electrostatic energy density in a plasma:

$$\bar{U} = \frac{d(\omega\varepsilon_{\alpha\beta})}{d\omega}\frac{E_\alpha^* E_\beta}{16\pi}. \tag{29}$$

The problem of the dynamics of the one-dimensional quasilinear relaxation of a beam is solved in ref. 8. The solution is obtained by using the small parameter representing the ratio of the energy density of thermal fluctuations U_T to the energy density of oscillations in the final state U_∞. The solution for the distribution function of the beam electrons is a step function, describing the process when the boundary of the relaxation region moves slowly toward lower velocities, and the plateau state has time to be established to the right of the boundary.

We are unable to obtain an analogous solution for our problem. One can expect, however, that the relaxation process goes on in a similar way in beam layers near the boundary. It is clear that the velocity of the boundary of the relaxation region must decrease with distance from the boundary. At large distances from the boundary the ratio U_T/U_∞ ceases to be small and the step function solution is not realized.

It was indicated above that the beam particles excite surface waves with phase velocities in the range $v_p \lessgtr v_0 - (\omega_H/\omega_0)v_0$ by the cyclotron mechanism. When the boundary of the relaxation region reaches these velocities, it is necessary to account for the cyclotron interaction of particles with waves under conditions of the anomalous Doppler effect in the quasilinear equations. Instead of using Eq. (17) for the growth rate it is necessary to use the expression

$$\gamma(v, t) = \frac{\pi}{4}\frac{\omega_p^2 - \omega_H^2}{\omega_H}\frac{v}{n_p}\left[\frac{\omega_H}{\omega_0}v\left\langle\frac{\partial f_0(v, t)}{\partial v}\right\rangle + \frac{1}{2}\left\langle f_0\left(v + \frac{\omega_H}{\omega_0}v, t\right)\right\rangle\right]. \tag{30}$$

The term

$$\frac{1}{\omega_H}\frac{\partial}{\partial v}D\left(\frac{\partial f_0}{\partial y} - \frac{\omega_0 + \omega_H}{v}f_0\right).$$

must be added to the right-hand side of the diffusion equation (14).

Taking account of the cyclotron interaction in the quasilinear approximation leads to the motion of the beam as a whole. When the Cerenkov excitation of waves causes the sharp boundary of the relaxation region to move at a velocity which necessitates taking account of the cyclotron excitation of waves, the diffusion coefficient is obviously increased. In this case the conditions for the existence of a step function solution can be violated.

The authors are grateful to K. N. Stepanov for discussion.

Instabilities in a finite-β plasma with transverse current. I

A. I. Pyatak and V. L. Sizonenko

(Submitted July 30, 1973)
Zh. Tekh. Fiz., 44, 1006-1013 (May 1974)

We consider a plasma with current that flows at right angles to the confining magnetic field; the high-frequency small-scale instabilities that propagate with a phase velocity along the magnetic field that is appreciably lower than the electron thermal velocity are analyzed. Allowance is made for inhomogeneity of the magnetic field. The instabilities are electromagnetic; frequencies and growth rates are determined.

1. INTRODUCTION

Interest in the stability of a plasma with a current that flows at right angles to an external magnetic field arises from the important role that related instabilities play in plasma containment, turbulent heating and anomalous resistance, and radiation from a plasma. Such instabilities can develop in theta pinches, in shock waves, in various kinds of plasma injectors, in plasmoids that enter an inhomogeneous magnetic field, when ion cyclotron and fast magnetoacoustic waves of large amplitude are excited in a plasma, and in other cases.

At the present time the excitation of high-frequency ($\omega \gg \omega_{Hi}$) electrostatic instabilities in a low-pressure plasma [$\beta = 4\pi n_0(T_e + T_i)/H_0^2 \ll 1$] has been investigated fairly fully. The existence of various instabilities has been established; these include the Bernstein modes ($\omega \equiv n\omega_{He}$, $\gamma \gg \sqrt{\omega_{He}\omega_{Hi}}$), which propagate precisely at right angles to the magnetic field,[1] and various instabilities ($\omega < \omega_{He}$, $\gamma \sim \sqrt{\omega_{He}\omega_{Hi}}$) which propagate almost at right angles to the magnetic field.[2-6]

The conjecture that Bernstein modes can play an important role in the structure of a shock front calls for a detailed study of the excitation of these instabilities in a finite-pressure plasma[7,8] ($\beta \sim 1$). At the same time, in a number of experimental situations the Bernstein modes play a secondary role. It is of interest to investigate the influence of the effects that the finite pressure has on the excitation of these current-driven instabilities. As is shown in ref. 9, allowance for a small but finite pressure leads to the appearance of electromagnetic branches with a growth rate $\gamma \sim \sqrt{\omega_{He}\omega_{Hi}\beta}$. In ref. 10, a study is made of the influence of a finite pressure on the development of electron acoustic and drift instabilities in a plasma with hot ions and cold electrons.

In the present paper we investigate the excitation of high-frequency ($\omega_{Hi} \ll \omega$, $\gamma \ll \omega_{He}$) short-wave ($kv_{Ti} \gg \omega_{Hi}$) oscillations in a finite-β plasma ($\beta \sim 1$) with transverse current. It is assumed that the current velocity u is appreciably greater than the drift velocities due to the inhomogeneity of the density and temperature of the plasma, so that terms $\sim \nabla n_0$, ∇T in the dispersion equation can be ignored. At the same time terms associated with the particle drift due to inhomogeneity of the magnetic field are retained and make an important contribution to the dispersion equation..

In Sec. 1 of this paper we study the excitation of oscillations whose phase velocities along the magnetic field are less than the electron thermal velocity ($\omega/k_{\parallel}v_{Te} \lesssim 1$). Such waves propagate at an angle θ to the magnetic field that is not too near $\pi/2$, so that $\cos\theta \gtrsim u/v_{Te}$. We show that in a hot electron plasma ($T_e \gg T_i$) the most rapidly growing modes are those with $\cos\theta \sim u/v_{Te}$, whose growth rate is approximately

$$\gamma \sim \sqrt{\omega_{He}\omega_{Hi}}. \qquad (1.1)$$

In the region of wavelengths of the order of the electron Larmor radius ($kv_{Te} \sim \omega_{He}$) this instability is a branch of the electromagnetic ion-acoustic oscillations in a magnetic field.

In an isothermal plasma ($T_e \sim T_i$) and in a plasma with hot ions ($T_i \gg T_e$) the unstable modes are also essentially electromagnetic and their growth rates are smaller than (1.1).

An important feature is the rapid decrease of the growth rates with increasing β in the region $\beta > 1$.

2. DISPERSION EQUATION

We first obtain a dispersion equation for unstable modes in a finite-β plasma. For simplicity we assume that the lines of force of the magnetic field $\mathbf{H}_0$ that confines the plasma are parallel to the z axis, while the field strength H_0 varies slowly with the y coordinate:

$$\frac{\varkappa_H v_{Ti}}{\omega_{Hi}} \ll 1, \quad \varkappa_H = \frac{1}{H_0}\frac{\partial H_0}{\partial y}.$$

We investigate the case in which the current velocity u, which is directed along the z axis, exceeds appreciably the Larmor drift velocity of the particles due to the inhomogeneity of the density and temperature of the plasma, so that terms $\sim \nabla n_0$, ∇T in the dispersion equation can be ignored.

It is convenient to introduce the scalar ψ and vector **A** potentials instead of the vectors **E** and **H**. Then the dispersion equation in the local approximation has the form[11]

$$\begin{aligned}\varepsilon_{00}N^4 + [\varepsilon_{03}^2 - \varepsilon_{02}^2 - \varepsilon_{00}(\varepsilon_{33} + \varepsilon_{22})]N^2 + \varepsilon_{00}\varepsilon_{23}^2 + \varepsilon_{02}^2\varepsilon_{33} \\ + 2\varepsilon_{02}\varepsilon_{03}\varepsilon_{23} + \varepsilon_{22}(\varepsilon_{00}\varepsilon_{33} - \varepsilon_{03}^2) = 0, \quad N \equiv kc/\omega, \qquad (2.1)\end{aligned}$$

where, for Maxwell ion distributions the components ε_{ij} are given by the expressions[9]

$$\varepsilon_{00} = 1 + \frac{\omega_{pe}^2}{k^2 v_{Te}^2}\left[1 - \int d\mathbf{v} f_{0e}\frac{J_0^2}{\Delta_e}\omega\right] + \delta\varepsilon_{00}^i,$$

$$\varepsilon_{02} = -\varepsilon_{20} = i\frac{\omega_{pe}^2}{k_z v_{Te}^2}\int d\mathbf{v} f_{0e}\frac{v_\perp}{\Delta_e}J_0 J_0',$$

$$\varepsilon_{03} = \varepsilon_{30} = -\frac{\omega_{pe}^2}{k_z v_{Te}^2}\int d\mathbf{v} f_{0e}\frac{v_\parallel}{\Delta_e}J_0^2,$$

$$\varepsilon_{23} = -\varepsilon_{32} = -i\frac{\omega_{pe}^2}{\omega v_{Te}^2}\int d\mathbf{v} f_{0e}\frac{v_\parallel v_\perp}{\Delta_e}J_0 J_0',$$

$$\varepsilon_{22}=1+\frac{\omega_{pe}^2}{\omega_{He}^2}-\frac{\omega_{pe}^2}{\omega v_{Te}^2}\int d\mathbf{v} f_{0e}\frac{v_\perp^2}{\Lambda_e}(J_0')^2,$$

$$\varepsilon_{33}=1-\frac{\omega_{pe}^2}{\omega v_{Te}^2}\int d\mathbf{v} f_{0e}\frac{v_\parallel^2}{\Lambda_e}J_0^2,$$

$$\delta\varepsilon_{00}^i=\frac{\omega_{pi}^2}{k^2v_{Ti}^2}[1+i\sqrt{\pi}\,z_iw_i],$$

where

$$\Lambda_e=\omega-k_\parallel v_\parallel-\frac{k_x\varkappa_H v_\perp^2}{2\omega_{He}},\quad z_i=\frac{\omega-k_xu}{\sqrt{2}\,kv_{Ti}},\quad k_\parallel=k\cos\theta,$$

$$\omega_{He}=\frac{eH_0}{m_ec}>0,\quad \omega_{pe}=\left(\frac{4\pi e^2n_0}{m_e}\right)^{1/2},$$

$$v_{Te}=\left(\frac{T_e}{m_e}\right)^{1/2},\quad J_0'=-J_1,\quad J_0\left(\frac{k_xv_\perp}{\omega_{He}}\right)$$

is the Bessel function, $w_i = w(z_i)$ is the Cramp function of complex argument.

The dispersion equation holds for frequencies ω and wave vectors **k** for which the ions can be assumed to be unmagnetized ($kv_{Ti}/\omega_{Hi} \gg 1$, $|\omega| \gg \omega_{Hi}$) and the electrons magnetized[1)] ($kv_{Te} \lessgtr \omega_{He}$, $|\omega| \ll \omega_{He}$). The current velocity u, which is associated with the relative motion of the ions and the electrons, is introduced into the ion distribution function. We also give the following relation between u and $\varkappa_H$, which follows from the Maxwell equation curl $H_0 = 4\pi/cj$:

$$u=\frac{cH_0\varkappa_H}{4\pi en_0}.\tag{2.2}$$

Equation (2.1) is simplified appreciably in the limiting case of fairly large $k_\parallel$, where $|\omega - k_x\varkappa_H v_{Te}^2/\omega_{He}| \ll k_\parallel v_{Te}$:

$$\left[1+i\sqrt{\pi}z_0A_0+\frac{T_e}{T_i}(1+i\sqrt{\pi}z_iW_i)\right]$$
$$\times\left\{1-2z_0^2q\left[A_0-\frac{k_xu_H}{\omega}(A_0+\mu A_0')+\beta_e(A_0')^2\right]\right.$$
$$\left.+2i\sqrt{\pi}z_0(\beta_eA_0'+z_0^2q\eta_1)\right\}+2z_0^2qA_0(A_0+2i\sqrt{\pi}z_0\eta_2)=0,\tag{2.3}$$

where

$$\eta_1=-A_0\left(1-\frac{k_xu_H}{\omega}\right)^2+2\mu A_0'\frac{k_xu_H}{\omega}(1+\beta_eA_0')$$
$$-\frac{k_x^2u_H^2}{\omega^2}(2A_0+4\mu A_0'+\mu^2A_0'')$$
$$-2\beta_eA_0'\left[A_0+A_0'-\frac{k_xu_H}{\omega}(A_0+2A_0'+\mu A_0'')\right],$$
$$\eta_2=A_0+\beta_eA_0'(A_0+A_0')-\frac{k_xu_H}{\omega}(A_0+\mu A_0'),$$
$$A_0=e^{-\mu}I_0(\mu),\quad A_0'=\frac{d}{d\mu}A_0,\quad \mu=k^2\rho^2\equiv\frac{k^2v_{Te}^2}{\omega_{He}^2},$$
$$u_H=\frac{\varkappa_Hv_{Te}^2}{\omega_{He}}=u\beta_e,\quad \beta_e=\frac{4\pi n_0T_e}{H_0^2},\quad q=\frac{\omega_{pe}^2}{k^2c^2},\quad z_0=\frac{\omega}{\sqrt{2}|k_z|v_{Te}},$$

and $I_0(\mu)$ is a modified Bessel function.

In what follows we analyze the dispersion equation (2.3).

3. HOT-ELECTRON PLASMA ($T_e \gg T_i$)

We first consider a plasma with hot electrons and cold ions. We assume that $|z_i| \gg 1$. In the case $\mu \ll 1$, Eq. (2.3) is simplified considerably and takes the form

$$\left[1-\frac{k^2v_s^2}{(\omega-k_xu)^2}+i\sqrt{\pi}z_0\right]\left\{1-2z_0^2q\left[1+\beta_e\left(1-\frac{k_xu}{\omega}\right)\right]\right.$$
$$\left.+2i\sqrt{\pi}z_0(-\beta_e+z_0^2q\eta_1)\right\}+2z_0^2q(1+2i\sqrt{\pi}z_0\eta_2)=0,\tag{3.1}$$

where

$$\eta_1=-\left(1-\frac{k_xu}{\omega}\beta_e\right)^2-2\beta_e^2\frac{k_xu}{\omega}\left(\frac{k_xu}{\omega}-1\right),$$
$$\eta_2=1-\frac{k_xu}{\omega}\beta_e,\quad v_s=\left(\frac{T_e}{m_i}\right)^{1/2}.$$

Equations (2.3) and (3.1) are valid only in the approximation $|z_0| \ll 1$ and terms proportional to iz_0 in Eq. (3.1) are small. Since $q = \beta_e/\mu \gg 1$, terms $\sim z_0^2q$ can be comparable with the remaining principal terms in (3.1). We therefore investigate the solutions of Eq. (3.1) in the first approximation, ignoring small terms $\sim iz_0$. Then Eq. (3.1) takes the form

$$[(\omega-k_xu)^2-k^2v_s^2][k_z^2v_{Te}^2-\omega^2(1+\beta_e)q$$
$$+\omega k_xu\beta_eq]+\omega^2(\omega-k_xu)^2q=0.\tag{3.2}$$

When $u \gg v_s$ the roots of Eq. (3.2) are

$$\omega_{1,2}=k_xu\left[1\pm i\sqrt{\frac{q}{\cos^2\theta}-\frac{v_{Te}^2}{u^2}\left(\frac{m_e}{m_i}\right)^{1/2}}\right],\tag{3.3}$$

$$\omega_{3,4}=\frac{k_xu}{2}\left(1\pm\sqrt{1+\frac{\cos^2\theta v_{Te}^2}{u^2q\beta_e}}\right),\tag{3.4}$$

where

$$\cos\theta=\frac{k_z}{k_x}.$$

It follows from (3.3) that when $|k_\parallel| < k_0 \equiv (u/c)\cdot(\omega_{pe}/v_{Te})^{-1}$ one of the roots is unstable; when $k_\parallel \ll k_0$ the growth rate of the instability is

$$\gamma\equiv\operatorname{Im}\omega=\frac{u}{v_{Te}|\cos\theta|}\sqrt{\omega_{He}\omega_{Hi}\beta_e}.\tag{3.5}$$

In this case the condition $|z_0| \ll 1$ means that $u/v_{Te}\cdot|\cos\theta| \ll 1$. Thus, the growth rate (3.5) increases with decreasing $|\cos\theta|$, and the oscillations that must be most rapidly excited are those that propagate in the interval of angles $|\theta-\pi/2| \lessgtr u/v_{Te}$.

When $|k_\parallel| > k_0$ all the solutions of Eq. (3.2) are stable and to determine the growth rate or the decay rate one must take account of the small residue terms $\sim i\sqrt{\pi}z_0$ in Eq. (3.1). For each of the oscillation branches we obtain the following values of γ:

$$\gamma_{1,2}=\mp\sqrt{\frac{\pi}{8}\frac{m_e}{m_i}}\frac{|k_x|u}{|\cos\theta|}\left(1-\frac{k_0^2}{k_z^2}\right)^{-1/2}\left[1-2\beta_e+2(1-\beta_e)\frac{k_0^2}{k_z^2}\right.\tag{3.6}$$
$$\left.+(\beta_e^2+2\beta_e-2)\frac{k_0^4}{k_z^4}\right],$$

$$\gamma_{3,4}=-3\sqrt{\frac{\pi}{2}}\beta_e\frac{\omega_{3,4}}{|k_z|v_{Te}}\left[\left(\frac{k_xu}{\omega_{3,4}}-\frac{2}{3}\right)^2\right.$$

$$+\frac{2}{9}\Big]\left(1-\frac{k_x u}{\omega_{3,4}}\right)\left(2-\frac{k_x u}{\omega_{3,4}}\right)^{-1}. \quad (3.7)$$

It follows from (3.6) that one of the branches is always unstable, although the growth rate (3.6) for $|k_{\parallel}| > k_0$ is smaller by a factor $1/|z_0|$ than the growth rate (3.5) obtained in the case $|k_{\parallel}| < k_0$. The branches (3.4) and (3.7) are always stable. It is interesting to note that the branches ω_3 and ω_4 are purely electron oscillations for $u \gg v_s$; in the absence of resonant ions, these are damped.

Solutions of Eq. (3.2) can also be readily be found in the case $u - v_s \ll v_s$:

$$\omega_{1,2}=\frac{\sqrt{2}\,u^2\kappa_x}{2|\cos\theta|v_{Te}q(1-2\beta_e)}\left\{\cos^2\theta\frac{v_{Te}^2}{u^2}-\frac{q\beta_e}{2}\left(1-\frac{v_s^2}{u^2}\right)\right. \quad (3.8)$$

$$\left.\pm\sqrt{\left[\cos^2\theta\frac{v_{Te}^2}{u^2}+\frac{\beta_e q}{2}\left(1-\frac{v_s^2}{u^2}\right)\right]^2-\cos^2\theta\frac{v_{Te}^2}{u^2}q\left(1-\frac{v_s^2}{u^2}\right)}\right\},$$

$$\omega_{3,4}=\frac{k_x v_s}{2}\left(3\beta_e\pm\sqrt{9\beta_e^2-8\beta_e+4}\right). \quad (3.9)$$

It follows from the form of the radicand in (3.8) that these solutions are unstable only when $u > v_s$ and $\beta_e < 0.5$. In the region of instability of the roots (3.8) the growth rate is a maximum when

$$q\left(1-\frac{v_s^2}{u^2}\right)=4\frac{v_{Te}^2\cos^2\theta}{\beta^2u^2}\left(1-\beta_e-\sqrt{(1-\beta_e)^2-\frac{3}{4}\beta_e^2}\right),$$

this maximum being equal to

$$\gamma_m=\frac{u(1-\beta_e)^{-3/2}\left(1-\frac{v_s^2}{u^2}\right)^{3/2}}{8v_{Te}|\cos\theta|\sqrt{1-2\beta_e}}\left[1-\sqrt{1-\frac{3}{4}\frac{\beta^2}{(1-\beta)^2}}\right]^{-3/2}$$

$$\times\left[1-2\beta_e+\frac{\beta_e^2}{2}+(1-\beta_e)\sqrt{1-2\beta_e+\frac{\beta_e^2}{4}}\right]^{-1/2}\sqrt{\omega_{He}\omega_{Hi}\beta_e}. \quad (3.10)$$

When $\beta_e > 0.5$ all solutions of Eq. (3.2) are stable. A growth rate appears in this case only when allowance is made for the small residue terms $\sim iz_0$ in Eq. (3.1). Analysis of the solutions obtained in this manner shows that the branches (3.9) are always damped (for any β_e).

One of the branches (3.8) for $\beta_e > 0.5$ is unstable, its growth rate being smaller by a factor $|\cos\theta|\,v_{Te}/u$ than the growth rate (3.10).

An exceptional case arises when $\beta_e = 0.5$ since the growth rate (3.10) increases rapidly. However, one cannot use Eq. (3.2), because all the terms $\sim iz_0$ in Eq. (3.1) are then not small. Bearing this in mind, from Eq. (3.1) we have

$$z_0^2+i\frac{\sqrt{\pi}}{6}\frac{u^2}{v_{Te}^2\cos^2\theta}z_0+\left[\left(1-\frac{v_s^2}{u^2}\right)\frac{u^2}{12\cos^2\theta v_{Te}^2}-\frac{1}{3q}\right]=0.$$

It is not difficult to make an extremum investigation of this equation. The growth rate is a maximum when

$$q=\frac{48\alpha^4}{\pi a(a-1)}\left[2a+\sqrt{2a}-\frac{1}{2}\right],$$

$$a\equiv1+\frac{12\cos^2\theta v_{Te}^2}{\pi u^2}\left(1-\frac{v_s^2}{u^2}\right),\quad \alpha=\cos\theta\frac{v_{Te}}{u}$$

and is equal to

$$\gamma_m=\frac{\sqrt{\omega_{He}\omega_{Hi}}}{4\sqrt{\pi}}\left(1-\frac{v_s^2}{u^2}\right)^{3/2}x(a)^{1/4}\left[(a)^{1/2}+\frac{\sqrt{2}}{2}\right]^{-3/2}. \quad (3.11)$$

Thus, when $\beta_e = 0.5$ the growth rate is larger by at least a factor $(1-v_s^2/u^2)^{-1/2}$ than the growth rate when $\beta_e \neq 0.5$.

There are of course unstable solutions of Eq. (3.2) when $u \gtrsim v_s$. In particular, for angles θ defined by the relation

$$\cos^2\theta=q\left[(\beta_e+3)\frac{m_e}{m_i}-\frac{u^2}{v_{Te}^2}\beta_e\right],$$

one can readily obtain solutions of Eq. (3.2) in explicit form:

$$\left(\omega-\frac{3}{4}k_x u\right)^2=\left(\frac{k_x^2u^2}{16}+k^2v_s^2+2k^2v_A^2\right)$$

$$\times\left(1\pm\left\{1-\left[\left(1-\frac{16v_s^2}{u^2}\right)^2+\frac{3}{4}16^2\frac{v_A^2}{u^2}\left(4\frac{v_s^2}{u^2}-1\right)\right]\right.\right.$$

$$\left.\left.\times\left[1+16\frac{v_s^2}{u^2}+32\frac{v_A^2}{u^2}\right]^{-2}\right\}^{1/2}\right),\quad v_A^2=\frac{v_s^2}{\beta_i}. \quad (3.12)$$

It follows, for example, that the expression in the braces in (3.12) is negative (there is an unstable solution) if tion) if

$$\frac{8(\beta_e+3)}{\beta_e+6}<\frac{u^2}{v_s^2}<4\left(1+\frac{3}{\beta_e}\right),\quad (\beta_e<6).$$

Thus, our investigation of the instabilities shows that electromagnetic modes, like electrostatic modes, are excited by a transverse current only when $u > v_s$; the growth rate increase in proportion to $u(1+\beta_e)/v_{Te}|\cos\theta|$. The maximum growth rate obviously arises in the case $|\cos\theta| \sim u/v_{Te}$, $\mu \sim 1$, when Eq. (2.3) can no longer be used.

Unstable electrostatic modes for such angles and wavelengths in a low-pressure plasma ($\beta \to 0$) are investigated in ref. 5, and called magnetized ion sound waves. Naturally, in a finite-B plasma ($\beta_e \sim 1$) this branch must become essentially electromagnetic.

Below we shall investigate the excitation of this branch of oscillations when $\beta_e \sim 1$ in the limiting case of fairly large current velocities $u \gg v_s$.

An important circumstance facilitating the finding of unstable solutions is the fact that the ion terms need be taken into account only in the component ε_{00} in Eq. (2.1):

$$\varepsilon_{00}^i=-\frac{\omega_{pi}^2}{(\omega-k_x u)^2}.$$

In this case the complex frequency can be sought in the form $\omega = k_x u + \Delta\omega$, where $\Delta\omega \ll k_x u$. Then, substituting into the electron part of the tensor ε_{ij} the value $\omega = k_x u$ and ignoring the correction $\Delta\omega$, from Eq. (2.1) we have

$$\Delta\omega=\pm\omega_{pi}\left[\frac{c^4}{u^4}-\frac{c^2}{u^2}(\varepsilon_{33}+\varepsilon_{22})+\varepsilon_{23}^2+\varepsilon_{22}\varepsilon_{33}\right]^{1/2}\left\{\frac{c^4}{u^4}\varepsilon_{00}^e\right.$$

$$+\frac{c^2}{u^2}\left[\varepsilon_{03}^2-\varepsilon_{02}^2-\varepsilon_{00}^e(\varepsilon_{33}+\varepsilon_{22})\right]+\varepsilon_{00}^e\varepsilon_{23}^2+\varepsilon_{02}^2\varepsilon_{33}$$

$$\left.+2\varepsilon_{02}\varepsilon_{03}\varepsilon_{23}+\varepsilon_{22}(\varepsilon_{00}^e\varepsilon_{33}-\varepsilon_{03}^2)\right\}^{-1/2}. \quad (3.13$$

As we have noted above, the right-hand side of (3.13) does not contain the frequency $\Delta\omega$. This quantity can be ignored in the electron terms since the terms in the resonance denominators associated with the drift in the inhomogeneous magnetic field are large compared with $\Delta\omega$:

$$\Lambda_e \sim \frac{k_x \varkappa_H v_\perp^2}{\omega_{He}} \sim k_x u \beta_e \gg \Delta\omega, \quad (\beta_e \sim 1).$$

Since $\mu \sim 1$ the integrals in ε_{ij} cannot be expressed in terms of known functions. However, when $\mu \sim 1$, $k_x u \sim k_\parallel v_{Te} \sim k_x \varkappa_H v_\perp^2/\omega_{He}$, we have the estimate $\mathrm{Im}\,\varepsilon_{ij} \sim \mathrm{Re}\,\varepsilon_{ij}$, so that the components of the tensor ε_{ij} are of order

$$|\varepsilon_{00}^e| \sim \frac{\omega_{pe}^2}{\omega_{He}^2}, \; |\varepsilon_{33}| \sim |\varepsilon_{22}| \sim |\varepsilon_{23}| \sim \frac{c^2}{u^2}, \; |\varepsilon_{02}| \sim |\varepsilon_{03}| \sim \frac{c}{u}\frac{\omega_{pe}}{\omega_{He}}.$$

Since the expression on the right-hand side of (3.13) is complex, with a real part of the same order as the imaginary part, one of the roots $\Delta\omega$ will always correspond to instability with growth rate of order $\gamma \sim \sqrt{\omega_{He}\omega_{Hi}}$.

Thus, in a finite-β plasma the magnetized ion sound wave with wavelength of the order of electron Larmor radius is an electromagnetic branch whose growth rate, as in a low-β plasma,[2,5] is of the order of magnitude given by (1.1). It should be pointed out that a magnetized ion sound wave in the short-wave region $\mu \gg 1$ is an electrostatic mode even in a finite-β plasma.

4. HOT-ION PLASMA

Let us now consider a hot-ion plasma in which one can assume $|z_i| \ll 1$, $\mu \ll 1$. Then, from Eq. (2.3) we have

$$\Big[1 + \frac{T_e}{T_i}(1 + i\sqrt{\pi}z_i) + i\sqrt{\pi}z_0\Big]\Big[1 - 2z_0^2 q\Big(1 + \beta_e - \beta_e\frac{k_x u}{\omega}\Big) + 2i\sqrt{\pi}z_0(-\beta_e + z_0^2 q\eta_1)\Big] + 2z_0^2 q(1 + 2i\sqrt{\pi}z_0\eta_2) = 0, \qquad 4.1)$$

where

$$\eta_1 = -\Big(1 - \frac{k_x u}{\omega}\beta_e\Big)^2 + 2\beta_e^2\frac{k_x u}{\omega}\Big(1 - \frac{k_x u}{\omega}\Big), \quad \eta_2 = 1 - \frac{k_x u}{\omega}\beta_e.$$

Using the fact that the imaginary terms are small in (4.1) we can readily obtain expressions for the frequency and growth rate:

$$\mathrm{Re}\,\omega \equiv \omega_\pm = \mathrm{sgn}\,k_x\Big(\frac{b}{2}k_x u \pm \sqrt{\frac{b^2k_x^2u^2}{4} + b\frac{k_\parallel^2 v_{Te}^2}{q}}\Big),$$
$$\gamma = -\sqrt{\pi}z_0\frac{q\omega^3}{q\omega^2\beta_e + k_\parallel^2 v_{Te}^2}\Big[|\cos\theta|\sqrt{\frac{m_i}{m_e}}\Big(\frac{T_e}{T_i}\Big)^{3/2}\Big(1 - \frac{k_x u}{\omega}\Big) + \beta_e^2\Big(\frac{k_x u}{\omega}\Big)^2 + 2\beta_e\Big(1 - \frac{k_x u}{\omega}\Big)\Big], \qquad (4.2)$$

where

$$b \equiv \beta_e\Big(1 + \frac{T_e}{T_i}\Big)\Big[\beta_e + (1 + \beta_e)\frac{T_e}{T_i}\Big]^{-1} \simeq 1 - \frac{T_e}{T_i\beta_e}. \qquad (4.3)$$

It follows from (4.3) that waves with frequency ω_- are damped, since $k_x u/\omega_- < 0$; excitation of waves with frequency ω_+ requires the condition $k_x u > \omega_+$, i.e., $k_\parallel^2 v_{Te}^2 \cdot q^{-1} < k_x^2 u^2/\beta_e(T_e/T_i) \ll k_x^2 u^2$. Thus from (4.2) and (4.3) we have

$$\mathrm{Re}\,\omega = \omega_+ = \Big(1 - \frac{T_e}{T_i\beta_e}\Big)k_x u + \frac{k_\parallel^2 v_{Te}^2}{q k_x u},$$
$$\gamma = \sqrt{\frac{\pi}{2}}\frac{|k_x|u^2}{v_{Te}\beta_e|\cos\theta|}\Big\{|\cos\theta|\sqrt{\frac{m_i}{m_e}}\Big(\frac{T_e}{T_i}\Big)^{3/2}\Big[\frac{T_e}{T_i\beta_e} - \frac{k_\parallel^2 v_{Te}^2}{k_x^2 u^2 q}\Big] - \beta_e^2\Big\}. \qquad (4.4)$$

It is evident that the growth rate (4.4) is a maximum when

$$|\cos\theta| = \Big[\frac{3\sqrt{3}}{4}\beta_e^{11/3}\frac{m_e}{m_i}\frac{u}{v_{Te}}\Big(\frac{T_i}{T_e}\Big)^{3/2}\Big]^{1/3},$$

$$k = \frac{2}{3\sqrt{3}}\beta_e^{-7/3}\frac{u}{v_{Te}}\sqrt{\frac{m_i}{m_e}}\Big(\frac{T_e}{T_i}\Big)^3\frac{\omega_{pe}}{c}$$

being equal to

$$\gamma_m = \sqrt{\frac{\pi}{10}}\frac{4}{25}\beta_e^{-8}\Big(\frac{u}{v_{Ti}}\Big)^3\Big(\frac{T_e}{T_i}\Big)^4\sqrt{\omega_{He}\omega_{Hi}}. \qquad (4.5)$$

In this case, to satisfy the inequalities $z_0 \ll 1$, $\mu \ll 1$, and $z_i < 1$ it is necessary that $u/v_{Ti} < \beta_i = \beta_e T_i/T_e$.

We introduce a certain limiting value for the current velocity $u = u^*$, for which the condition $\gamma_m \sim \omega_{Hi}$ is satisfied:

$$u^* \simeq 2v_{Ti}\Big(\frac{m_e}{m_i}\Big)^{1/6}\beta_e^{8/3}\Big(\frac{T_i}{T_e}\Big)^{4/3}. \qquad (4.6)$$

Then the above instability exists in the range of current velocities $u^* < u < \beta_i v_{Ti}$.

5. ISOTHERMAL PLASMA ($T_e \sim T_i$)

In an isothermal plasma one can investigate analytically only the case in which the phase velocity of the wave at right angles to the magnetic field is smaller than the ion thermal velocity ($z_i < 1$). Then the dispersion equation has the form (4.1), in which $T_e/T_i \sim 1$. As in the case of a plasma with hot ions, the unstable branch is the one with frequency $\omega = \omega_+$ defined by the expression (4.2), and the growth rate γ is equal to

$$\gamma = \sqrt{\pi}z_0\Big(1 + \frac{T_e}{T_i}\Big)^{-1}\omega\Big[\Big(1 + \frac{T_e}{T_i}\Big)\Big(1 + \beta_e + \frac{k_\parallel^2 v_{Te}^2}{q\omega^2}\Big) - 1\Big]^{-1}$$
$$\times\Big\{|\cos\theta|\sqrt{\frac{m_i}{m_e}}\Big(\frac{T_e}{T_i}\Big)^{3/2}\Big(\frac{k_x u}{\omega} - 1\Big) - \Big[\Big(1 + \frac{T_e}{T_i}\Big)\Big(1 - \frac{k_x u}{\omega}\beta_e\Big) - 1\Big]^2 - 2\beta_e\Big(1 + \frac{T_e}{T_i}\Big)^2\Big[\Big(1 - \frac{k_x u}{\omega}\Big)^2\beta_e + \frac{T_e}{T_i}\Big(1 + \frac{T_e}{T_i}\Big)^{-1}\Big]\Big\}. \qquad (5.1)$$

The growth rate (5.1) has a maximum at certain values of $k_\parallel$ and k, although an extremum investigation is very cumbersome. In order to elucidate the characteristic features of the excitation of oscillations in an isothermal finite-β plasma, let us consider the special case $T_e = T_i$, $qu^2/\cos^2\theta\, v_{Te}^2 \gg 1$. Then the expression (5.1) is simplified and takes the form

$$\gamma = \sqrt{\frac{\pi}{2}}\frac{\beta_e}{(2\beta_e + 1)^3}|k_x|u\frac{u}{v_{Ti}}\Big[1 - \frac{4\beta_e}{|\cos\theta|}\sqrt{\frac{m_e}{m_i}}(2\beta_e^2 + 2\beta_e + 1)\Big], \qquad (5.2)$$

where $\beta_e = \beta_i \equiv \beta$.

The growth rate (5.2) will be positive when $1 \gg |\cos\theta| > 4\beta_e\sqrt{m_e/m_i}(2\beta^2+2\beta+1)$. For a hydrogen plasma when $\beta = 1$ it is difficult to satisfy these inequalities because the growth rate (5.2) is positive only for $|\cos\theta| \sim 1$. On the basis of this observation, we can introduce a certain limiting pressure $\beta = \beta^*$ above which instability is impossible:

$$4\beta^*(2\beta^{*2}+2\beta^*+1)\sqrt{\frac{m_e}{m_i}} \approx 0.3. \qquad (5.3)$$

To satisfy the condition $|z_i| < 1$ one requires $u/v_{Ti} < 1$ and this reduces the value of the growth rate. It is obvious that when $\beta \sim 1$ the solutions (5.1) and (5.2) are valid only in a plasma with heavy ions (for example, for the gas Xe), since it is only in this case that the conditions $\gamma \gg \omega_{Hi}$, $\beta^* > \beta > 1$ can be satisfied.

---

1) The condition $|\omega| \ll \omega_{He}$ enables us to retain only the term with $n = 0$ in ε_{ij} and to ignore effects associated with electron cyclotron resonances.

Instabilities in a finite-β plasma with transverse current. II

A. I. Pyatak and V. L. Sizonenko

(Submitted July 30, 1973)
Zh. Tekh. Fiz., 44, 1014-1021 (May 1974)

We treat a finite-β plasma with current that flows at right angles to the confining magnetic field; high-frequency small-scale instabilities that propagate at right angles to the magnetic field are analyzed. Allowance is made for the inhomogeneity of the magnetic field due to the flowing current. The instabilities are electromagnetic; frequencies and growth rates are determined.

1. INTRODUCTION

In the second part of the present paper, which is a continuation of ref. 1, we investigate high-frequency (γ, $\omega \gg \omega_{Hi}$) small-scale ($k_\perp v_{Ti} \gg \omega_{Hi}$) instabilities of a finite-β plasma $\beta = 4\pi n_0 (T_e + T_i/H_0^2 \gtrsim 1)$ with transverse current. In the linear approximation we consider modes that propagate exactly at right angles to the external magnetic field ($\theta = \pi/2$). It is assumed, as before, that the current velocity u responsible for the instabilities is appreciably greater than the Larmor drift velocity due to the inhomogeneity of the density and temperature of the electrons, so that the terms ∇n_0 and ∇T in the dispersion equation can be ignored. The inhomogeneity of the magnetic field due to the transverse current is taken into account and plays an important role in the excitation of instabilities in a finite-β plasma. In the considered range of frequencies and wavelengths the ions can be assumed to be unmagnetized so that the effects associated with gradients of the density, temperature, and magnetic field in the ion terms can be ignored.

It is shown that in a hot-electron plasma ($T_e \gg T_i$) one can have the excitation of hydrodynamic electromagnetic modes with wave vectors $k \sim \omega_{pe}/c(v_A/u)^{1/3}$, whose growth rates are of order

$$\gamma \sim \sqrt{\omega_{He}\omega_{Hi}} \quad (u \gtrsim v_A). \tag{1.1}$$

We find a threshold value of the current velocity below which the solutions we obtain do not apply.

In the region of shorter wavelengths kinetic instabilities are excited by the Cerenkov resonance between the waves and electrons drifting in the inhomogeneous magnetic field. The growth rate of these instabilities increases with increasing plasma pressure, reaching the value in (1.1) when $\beta \approx 0.25$.

Unstable modes propagating at right angles to the magnetic field in a plasma with hot ions ($T_i \gg T_e$) and finite ion pressure ($\beta_i = 4\pi n_0 T_i/H_0^2 \sim 1$, $\beta_e = 4\pi n_0 T_e/H_0^2 \ll 1$) are investigated in ref. 1. Here, we investigate the excitation of such modes for a finite electron pressure. ($\beta_e \sim 1$, $\beta_i \gg 1$). It is shown that allowance for the residue terms associated with the magnetic drift of the electrons has a stabilizing influence on the instability.

We also consider the excitation of instabilities in an isothermal plasma ($T_e \sim T_i$) at high pressure ($\beta \gg 1$). We determine the boundaries of the instability region with respect to the current velocity and we find expressions for the frequencies and growth rates.

It is shown that all these instabilities disappear in a plasma of infinitely high pressure ($\beta \to \infty$) because of the rapid decrease of the growth rate with increasing β.

2. DISPERSION EQUATION

We obtain first a dispersion equation, assuming that the equilibrium distribution functions of the electrons and the ions are Maxwellian in the first approximation in the weak inhomogeneity parameter. The electromagnetic field will be described by the scalar and vector potentials. Then, taking $k_\parallel = 0$ ($\theta = \pi/2$) in the tensor ε_{ij} given in Part 1 of the present work, we find that

$$\left.\begin{aligned} &\varepsilon_{03} = \varepsilon_{23} = 0,\\ &\varepsilon_{33} = N^2 \equiv \frac{k^2c^2}{\omega^2},\\ &\varepsilon_{00}(\varepsilon_{22} - N^2) + \varepsilon_{02}^2 = 0, \end{aligned}\right\}. \tag{2.1}$$

where

$$\left.\begin{aligned} &\varepsilon_{33} = 1 - 2\frac{\omega_{pe}^2}{\omega v_{Te}^2}\int d\mathbf{v} f_{0e}\frac{v_\perp^2 J_0^2}{2\omega - k_x\varkappa_H v_\perp^2\omega_{He}^{-1}},\\ &\varepsilon_{00} = 1 + \frac{\omega_{pe}^2}{k^2v_{Te}^2}\left[1 - 2\int d\mathbf{v} f_{0e}\frac{\omega J_0^2}{2\omega - k_x\varkappa_H v_\perp^2\omega_{He}^{-1}}\right] + \delta\varepsilon_{00}^i,\\ &\varepsilon_{02} = 2i\frac{\omega_{pe}^2}{k_x v_{Te}^2}\int d\mathbf{v} f_{0e}\frac{v_\perp J_0 J_0'}{2\omega - k_x\varkappa_H v_\perp^2\omega_{He}^{-1}},\\ &\varepsilon_{22} = 1 + \frac{\omega_{pe}^2}{\omega_{He}^2} - 2\frac{\omega_{pe}^2}{\omega v_{Te}^2}\int d\mathbf{v} f_{0e}\frac{v_\perp^2 (J_0')^2}{2\omega - k_x\varkappa_H v_\perp^2\omega_{He}^{-1}},\\ &\delta\varepsilon_{00}^i = \frac{\omega_{pi}^2}{k^2v_{Ti}^2}[1 + i\sqrt{\pi}z_i w_i]. \end{aligned}\right\} \tag{2.2}$$

When $\mu \ll 1$, the Bessel functions can be expanded in the small parameter $k_\perp v_\perp/\omega_{He}$. Then the integrals in the components of the tensor ε_{ij} can be readily expressed in terms of the exponential integral $Ei(\zeta)$, where

$$Ei(\zeta) \equiv e^\zeta \int_0^\infty \frac{e^{-x}dx}{\zeta - x}, \quad \zeta = \frac{\omega\omega_{He}}{k_x\varkappa_H v_{Te}^2} = \frac{\omega}{k_x u\beta_e}. \tag{2.3}$$

This function shows the following aymptotic behavior:

$$Ei(\zeta) = e^\zeta \sum_{n=0}^\infty \frac{n!}{\zeta^{n+1}} - i\pi\,\mathrm{sgn}\,k_x \quad \text{for} \quad |\zeta| \gg 1,\ \omega \gg \gamma, \tag{2.4}$$

$$Ei(\zeta) \simeq C + \ln(-\zeta) \quad \text{for} \quad |\zeta| \ll 1, \tag{2.5}$$

where C ≈ 0.57 is Euler's constant.

If $|\zeta| \gg 1$ but $\gamma \gtrsim \omega$, in the asymptotic expression (2.4) one must ignore the imaginary part, because the residue terms vanish in the integrand of (2.3). The dispersion equations (2.1) and (2.2) take the following form:

$$1 + q\zeta e^{-\zeta}Ei = 0; \tag{2.6}$$

$$\left[(1-\zeta e^{-\zeta}Ei)\left(1-\zeta\mu+\frac{3}{8}\zeta^2\mu^2\right)+\frac{3}{8}\zeta\mu^2+\frac{T_e}{T_i}(1+i\sqrt{\pi}z_iw_i)\right]$$
$$\times\left\{\frac{\omega}{k_xu}\left[1+\zeta(1-\zeta e^{-\zeta}Ei)\left(1-\frac{\mu}{2}\zeta+\frac{5}{48}\mu^2\zeta^2\right)-\frac{\mu}{2}(2+\zeta)\right.\right.$$
$$\left.\left.+\frac{5}{48}\mu^2(\zeta^2+2\zeta+6)\right]-1\right\}$$
$$-\frac{\omega}{k_xu}\zeta\left\{(1-\zeta e^{-\zeta}E_i)\left(1-\frac{3}{4}\zeta\mu-\frac{5}{24}\mu^2\zeta^2\right)\right.$$
$$\left.-\frac{3}{4}\mu-\frac{5}{24}\mu^2(\zeta+2)\right\}^2=0. \qquad (2.7)$$

Here and in what follows Ei ≡ Ei(ζ).

In Eq. (2.6) we have retained only the highest terms in the expansion in the parameter μ, and in Eq. (2.7) we have omitted the terms $\sim\mu^3$ and higher.

Analysis shows that Eq. (2.6) has only a damped solution, since the contribution of the ions to ε_{33} is ignored. Therefore, in what follows we investigate the solutions of Eq. (2.7).

3. HOT-ION PLASMA ($T_e \gg T_i$)

If the ion temperature is low one can assume that $|z_i| \gg 1$, so that the ion term takes the form

$$\frac{T_e}{T_i}(1+i\sqrt{\pi}z_iw_i)=-\frac{k^2v_s^2}{(\omega-k_xu)^2}.$$

Let us investigate the instabilities in a low-β plasma ($\beta_e \ll 1$), in which $|\zeta| \gg 1$. In this case Eq. (2.7) becomes

$$1+q\left(1-\frac{k_xu}{\omega}\right)-\frac{\omega_{He}\omega_{Hi}}{(\omega-k_xu)^2}=\frac{\pi^2}{16}\frac{\omega^2}{k_x^2u^2q}\zeta^4e^{-2\zeta}+i\pi\zeta^2e^{-\zeta}$$
$$\times\left\{1+q\left(1-\frac{k_xu}{\omega}\right)-\frac{\omega}{k_xu}\frac{\omega_{He}\omega_{Hi}}{(\omega-k_xu)^2}-\frac{\omega^2}{2k_x^2u^2q}\left[1-\frac{\omega_{He}\omega_{Hi}}{(\omega-k_xu)^2}\right]\right\}. \qquad (3.1)$$

It must be remembered that the right-hand side of Eq. (3.1) is nonvanishing only in the case Re $\omega \gg$ Im ω and is equal to zero if Re $\omega \lessgtr$ Im ω.

Let us first consider the solutions of Eq. (3.1) for which the right-hand side of this equation can be ignored (this is the case for which Im $\omega \sim$ Re ω or small β_e). The problem now reduces to finding the roots of a cubic equation. It is not difficult to show that one of the roots of this equation will give an instability when

$$\left[1+\frac{u^2}{3qv_A^2}\frac{1}{(1+q)}\right]\left(1+\sqrt{1+3q\frac{v_A^2}{u^2}(1+q)}\right)<\frac{9}{2}\left(q+\frac{8}{9}\right). \qquad (3.2)$$

The limits of the stability region ($q = q_0$) can now be readily determined by replacing the inequality sign in (3.2) by the equality sign.

The growth rate of the instability can be written explicitly in certain limiting cases.

When $u \gg v_A$, from (3.2) we have $q_0 = 2^{2/3}/3(u/v_A)^{2/3}$. In this case, in the region $q-q_0 \ll q_0$ the growth rate has the form

$$\gamma=\sqrt{\omega_{He}\omega_{Hi}}\left(\frac{q-q_0}{q_0}\right)^{1/3}, \qquad (3.3)$$

in the region $q \gg q_0$ it is

$$\gamma=\left(\frac{27}{16}\right)^{1/3}\sqrt{\omega_{He}\omega_{Hi}}\left(\frac{q_0}{q}\right)^{1/3}. \qquad (3.4)$$

Thus, the growth rate attains a maximum value for wave vectors $k \sim \omega_{pe}/c(v_A/u)^{1/3}$ and is of order

$$\gamma_m \simeq \sqrt{\omega_{He}\omega_{Hi}} \quad (q \geqslant q_0). \qquad (3.5)$$

When $u \ll v_A$ the unstable solutions lie in the region $|\omega| \ll |k_xu|$ and are determined by the expressions

$$\omega=\frac{k_xu}{4}\left(\frac{u^2}{v_A^2q}-1\right)\pm i\frac{u}{4}\frac{\omega_{pe}}{c}\sqrt{\frac{8}{q}\frac{u^2}{v_A^2}-\frac{1}{q}\left(\frac{u^2}{v_A^2q}-1\right)^2}. \qquad (3.6)$$

When $k = (v_A/u)(\omega_{pe}/c)$ the growth rate is a maximum:

$$\gamma_m=\frac{1}{2}\frac{u}{v_A}\sqrt{\omega_{He}\omega_{Hi}}. \qquad (3.7)$$

Finally, we give the solutions of Eq. (3.1) in the following special case:

$$\omega=\left\{\frac{1}{2}+i\left[\frac{3\sqrt{2}-2}{4(2+\sqrt{2})}\right]^{1/2}\right\}\sqrt{\omega_{He}\omega_{Hi}},\quad q=\frac{u^2}{v_A^2}=1+\sqrt{2}. \qquad (3.8)$$

It follows from (3.5)-(3.8) that the growth rates increase with increasing u and reach saturation ($\gamma \simeq \sqrt{\omega_{He}\omega_{Hi}}$) in the region $u \gtrsim v_A$.

The threshold value $u = u^*$ of the velocity below which these solutions become inapplicable can be determined from the conditions $\gamma > kv_{Ti}, \omega_{Hi}$. Taking the smallest γ to be that from (3.7) we find

$$u^*\simeq\max\left\{v_A\sqrt{\frac{m_e}{m_i}};\ v_A\beta_i^{1/2}\right\},\quad \beta_i=\frac{4\pi n_0T_i}{H_0^2}. \qquad (3.9)$$

We now investigate the solutions of Eq. (3.1) that give a nonvanishing growth rate only when allowance is made for the right-hand side of (3.1). In the case $u \gg v_A$ we set $\omega = k_xu + \Delta\omega$, where the small correction $\Delta\omega$ is determined by

$$(\Delta\omega)^2=\omega_{He}\omega_{Hi}\frac{16q+8i\pi\zeta^2e^{-\zeta}(1-2q)}{16q+8i\pi\zeta^2e^{-\zeta}-i\pi\zeta^2e^{-\zeta}(16q-i\pi\zeta^2e^{-\zeta})},\quad \zeta=\frac{1}{\beta_e}. \qquad (3.10)$$

It follows from (3.10) that Im $\omega \sim \zeta^2e^{-\zeta} \to 0$ in the limit $\beta_e \to 0$. However, even in the region $\beta_e \ll 1$ the growth rate determined by the residue terms can become large if $\beta_e > \beta_{cr}$:

$$\mathrm{Im}\,\Delta\omega \sim \mathrm{Re}\,\Delta\omega \sim \sqrt{\omega_{He}\omega_{Hi}},\quad q \leqslant 1. \qquad (3.11)$$

Here, $\beta_{cr} \simeq 0.25$ is determined from the condition

$$\pi\beta_{cr}^{-2}\exp\left(-\frac{1}{\beta_{cr}}\right)\simeq 1.$$

The solution found above satisfies the conditions $|\zeta| \gg 1$, Im ω/Re $\omega \lessgtr v_A/u \ll 1$ and lies in the region of wavelengths in which the hydrodynamic instability (3.3)-(3.5) vanishes. It is interesting to note that when $\beta_e \approx \beta_{cr}$ the growth rate (3.11) is of the order of the maximum hydrodynamic growth rate (3.5).

In the case $u \ll v_A$ and $|1-q(v_A^2/u^2)| > 2\sqrt{2}(u/v_A)$, the hydrodynamic solutions (3.6) become stable. Allowance for the residue terms in (3.1) for these roots gives the following value of the growth rate:

$$\gamma=\sqrt{\frac{\pi}{2}}\zeta^2e^{-\zeta}q^{3/2}\frac{u}{v_A}\left[2\frac{v_A^2}{u^2}\left(1-q\frac{v_A^2}{u^2}\right)-1\right]\left(1-q\frac{v_A^2}{u^2}\right)^{-3}\sqrt{\omega_{He}\omega_{Hi}}. \tag{3.12}$$

When the right-hand side is ignored, the third root of Eq. (3.13) is always stable:

$$\omega=k_xu+\Delta\omega,\ \Delta\omega=\pm\sqrt{\omega_{He}\omega_{Hi}},\ \ q\ll 1.$$

With allowance for the residue terms, this root of the equation also gives an instability with growth rate equal to

$$\gamma=\frac{\pi}{16}\sqrt{\omega_{He}\omega_{Hi}}\frac{1}{\beta_e^2}\exp\left(-\frac{1}{\beta_e}\right). \tag{3.13}$$

In a plasma with a reasonably high pressure (for example, for $\beta_e \sim \beta_{cr}$) the growth rate (3.13) can exceed the growth rate (3.7).

Finally, we give the solutions of (3.1) when $u \sim v_A$ for waves with $q \ll 1$, which are not excited in the hydrodynamic approximation. Then two solutions can be sought in the form $\omega = k_xu + \Delta\omega$ ($\Delta\omega \ll k_xu$), where

$$\Delta\omega=\pm\sqrt{\omega_{He}\omega_{Hi}}\left[1-i\frac{\pi}{16}\frac{1}{\beta_e^2}\exp\left(-\frac{1}{\beta_e}\right)\right]. \tag{3.14}$$

The third root of Eq. (3.1) lies in the region of frequencies $|\omega| \ll |k_xu|$ and is determined by the expression

$$\left.\begin{aligned}\omega&=k_xuq+i\gamma,\\ \gamma&=k_xuq^2\left(\frac{v_A^2}{u^2}-\frac{1}{2}\right)\pi\zeta^2e^{-\zeta}.\end{aligned}\right\} \tag{3.15}$$

It follows from (3.15) that this solution gives an instability only when $u < \sqrt{2}v_A$. Nothing that $\zeta = q/\beta_e$, we can readily find the maximum value of the growth rate (3.15), which is attained when $q = (7/2)\beta_e \ll 1$ and is equal to

$$\gamma_m=8\beta_e^{3/2}\frac{u}{v_A}\left(\frac{v_A^2}{u^2}-\frac{1}{2}\right)\sqrt{\omega_{He}\omega_{Hi}}. \tag{3.16}$$

We now turn to the investigation of instabilities in a hot-electron plasma at finite pressure ($\beta_e \gtrsim 1$).

When $\beta_e \sim 1$ and $u \gg v_s$, a solution of Eq. (2.7) can be sought in the form $\omega = k_xu + \Delta\omega$ ($\Delta\omega \ll k_xu$). Then, bearing in mind that $\zeta = 1/\beta_e \gg \mu$, from (2.7) we have

$$\left(\frac{\Delta\omega}{k_xu}\right)^3+\left(\frac{1-\beta_e}{\beta_e}\right)\mu\left(\frac{\Delta\omega}{k_xu}\right)^2-\frac{v_A^2}{u^2}=0. \tag{3.17}$$

It is evident that when $\beta_e < 1$ Eq. (3.17) has unstable solutions if

$$\mu<\frac{3}{2^{2/3}}\frac{\beta_e}{1-\beta_e}\left(\frac{v_A}{u}\right)^{4/3}, \tag{3.18}$$

and that when $\beta_e > 1$ an instability occurs for all values $\mu < 1$. We give a solution of Eq. (3.17) when $\beta_e > 1$ in certain limiting cases. If $\mu \gg (v_A/u)^{4/3}$, we can ignore the first term in (3.17) and find that

$$\Delta\omega=\pm i\sqrt{\frac{\omega_{He}\omega_{Hi}}{\beta_e-1}}. \tag{3.19}$$

If $\mu \ll (v_A/u)^{4/3}$, the complex roots have the form

$$\Delta\omega=-\sqrt{\mu}\left(\frac{u}{v_A}\right)^{1/3}\left(\frac{1}{2}\pm i\frac{\sqrt{3}}{2}\right)\sqrt{\frac{\omega_{He}\omega_{Hi}}{\beta_e}}\frac{k_x}{|k_x|}. \tag{3.20}$$

It follows from the form of (3.19) and (3.20) that the growth rate of the instability increases with increasing μ and becomes saturated in the region $\mu \gtrsim (v_A/u)^{4/3}$ (there is a plateau region). On the plateau, the growth rate is of order $\gamma \sim \sqrt{\omega_{He}\omega_{Hi}}$.

When $\beta_e \gg 1$ and $u \gg v_s$, Eq. (3.17) becomes inapplicable in the region $\mu \gtrsim \zeta = 1/\beta_e$. It is not difficult to see that in this case one must replace (3.17) by the following equation:

$$\left(\frac{\Delta\omega}{k_xu}\right)^3-\mu\left(\frac{\Delta\omega}{k_xu}\right)^2-\frac{v_A^2}{u^2}(1-\mu\beta_e)=0. \tag{3.21}$$

Equation (3.21) will have complex-conjugate roots when

$$\mu<\frac{1}{\beta_e}\quad\text{or}\quad\mu-\frac{1}{\beta_e}>\frac{4}{27}\frac{u^2}{v_s^2}\mu^3. \tag{3.22}$$

In the case $\beta_e \gg u/v_s$, the inequalities are satisfied when $\mu < 1/\beta_e$ or when $(1/\beta_e)[1+ 4/27\beta_e^2(u^2/v_s^2)] < \mu < \sqrt{27}/2(v_s/u)$. In the region $\mu < 1/\beta_e$ one can ignore the second term in Eq. (3.21).

Then the growth rate is

$$\gamma=\frac{\sqrt{3}}{2}\left(\frac{u}{v_A}\right)^{1/3}\sqrt{\frac{\omega_{He}\omega_{Hi}}{\beta_e}}\sqrt{\mu}(1-\beta_e\mu)^{1/2}. \tag{3.23}$$

The growth rate (3.23) reaches a maximum when $\mu \doteq 3/5\beta_e$; this maximum is

$$\gamma_m=\frac{3}{5\sqrt{5}}\left(\frac{u}{v_A}\right)^{1/3}\frac{1}{\beta_e}\sqrt{\omega_{He}\omega_{Hi}}. \tag{3.24}$$

In the region $1/\beta_e < \mu < \sqrt{27}/2(v_s/u)$ all the terms in (3.21) are of the same order; hence

$$\gamma\sim\operatorname{Re}\Delta\omega\sim\sqrt{\mu\omega_{He}\omega_{Hi}}<\sqrt{\omega_{He}\omega_{Hi}}\left(\frac{v_s}{u}\right)^{1/2}. \tag{3.25}$$

The solutions of Eq. (2.7) can also be found in the case $u \sim v_s$, $\beta_e \gg 1$:

$$\omega=\frac{u-v_s}{v_s}\left(1+i\frac{\pi}{2\beta_e}\operatorname{sgn}k_z\right)\sqrt{\omega_{He}\omega_{Hi}}\,k_z\rho_e. \tag{3.26}$$

It follows that the modes are unstable only when $u > v_s$.

Comparison of the growth rates (3.19) and (3.20) for $\beta_e \sim 1$ with the growth rates (3.23)-(3.26) for $\beta_e \gg 1$ shows that the instability growth rates decrease with increasing β_e and become appreciably smaller than $\sqrt{\omega_{He}\omega_{Hi}}$.

It should be emphasized that all of the above instabilities in a hot-electron plasma are due to the finite plasma pressure; as a rule, these are electromagnetic modes (electrostatic instabilities do not appear in the limiting cases $\beta_e \to 0$ and $\theta = \pi/2$). An important feature of these instabilities is the high growth rate ($\gamma \sim \sqrt{\omega_{He}\omega_{Hi}}$), which is comparable with the maximum growth rate of electrostatic modes of a zero-pressure plasma, which propagate at oblique angles to the external magnetic field.[2]

HOT-ION PLASMA ($T_i \gg T_e$)

We now consider instabilities in a hot-ion plasma when the influence of the finite electron pressures must be included. In the case $\beta_e \gg 1$ (β_i is arbitrary) the quantity $\zeta \sim 1/\beta_e$ is large in Eq. (2.7). Then Eq. (2.7) can be simplified and reduced to the dispersion equation

$$1 + q\left(1 - \frac{k_x u}{\omega}\right) + \frac{q}{\beta_i}\left(1 + i\sqrt{\pi} z_i w_i\right) - \frac{\pi^2}{16}\frac{\omega^4}{k_x^2 u^2 q}\zeta^4 e^{-2\zeta}$$
$$- i\pi\zeta^2 e^{-\zeta}\left\{1 + q\left(1 - \frac{k_x u}{\omega}\right) + \frac{\omega}{k_x u}\frac{q}{\beta_i}\left(1 + i\sqrt{\pi} z_i w_i\right)\right.$$
$$\left.\times\left(1 - \frac{\omega}{2k_x u q}\right) - \frac{\omega^2}{2k_x^2 u^2 q}\right\} = 0. \qquad (4.1)$$

If we ignore the residue terms $\sim e^{-\zeta}$, Eq. (4.1) reduces to the dispersion equation investigated in ref. 1, in which it is shown that drift waves propagating at an angle $\theta = \pi/2$ in a plasma with $\beta_i \sim 1$ have a high growth rate; this growth rate can be higher than for electron-acoustic oscillations ($\gamma \sim 0.1\,(u^2/v_{Ti}^2)\sqrt{\omega_{He}\omega_{Hi}}$).

Let us now investigate the role of the residue terms in (4.1). Assuming that the terms $\sim e^{-\zeta}$ make a contribution only to the growth rate, from (4.1) we have

$$\left.\begin{aligned}\omega &= \frac{k_x u q \beta_i}{\beta_i + q(1+\beta_i)},\\ \gamma &= \sqrt{\frac{\pi}{2}}\, u\frac{\omega_{pe}}{c}\frac{q^{3/2}\beta_i(\beta_i + q)}{[\beta_i + q(1+\beta_i)]^3}\\ &\times\left\{\frac{u}{v_{Ti}} - \sqrt{\frac{\pi}{2}}\zeta^2 e^{-\zeta}\left[2 + \frac{\beta_i^2}{\beta_i + q(1+\beta_i)}\right]\right\},\end{aligned}\right\} \qquad (4.2)$$

where

$$\zeta = \frac{q}{\beta_i + q(1+\beta_i)}\frac{T_i}{T_e}.$$

Therefore, allowance for the residue terms in (4.1) has a stabilizing influence on the instability, since it reduces the growth rate. There exists a certain critical value $\beta_e = \beta_{cr} \ll 1$ at which the maximum growth rate (4.2) becomes equal to zero. This β_{cr} can be found from the following arguments. The residue term in (4.2) is a minimum for $q \gg 1$, so that in this case $\zeta = \beta_i/(1+\beta_i)\,1/\beta_e$. The vanishing of the maximum growth rate is possible when

$$\left(\frac{\beta_i}{1+\beta_i}\right)^2\frac{1}{\beta_{cr}^2}\exp\left[-\frac{\beta_i}{1+\beta_i}\frac{1}{\beta_{cr}}\right] = \frac{1}{\sqrt{2\pi}}\frac{u}{v_{Ti}} \ll 1. \qquad (4.3)$$

It follows from (4.2) and (4.3) that in a plasma with $\beta_e \sim 1$ instability occurs only when $u \gtrsim v_{Ti}$.

Let us now investigate the instability in a plasma with $\beta_e \gtrsim 1$ ($\beta_i \gg 1$). Setting $|z_i| \ll 1$, $\omega = k_x u + \Delta\omega$ ($\Delta\omega \ll k_x u$), $\zeta = 1/\beta_e \lesssim 1$ we obtain from Eq. (2.7)

$$\mathrm{Re}\,\Delta\omega = -\frac{k_x u}{\beta_i} + k_x u\frac{(\beta_e - 1)}{q},$$

$$\frac{\gamma}{|k_x|u} = \sqrt{\frac{\pi}{2}}\frac{u}{v_{Ti}\beta_i^2}\left[1 + (1-\beta_e)\mu\frac{T_i}{T_e}\right]$$
$$- \frac{\pi e^{-1/\beta_e}}{\beta_i^2}\frac{\left(1 + \frac{3}{2}\mu\frac{T_i}{T_e}\right)^2\beta_e^2}{(\beta_e - e^{-1/\beta_e}\,\mathrm{Re}\,Ei)^2 + \pi^2 e^{-2/\beta_e}} - \frac{5}{6}\frac{\pi e^{-1/\beta_e}}{q}. \qquad (4.4)$$

For $\mu \ll 1/\beta_i$ the growth rate (4.4) has the form

$$\gamma = \sqrt{\frac{\pi}{2}}\frac{u}{v_{Ti}\beta_i^2}\sqrt{\frac{T_i}{T_e}\mu}\left[\frac{u}{v_{Ti}} - \frac{\sqrt{2\pi}e^{-1/\beta_e}\beta_e^2}{(\beta_e - e^{-1/\beta_e}\,\mathrm{Re}\,Ei)^2 + \pi^2 e^{-2/\beta_e}}\right]\sqrt{\omega_{He}\omega_{Hi}}$$

and increases with increasing μ. When $\mu \gg 1/\beta_i$, the modes are absorbed by resonant electrons more strongly than they are excited by the resonant ions, so that the growth rate (4.4) becomes negative. The waves that are most rapidly excited are those with $\mu \sim (T_e/T_i)(1/\beta_e) = 1/\beta_i$, whose growth rate is of order

$$\gamma_m \sim \left(\frac{T_e}{T_i}\right)^2\beta_e^{-3/2}\sqrt{\omega_{He}\omega_{Hi}}\left(\frac{u}{v_{Ti}}\right)^2. \qquad (4.5)$$

The condition $z_i \ll 1$ is then satisfied for $u/v_{Te} \ll \beta_i$.

It is interesting to note that the growth rate (4.5) decreases rapidly with increasing β_e; in a plasma at very high pressure ($\beta_e \gg 1$) the condition $\gamma > \omega_{Hi}$ breaks down and the above instabilities disappear.

5. ISOTHERMAL PLASMA ($T_e \sim T_i$)

We now investigate the excitation of modes propagating at right angles to a magnetic field in an isothermal plasma at high pressure $\beta \gg 1$. Assuming in this case $\omega = k_x u + \Delta\omega$ ($\Delta\omega \ll k_x u$), $\zeta \simeq 1/\beta_e \ll 1$ and ignoring the terms $\sim \mu^2$, we find from Eq. (2.7) that

$$\mathrm{Re}\,\Delta\omega = k_x u\left[\mu - \frac{1}{\beta_i}\left(1 + \frac{T_e}{T_i}\right)^{-1}\right],$$

$$\gamma = \sqrt{\frac{\pi}{2}}\left(1 + \frac{T_e}{T_i}\right)^{-3}\frac{|k_x|u}{\beta_i^2}\left\{\frac{u}{v_{Ti}}\left[1 - \mu\beta_e\left(1 + \frac{T_i}{T_e}\right)\right] - \sqrt{2\pi}\left(1 + \frac{T_e}{T_i}\right)\right\}.$$

The quantity γ attains a maximum value when $\mu = 1/3\,(v_{Ti}/u\beta_e)(1 + T_i/T_e)^{-1}[u/v_{Ti} - \sqrt{2\pi}(1 + T_e/T_i)]$ and is then equal to

$$\gamma_m = \frac{1}{3}\sqrt{\frac{2\pi}{3}}\beta_e^{-5/3}\left(\frac{T_e}{T_i}\right)^2\left(1 + \frac{T_e}{T_i}\right)^{-7/3}\left(\frac{u}{v_{Ti}}\right)^{1/3}$$
$$\times\left[\frac{u}{v_{Ti}} - \sqrt{2\pi}\left(1 + \frac{T_e}{T_i}\right)\right]^{3/2}\sqrt{\omega_{He}\omega_{Hi}}. \qquad (5.1)$$

It follows from (5.1) that the instability occurs when the current velocity exceeds a certain value:

$$u > u^* = \sqrt{2\pi}\left(1 + \frac{T_e}{T_i}\right)v_{Ti}. \qquad (5.2)$$

At the same time, the condition $z_i \ll 1$ is satisfied for $u < u^*\beta_i$, so that the solution obtained above is valid if the current velocity lies in the range $u^* < u < u^*\beta_i$. Let us estimate the value of γ_m in the limiting case $u \sim u^*\beta_i$, for which the growth rate takes its largest value. We find that

$$\gamma_m \sim \frac{1}{\sqrt{\beta}}\sqrt{\omega_{He}\omega_{Hi}}. \qquad (5.3)$$

Thus, in an isothermal plasma at high pressure ($\beta \gg 1$), as in a nonisothermal plasma, the growth rates decrease with increasing pressure.

We thank K. N. Stepanov for helpful comments.

Charge-carrier density of the plasma produced in a Penning mixture by irradiation by uranium fission fragments and reactor radiation

G. A. Batyrbekov, Yu. D. Kuznetsov, and Zh. S. Takibaev

(Submitted June 27, 1973; resubmitted November 2, 1973)
Zh. Tekh. Fiz., 44, 1022-1024 (May 1974)

An experimental study has been made of a plasma produced in a Penning mixture (Ar/Ne $\sim 10^{-3}$) under the influence of uranium fission fragments and of reactor radiation. The apparatus for producing and diagnosing the plasma is described, and measurements of the electron density and temperature in the plasma for a neutron flux of $2\cdot 10^{13}$ neutrons/cm^2 are reported.

A question which arises in connection with efforts to achieve direct conversion of the thermal energy in a nuclear reactor into electrical energy is that of producing a plasma under reactor conditions. This plasma is required in a thermionic converter in order to neutralize the electronic space charge between the electrodes; it is required in MHD generators to produce a gas which is a good electrical conductor.[1,2]

It has been suggested[3,4] that a thermionic converter with an inert-gas plasma can be obtained by ionization of the gas by reactor radiation and uranium fission fragments.

It is therefore of interest to study a plasma produced under reactor conditions and to optimize the plasma-production conditions (the composition and pressure of the gas and the neutron flux) in order to produce a plasma of maximum possible density in the active zone of a reactor.

We report here on the construction of apparatus suitable for plasma diagnostics within a reactor and a study of the plasma produced in a Penning mixture in ionization caused by uranium fission fragments and reactor radiation.

EXPERIMENTAL PROCEDURE

The properties of the plasma produced under the reactor conditions are studied by means of electrostatic probes. The probe method is used most frequently for plasma diagnostics at low gas pressures, in which case the probe radius is much shorter than the electron mean free path ($R_p \ll \lambda_e$). Since relatively high inert-gas pressures (above 100 torr) are required to produce a plasma of the maximum density, we use the theory derived in ref. 5 for the operation of electrostatic probes in a dense plasma.

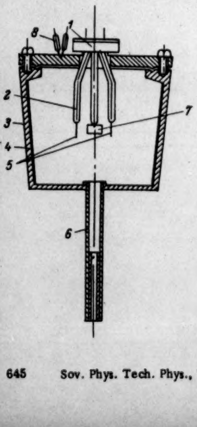

Fig. 1. The ampoule. 1) Radiation-resistant vacuum-tight connector; 2) quartz insulator; 3) body of ampoule; 4) uranium layer; 5) cylindrical probes; 6) fitting for evacuation; 7) flat probe; 8) thermocouple.

In accordance with this theory, we use three probes – two cylindrical probes and one flat probe – for the measurements.

The two cylindrical probes (the "probe" and the "counterprobe") are used to determine the electron temperature,[6] while the flat probe and the cylindrical probes are used to determine the ion and electron densities.

To perform tests on plasma within the reactor by the probe method, we constructed an apparatus consisting of the following basic elements:

1. An ampoule of Kh18N9T steel, which holds the electrostatic probe and a layer of uranium enriched to 90% U^{235}, filled with the inert gas (Fig. 1). The probes are connected electrically to the apparatus outside the chamber through a radiation-resistant, vacuum-tight multiconductor connector. The working surfaces of the probes are convered by quartz insulators. The uranium layer is deposited on a thin tungsten substrate, which is itself mounted on the lateral inner surface of the ampoule. The uranium layer is at least 15 mg/cm^2 thick. The ampoule is evacuated and filled with gas through fittings welded to its bottom. After the ampoule is filled with the gas mixture it is sealed off.

2. A vacuum channel 60 mm in diameter of type SAV alloy, in which the ampoule with the gas mixture is placed and through which the probe leads run from the ampoule to the measuring apparatus. The probe circuit is shielded by radiation-resistant insulation (alundum shavings) within the vacuum channel. The top of the vacuum channel is finished in a flange having an end cap, which holds a vacuum-tight connector for electrical connection between the probe and the measuring apparatus. The end cap can be removed or replaced by a special wrench during an experiment.

The channel has a conical recess which holds the ampoule, whose lateral surface has the same taper. This arrangement provides good thermal contact so that heat can be transferred from the ampoule to the channel and to the coolant water which flows around the channel.

3. A tube 90 mm in diameter and 15 m long which connects the vacuum pumps with the vacuum channel.

4. A system of pumps consisting of a TMN-200 turbomolecular pump and a VN-2MG forevacuum pump, which evacuates the vacuum chamber after the ampoule is replaced.

The channel with the ampoule is placed in the center of the active zone of a VVR-K reactor.

EXPERIMENTAL RESULTS

We measured the properties of the plasma in a Penning mixture with an argon : neon concentration ratio of 10^{-3} and a pressure of 200 torr. The ion branches of the probe characteristic are analyzed on the basis of the Ul'yanov theory cited above. The values of the recombination coefficient in the Penning mixture, 10^{-9}, are taken from ref. 7. In calculating the ambipolar-diffusion coefficient we take into account only the mobility of the predominant gas in the mixture.

The electron or ion density in the plasma determined in this manner for a reactor power of 2 MW and a thermal-neutron flux of $\sim 2 \cdot 10^{13}$ neutrons/(cm^2 · sec) in the central channel turns out to be

$$n_i = n_e = (6 \pm 2) \cdot 10^{12}\ \text{cm}^{-3}$$

The electron temperature is $T_e = 1200$°K.

This electron density is apparently close to the optimum value for the given reactor power; it can be raised by increasing the power.

The expansion, in vacuum, of a recombining lithium plasma initially in a state of ionization equilibrium is treated by numerical solution of gas-dynamic equations. If the characteristic recombination length of singly charged particles exceeds the initial radius of the cloud, the number density of the particles of given charge is a monotonic function of the radius. An inverse relationship between the recombination length and the initial radius produces nonuniform heating due to recombination. As a result, the ion distribution along the coordinate is characterized by maxima at the periphery of the cloud. The density maxima corresponding to ions of different charge are separate; the maxima for ions of smaller charge are shifted toward smaller radii and velocities. The solution indicates that recombination heating produces additional acceleration of the ions.

INTRODUCTION

In this paper we examine the spatial distribution of ions of different charge in a vacuum. An example of this process is the plasma generated by the action of a powerful laser beam on the surface of a solid target. Mass-spectroscopic techniques are used in refs. 1 and 2 to obtain the energy distributions of ions of different charge in a late stage of expansion of a laser plasma. It turns out that the ion energy distribution has sharp maxima, with the maxima for ions of high charge shifted toward high energies. Another important feature of the ion energy distribution is noted in refs. 1 and 2: the distributions for ions of different charge (with $Z \leqslant 5$) have a common upper limit. The interpretation of the experimental results given in ref. 2 ascribes the shape of the ion distributions to recombination in the expanding plasma; however, the results only give a qualitative picture of the expansion. In ref. 3, the formation of ion energy spectra and the spatial distribution are analyzed on the basis of a self-similar solution of the gas-dynamic equations describing the expansion of a recombining plasma. The results obtained in ref. 3 are limited to the case of photorecombination and refer to a plasma in which ionization equilibrium has completely broken down at the initial time. In the present paper, the problem of expansion of a plasma cloud in vacuum is solved by numerical integration of the gas-dynamic equations allowing for ionization and recombination. It is established that the recombination process is different in different regions of the cloud and that it depends sensitively on the initial plasma dimension.

If the initial cloud dimension R_0 is smaller than the characteristic length for recombination of singly charged ions l_1, the plasma is set in motion until there is an appreciable recombination of ions with $Z > 1$. Strong recombination occuring after ionization equilibrium breaks down produces an intense heating of the entire mass of the cloud; as a result the degree of ionization and the charged particle densities vary almost monotonically from the center to the periphery. When $R_0 > l_1$, a small plasma layer near the plasma–vacuum interface is subjected to strong recombination heating. The major portion of the ions with $Z > 1$ succeed in recombining until ionization equilibrium breaks down due to rarefaction, and the stored potential ion energy becomes small. Therefore, heat release in the plasma core is small and is not able to retard the recombination process. Freezing of the degree of ionization occurs only in the periphery of the plasma. The spatial distributions of the ions have separate maxima.

1. INITIAL EQUATIONS

Expansion of a multicomponent plasma in a vacuum can be described by using multifluid gas-dynamic equations including ionization and recombination processes. Then the ions are driven by the electric field, the pressure, and the friction between the different groups of ions.[4] In the electric field ions of different charge are accelerated to different velocities. However, the strong friction between ion species equalizes these velocities. The numerical calculations performed in ref. 5 indicate that for parameters corresponding to a laser-produced plasma the ion–ion collisions equalize the velocities of ions of different species. In the initial stage of the expansion this assertion is valid for the entire volume of the expanding plasma, excluding only a small region on the periphery of the cloud with dimensions of the order of the ion mean free path for ion–ion collisions. In this region the ion friction is small, and the electric field forces can lead to a relative acceleration of charges with different Z. We note that for the approximate experimental conditions the ratio between the ion mean free path and the initial cloud dimension is less than 10^{-3}.

In the present paper recombination effects are included in the analysis of plasma expansion. The behavior of the plasma in the peripherial region is neglected. Therefore, the relative motion of ions of different charge can be neglected and the expansion of the plasma can be considered as a whole.

We consider radiative recombination with electron capture in the ground state[6] and three-body recombination to a highly excited level with the electron as the third particle.[7] It is well known[8] that a portion of the energy freed in three-body recombination heats the electron gas.

Assuming that all the plasma particles have the same temperature, we include recombination heating in the equation for the total plasma pressure. Thermal conductivity effects are neglected; this procedure is valid if the following condition is satisfied:

$$R_0 > \sqrt{\frac{M}{m}}\,\frac{6\sqrt{2}\,\pi^{3/2}}{L}\,(n_a r_D^3)\, r_D,$$

where L is the Coulomb logarithm and r_D is the Debye radius. This condition is satisfied for the values of the parameters given below.

Assuming neutrality and neglecting electron inertia and electron–ion collisions in the equations of motion, we can write the system of equations describing spherically symmetric expansion of the plasma in a vacuum as

$$\left.\begin{aligned} &\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial r}=-\frac{1}{\rho}\frac{\partial P}{\partial r},\\ &\frac{\partial n_z}{\partial t}+\frac{1}{r^2}\frac{\partial}{\partial r}(r^2un_z)=A_z,\\ &\frac{\partial P}{\partial t}+u\frac{\partial P}{\partial r}+\frac{5}{3}\frac{P}{r^2}\frac{\partial}{\partial r}(ur^2)=\frac{2}{3}Q. \end{aligned}\right\} \quad (1)$$

The expression for A_Z and Q is

$$\left.\begin{aligned} A_z&=n_e\{n_{z+1}\Gamma_2(Z+1)+n_{z-1}\Gamma_1(Z-1)-n_z[\Gamma_1(Z)+\Gamma_2(Z)]\},\\ Q&=n_e\sum_{Z=0}^{Z_m}n_z\left\{E(Z)\Gamma_4(Z)-I(Z)\Gamma_1(Z)-\frac{3}{2}T\Gamma_3(Z)\right\}. \end{aligned}\right\} (2)$$

Here, P is the total plasma pressure, n_Z is the number density of particles with charge $Z(0 \leq Z \leq Z_m)$, Z_m is the maximum ionization multiplicity, I(Z) is the ionization potential of a Z-fold ionized ion, $n_e = \sum_{Z=0}^{Z_m} Zn_Z$ is the number of electrons per unit volume, $\rho = \sum_{Z=0}^{Z_m} n_Z M$ is the plasma density, and M is the ion mass.

The ionization coefficient is determined from the condition for detailed balance of the ionization and recombination process

$$\left.\begin{aligned} \Gamma_1(Z)&=2\left(\frac{2\pi mk}{h^2}\right)^{3/2}\frac{T^{3/2}}{n_e}e^{-\frac{I(Z)}{T}}\Gamma_4(Z),\\ \Gamma_2(Z)&=\Gamma_3(Z)+\Gamma_4(Z), \end{aligned}\right\} \quad (3)$$

and Γ_3 is the radiative recombination coefficient[6]

$$\Gamma_3(\Gamma)=2\cdot10^{-13}\frac{Z^2}{\sqrt{T}}. \quad (4)$$

The three-body recombination coefficient is taken in the form proposed in ref. 7:

$$\Gamma_4(Z)=\frac{4\pi\sqrt{2\pi}}{9}\frac{e^{10}Z^3}{\sqrt{m}\,T^{9/2}}n_e. \quad (5)$$

Finally, E(Z) is the energy released in the gas by a three-body recombination event:

$$E(Z)=\begin{cases} 6\cdot10^{-4}n_e^{1/6}T^{1/18} & E(Z)>T,\\ T & E(Z)<T,\\ I(Z-1) & E(Z)>I(Z-1). \end{cases} \quad (6)$$

The energy radiated from the plasma which is assumed to be optically thin, is I(Z − 1) − E(Z). The latter assumption is valid since the radiative mean free path exceeds the plasma dimension for our case. The approximate estimates are given in ref. 6.

After the appropriate transformations the system of equations (1) is replaced by a system of difference equations which is solved numerically for a lithium plasma with T_0 = 9 eV and $n_a = 10^{19}$ cm^{-3} (T_0 is the initial plasma temperature, which is assumed to be radially homogeneous, and $n_a = \sum_{Z=0}^{Z_m} n_Z(r, t = 0)$. The initial densities of all particles are independent of the radius.

We assume that when t = 0 the plasma is in a state of ionization equilibrium. Computer calculations for the ion and neutral-particle densities give

$$n_0=3.2\cdot10^{-7}n_a,\quad n_1=2.5\cdot10^{-2}n_a,$$
$$n_2=0.824n_a,\quad n_3=0.151n_a.$$

The boundary conditions selected are as follows: zero velocity in the center of the cloud and free expansion to the boundary with the vacuum.

2. NUMERICAL CALCULATIONS

In this section the results of a numerical solution of system (1) are given for a lithium plasma.

When the plasma expands from the boundary with the vacuum to the center, a spherical rarefaction wave arises in which the plasma density and temperature decline. Because of the exponential temperature dependence of the ionization coefficient, ionization equilibrium breaks down and recombination begins to dominate. The heat released by recombination increases the temperature and, thus, the rate of expansion of the plasma. This process is sensitive to the initial dimension of the cloud. Recombination occurs in all the cloud regions which are not yet in motion.

At the initial time the right-hand terms in the continuity equations are zero since the plasma is in a state of ionization equilibrium when t = 0. Three-body recombination is accompanied by heating and an increase in the temperature. This process is represented by the first term in the expression for Q. The second term is the energy expended on ionization and reduces the temperature (the third term, the radiative recombination, does not generally change the plasma temperature). Estimates from Eq. (6) indicate that the heating E(Z) is smaller than the ionization potential I(Z − 1), and this means that the difference between the first two terms in the expression for Q is negative. The temperature of the quiescent plasma declines, and A_α becomes nonzero. The most rapid recombination is for ions with Z = 2, 3.

Thus, if the initial radius of the cloud is small, the rarefaction wave covers the entire plasma volume until recombination of doubly and triply charged ions becomes appreciable. Ions with Z = 2, 3 recombine strongly in the rarefaction wave and produce a significant amount of heating. Since there are many doubly and triply charged ions in the entire volume, the heating produces a marked freezing of the degree of ionization over the entire cloud volume (curve 1 in Fig. 1). The plasma velocity is two or three times greater than the adiabatic expansion rate.

A different situation obtains when a cloud with large radius expands. When $R_0 \gg l_1$ (l_1 is the characteristic recombination length of singly charged ions), the time it takes for the rarefaction wave to reach the center of the cloud exceeds considerably the characteristic time for recombination of doubly and triply charged ions.

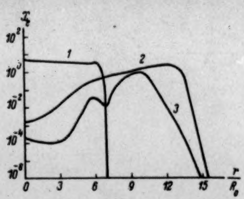

Fig. 1. Degree of ionization x_e as a function of radius. 1) $R_0 = l_1/2$, $t = 1.1\ t_p$; 2) $R_0 = l_1$, $t = 2.45\ t_p$; 3) $R_0 = 3\ l_1$, $t = 2.6\ t_p$.

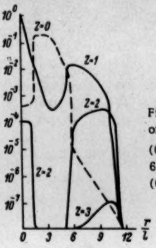

Fig. 3. Number density of particles of different charge in units of $\sum_n n_z \cdot (0, t)$. $R_0 = 3\ l_1$; $t = 0.6\ t_p$; $n_0(0, t) = 6.3 \cdot 10^{-4} n_a$; $n_1(0, t) = 0.99\ n_a$; $n_2 \cdot (0, t) = 1.74 \cdot 10^{-4} n_a$; $n_3 = 5.9 \cdot 10^{-3} n_a$.

Because of recombination the densities of doubly and triply charged ions in the core of the cloud are reduced until the disturbance from the boundary reaches the center. Therefore, strong heating occurs only in the periphery of the cloud, where there is an exponential breakdown of ionization equilibrium, due to the expansion, until appreciable recombination of ions with Z = 2, 3 occurs. The temperature near the vacuum boundary exceeds the temperature at the center of the plasmoid, which is already in motion. This effect can be seen clearly in Fig. 2 (curve 1). The temperature-dip region moves toward the center as time increases. The temperature peak produced at the periphery by strong recombination heating is retained, although its magnitude decreases with the expansion (curve 2 in Fig. 2). The strong heating at the periphery means that freezing of the degree of ionization occurs precisely in this region. The degree of ionization in the core of the cloud is several orders of magnitude lower (curves 2 and 3 in Fig. 1). It can be seen that the freezing effect at the periphery becomes sharper as R_0 increases. The radial particle density distribution is shown in Fig. 3. It is clear that "recombination" waves follow in the wake of the rarefaction wave. Strong recombination occurs within the recombination wave front. Due to the exponential dependence of $\Gamma_1(Z)$ on I(Z), ionization equilibrium breaks down faster for ions with large Z; therefore, different recombination waves correspond to ions with different charge. The recombination wave of ions with Z = 3 has already reached the center, and their density is nonzero only near the vacuum boundary. Recombination waves of ions with Z = 1, 2 have not yet reached the center. Recombination of ions with higher charge exceeds recombination of ions with smaller charge; this is due to the following dependence of the characteristic recombination time τ_Z of ions with charge Z:

$$\tau_z \sim Z^{-3}.$$

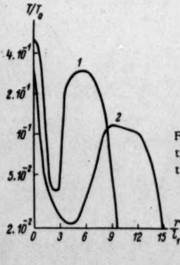

Fig. 2. Radial temperature distribution at different times. $R_0 = 3\ l_1$; 1) $t = 0.46\ t_p$; 2) $t = 0.6\ t_p$.

The dips in the curves of Fig. 3 correspond to the temperature dip.

The influence of the initial plasma parameter on the integrated ion yield for a given charge is shown in Fig. 4. The effective yield increases with decreasing radius. In the inertial stage of expansion the ion densities are frozen.

The energy characteristics of the plasma indicate the manner in which the potential ion energy is redistributed during expansion (Fig. 5). As the radius decreases the kinetic energy of the plasma, per initial unit volume,

$$\varepsilon_k(t) = \left(\frac{l_1}{R_0}\right)^3 \int dV \frac{\rho u^2}{2}$$

increases because of strong recombination heating for the expansion of a cloud with smaller radius. The origin of this effect is discussed above. The thermal energy

$$\varepsilon_T(t) = \left(\frac{l_1}{R_0}\right)^3 \int dV \frac{3}{2} P$$

decreases much faster for $R_0 = 3l_1$ by comparison with cloud with $R_0 = l_1/2$; again, this is due to the decrease in heating for the expansion of a large cloud. The total energy emitted by the plasma per initial unit volume for time t is

$$\varepsilon_{\text{rad}}(t) = \left(\frac{l_1}{R_0}\right)^3 \sum_{Z=0}^{Z_m} \int_0^t dt' \int dV n_z \{I(Z-1)\Gamma_4(Z)$$

$$+ (I(Z-1) - E(Z))\Gamma_z n_e\}.$$

The energy is composed of the energy radiated in photorecombination and three-body recombination. When $R_0 \gg l_1$, $\varepsilon_{\text{rad}}(t)$ is largely determined by three-body recombination, and when $R_0 = l_1/2$ photorecombination predominates.

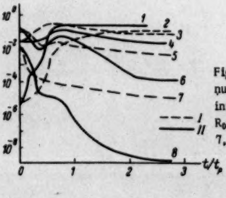

Fig. 4. Time variation of the total number of particles with charge Z per initial unit volume. I) $R_0 = l_1$; II) $R_0 = 3\ l_1$; Z: 1, 2) 0; 3, 4) 1; 5, 6) 2; 7, 8) 3.

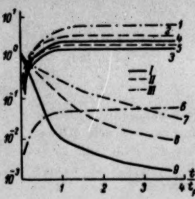

Fig. 5. Energy characteristics of the plasma. I) $R_0 = 3l_1$, II) $R_0 = l_1$, III) $R_0 = l_1/2$; 1, 2, 3) $\varepsilon_k(t)$; 4, 5, 6) $\varepsilon_{rad}(t)$; 7, 8, 9) $\varepsilon_T(t)$. All values refer to the initial unit volume.

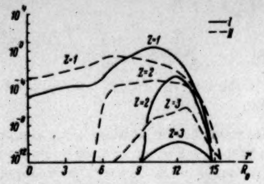

Fig. 6. Asymptotic behavior of ion densities in units of $N_0 = \sum_{z=0}^{z_m} n_z(0; t)$. I) $R_0 = 3l_1$, $t = 2.6t_p$, $N_0 = 5\cdot10^{-3}n_a$; II) $R_0 = l_1$, $t = 2.5t_p$, $N_0 = 4.8\cdot10^{-3}n_a$.

Curves 4, 5, and 6 in Fig. 5 indicate that the energy radiated by the plasma (per initial unit volume) increases with the initial cloud radius, as shown by the fact that the fraction of the potential energy expended in heating decreases with increasing initial plasma dimensions.

We now consider the densities of ions with different charge for times ($t > t_p = R_0\sqrt{M/T_0}$) sufficiently large so that the ion densities are already frozen (Fig. 6). Strong freezing is experienced only by the ions at the periphery of the cloud. Intense ion recombination occurs in the plasma core, and doubly and triply charged ions disappear from this region. It is clear that the maxima of the asymptotic distributions are shifted toward the center with decreasing Z. Since the radial dependence of the velocity in the calculated cases is almost linear the ion energy distribution has similar properties, namely: The maxima of the energy distributions are shifted toward lower energies with decreasing ion charge. It is characteristic that all the spectra have a common right-hand limit.

It should be noted that the periphery ions are appreciably accelerated, and their energy increases by a factor of 30-50 (for adiabatic expansion the acceleration of the boundary is relatively small and the particle energy increases by less than a factor of 10). Similar data agree with the data of ref. 9, in which a 400-eV lithium plasma is investigated.

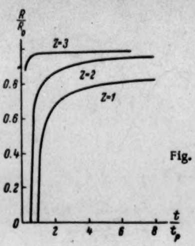

Fig. 7. Time variation of ion density maxima ($R_0 = l_1$).

The behavior of the ion density maxima is shown in Fig. 7 in Lagrange coordinates.

It is clear that when $t > 6t_p$ the curves form a plateau corresponding to a steady motion of the maxima. The resolution between the individual maxima is fairly good.

The results of the numerical calculation indicate that the presence of accelerated ions and the shape of the energy spectra in the experiments[1,2] can be attributed to recombination in the expanding plasma.

In conclusion the authors thank V. E. Kondrashov for help with the programming.

(Submitted August 6, 1973)
Zh. Tekh. Fiz., 44, 1032-1036 (May 1974)

Results are presented of investigations of ionization properties of an argon plasma, in a shock tube, obtained from measurements of the electrical conductivity ion behind the incident shock. The investigations pertain to the initial pressure range P_1 = 5 to 14 torr and the Mach number range M_1 = 8 to 10. It is shown that the addition of about $2 \cdot 10^{-2}$ parts of air leads to contraction of the ionization relaxation zone.

The flush-mounted wall gauge for measurement of electrical conductivity of shock-heated gas flows described in ref. 1 has a number of advantages over the other type consisting of a high-frequency coil which either surrounds a stream of conducting gas[2,3] or is inserted into the stream.[4] The flush gauge allows measurement of the conductivity of supersonic plasma flow with good temporal and spatial resolution, does not introduce gasdynamic perturbations into the stream, and has good sensitivity over a wide range of electrical conductivity. The gauge can easily be calibrated by means of electrolytes and slabs of graphite and metals. When there is no skin effect the gauge probe field penetrates into the plasma to a depth of the order of the coil diameter. The readings of a wall gauge of relatively small size depend appreciably on the properties of the boundary layer near the gauge surface. Direct measurement of the electrical conductivity of the unperturbed plasma stream is only possible when the wall gauge diameter is much greater than the boundary layer thickness.[1] If the gauge and the boundary layer are comparable in dimension, or if an easily ionized impurity is present, it is difficult to interpret the readings of the wall conductivity gauge.

The aim of the present work is to explore the possibility of measuring conductivity and ionization relaxation time in a gas behind strong shock waves in a plasma with relatively high impurity content using a high-frequency coil located in the shock tube wall.

EXPERIMENTAL ARRANGEMENT

The investigations are conducted in a shock tube consisting of a high-pressure driver 100 mm in diameter and 1.0 m long, and a driven section 5.4 m long, separated by a copper diaphragm 1.5 mm thick. At a distance of 3.5 m from the diaphragm the driver section is connected through a transition section (0.2 m long) to a section of square channel, 72 × 72 mm in size and 1.8 m long. The square channel has a clear plastic measurement section (Fig. 1), 100 mm long, distant 0.8 m from the transition section and 0.9 m from the end of the tube; this section corresponds to the steady shock speed region. The reflected shock does not reach the measuring section during the experiment. The investigations are carried out with an initial pressure of 40 to 50 atm of hydrogen in the driver section, and an initial pressure of p_1 = 5 to 14 torr of argon in the driven section. Before filling, the driven section is pumped down to $5 \cdot 10^{-2}$ torr. Taking leakage into account, the relative air impurity in the test gas is $2 \cdot 10^{-2}$. The incident shock speed is measured by means of two ionization gauges. The signal from a third gauge is used to trigger the recorders. The accuracy of Mach number measurement in the range 8 to 10 is 2.5%. The error in meassurement of the initial pressure p_1 does not exceed 1%.

EXPERIMENTAL METHOD

In this work we use the high-frequency wall-mounted conductivity gauge described in ref. 1. The sensor coil is mounted on a ferrite rod, flush with the metal shock tube wall. The sensor is connected to an oscillator.[5,6] When the coil is in contact with a conducting medium the "Q" of the coil is reduced, reducing the amplitude of the oscillations. The change in the amplitude of oscillation ΔU_σ is detected by a balanced detector and recorded by an S1-16 oscilloscope. The sensor parameters: R_k = 0.3 cm, $f = \omega/2\pi$ = 5.3 MHz are chosen to suit the condition for zero skin effect, according to ref. 1, i.e., $R_k\sqrt{\sigma\mu\omega} \leq$

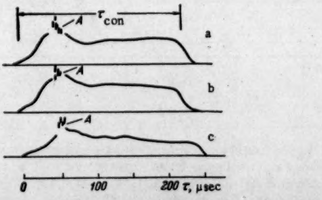

Fig. 2. Oscillograms of conductivity gauge signals (first series of experiments). p_1 = 7 torr; a) M_1 = 9.28; b) M_1 = 9.14; c) M_1 = 8.75. "A" indicates interference from the ionization gauge.

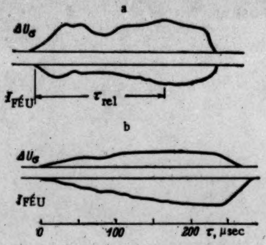

Fig. 3. Oscillograms of conductivity gauge signals ΔU_σ and continuum radiative intensity $I_{FÉU}$. a) First series of experiments, $p_1 = 10$ torr; $M_1 = 9$; b) second series, $p_1 = 7$ torr, $M_1 = 8.9$.

0.8 (R_k is the coil radius, σ is the electrical conductivity; μ is the magnetic permeability; ω is the angular frequency), for a maximum conductivity of $\sigma_{max} \sim 2000$ mho/m. The spatial resolution of the gauge is 0.8 cm.

Simultaneously with the recording of the electrical conductivity, measurements are taken of the relative intensity of the continuum spectra, which depends on the density of free electrons and ions. The axial region of the shock tube is imaged on the entrance slit of a type UM-2 monochromator with slit width 0.3 mm. The optical system comprises two lenses with focal lengths 94 and 110 mm. The spectral region selected is recorded by means of a type FÉU-19 M photomultiplier, and the output signal goes to the S1-16 oscilloscope through a cathode follower.

The investigation of the spectra composition of the gas radiation behind the shock is performed using a type ISP-51 spectrograph. Besides the argon lines, the spectrum shows lines of Na, and also Fe and Cu. The continuum is recorded in the 5300 Å region where there are no strong argon and impurity lines.

For the present experimental conditions the boundary layer is laminar.[1] Two series of experiments are made to elucidate the effect of easily ionized impurities, coming from the shock tube walls, on the nature of the conductivity gauge signal. In the first series no special measures are taken to keep the shock tube walls free from impurities; in the second series the inside surface of the shock tube is carefully cleaned and flushed out.

EXPERIMENTAL RESULTS AND DISCUSSION

Figure 2 shows three typical oscillograms of conductivity gauge signals behind the incident shock, for different Mach numbers (M_1). Earlier experiments with a thin-film temperature gauge[1] showed that the shock front coincides with the start of growth of the conductivity gauge signal ΔU_σ. There is a characteristic sharp fall in conductivity in the region of the shock-heated gas at the contact surface between the driver gas and the heated gas. The signal length from the shock front to the contact zone τ_{con} is taken to indicate the extent of shock-heated argon (test sample length). The oscillograms (Fig. 2) show a rapid signal increase up to a maximum. After the first maximum, depending on the Mach number M_1, the signal either decreases as the contact zone is approached (Fig. 2, c), or stays constant (Fig. 2, b). At the higher M_1 values (Fig. 2, a) a second weak maximum is observed. Sometimes the signal increases at the plateau. These features are typical of all the initial pressure p_1 levels tested.

Figure 3, a shows an oscillogram of the photomultiplier signal for the first series of experiments. The oscillograms of $I_{FÉU}$ typically show a first maximum, like that on the conductivity oscillograms. In the second series the inside walls of the shock tube are carefully cleaned. No first maxima are seen (Fig. 3, b) on the conductivity and intensity oscillograms in the first experiments after cleaning the walls. Analysis of the experimental data show that the first maximum on the oscillograms (Figs. 2 and 3, a) is probably due to the efflux of easily ionized impurities (Na) from the shock tube wall into the boundary layer. The fall in intensity of continuum radiation of the photomultiplier oscillogram following the first maximum is apparently due to the drop in the effective gas temperature in the boundary layer as its thickness increases, which leads to a decrease in charged-particle concentration. The falloff in conductivity gauge signal after the first maximum is also due to fall of temperature in the boundary layer as the latter grows. The effective conductivity in the boundary layer decreases sharply. The sharp maximum of distributed current observed in shock-heated argon in ref. 7 is probably also due to processes involving ionization of easily ionized impurities coming from the shock tube walls.

The subsequent growth of the continuum intensity and of the gauge signal, as well as the rise to the second maximum, are evidently connected with the process of ionization of argon in the flow core. In Fig. 3,a the zone of ionization relaxation for argon (τ_{rel}) is located between the shock front and the second maximum of the radiation (see the $I_{\text{FÉU}}$ signal). Since the time to equilibrate the electron and gas temperatures is relatively short (for $M_1 \sim$ 8 to 10), we can assume that the increase in conductivity behind the shock is determined uniquely by the increase in electron density.[8] Therefore, the gauge oscillogram can also be used to determine the ionization relaxation time. The relaxation time for argon, determined from the ΔU_σ signal as being the time from arrival of the shock up to the second maximum, is equal to the relaxation time τ_{rel} measured from the intensity FÉU oscillogram Fig. 3,a). Ionization equilibrium is not reached in the shock-heated argon in Fig. 3,b, since the photomultiplier signal increases throughout the entire test slug.

Figure 4 shows the results of measurements of the ionization relaxation time τ_{rel}. behind the incident shock, obtained from reduction of the oscillograms of the first and second experimental series. Good agreement is observed between the results obtained and individual data points of ref. 11, in which measurements were made of the absolute electron densities and the ionization relaxation time in argon with about 1% impurity.

The data of the present investigations are referred to the theoretical equilibrium temperatures of the flow core, without allowance for possible reduction of temperature due to dissociation and partial ionization of impurities (such estimates were made in refs. 1 and 10). The effect of air impurity on the relaxation time can be clearly seen by comparing with curves 10 and 11 for the relatively pure argon of Fig. 4.

Figure 5 shows the relaxation times τ_{rel} as averaged by straight lines, as a function of M_1 (points 1-3 of Fig. 4). Evidently, ionization equilibrium is reached for $M_1 < 10$ in the second half of the gas sample, for all test values of the initial pressure p_1. The duration of the shock-heated argon region τ_{con} is practically independent of the initial pressure, but decreases noticeably with increase of M_1. Ionization equilibrium is reached along the test slug for $p_1 = 7$ torr at $M_1 \geq 9.2$, for $p_1 = 10$ torr at $M_1 \geq 8.9$, and for $p_1 = 14$ torr at $M_1 \geq 8.6$.

Thus, we have used a conductivity gauge to show that, behind shock waves at $M_1 = 8$ to 10 in argon, an air impurity ($\sim 2 \cdot 10^{-2}$) reduces the extent of the ionization relaxation region appreciably.

Theory of the low-voltage arc in a narrow gap

F. G. Baksht, A. A. Kostin, and V. A. Nemchinskii

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad

(Submitted September 5, 1973)
Zh. Tekh. Fiz., 44, 1037-1043 (May 1974)

The low-voltage arc in a planar cesium diode is treated for the case in which the cathode current is comparable to the random electron current of the plasma. Numerical calculations for the voltage–current characteristic and plasma state are given.

1. Much attention is currently being given to the study of low-voltage arc discharges in highly ionized plasmas. In particular, Baksht et al.[1] and Dyuzhev et al.[2] have studied theoretically and experimentally a low-voltage arc in cesium at pressures $p \lessdot 1$ torr, between electrodes $d \sim 1$ mm apart, and current densities of the order of several tens of amperes per square centimeter. There is now considerable practical interest in arc discharges in highly ionized plasma with the same values of p and d but with current densities j of the order of hundreds of amperes per square centimeter. A theoretical study of such discharges is the subject of the present work.

2. When the interelectrode distances are great in comparison with the mean free paths and the plasma is in a state of local thermodynamic equilibrium, the plasma in the gap is described by the system of equations

$$j = -u_e n\left[q\frac{d\varphi}{dx} + 1.7k\frac{dT_e}{dx}\right] - qD_e\frac{dn}{dx}, \qquad (1)$$

$$Q_e = j\left(3.2\frac{kT_e}{q} + \varphi\right) - 1.6D_e nk\frac{dT_e}{dx}, \qquad (2)$$

$$-\frac{d}{dx}\left(\varkappa\frac{dT}{dx}\right) = \Delta q_{ei} + \Delta q_{ea}, \qquad (3)$$

$$p_e + p_i + p_a = p. \qquad (4)$$

Here Q_e is the energy flux transported by electrons, p is the plasma pressure, n is the charged particle density, T_e and T are the temperatures of electrons and heavy particles respectively, u_e and D_e are the electron mobility and diffusion coefficient, $p_e = nkT_e$, $P_i = nkT$, and $p_a = n_a kT$ are partial pressures of electrons, ions, and atoms respectively, φ is the electric potential, Δq_{ei} and Δq_{ea} is the energy transferred by electrons to ions and atoms in collision, and $\varkappa$ is the thermal conductivity of the heavy component (see ref. 1).

The atomic density n_a is related to the density of charged particles n through the Saha equation:

$$\frac{n^2}{n_a} = \frac{(2\pi m_e kT_e)^{3/2}}{h^3} e^{-\frac{\varepsilon_i}{kT_e}}.$$

Here, $\varepsilon_i = 3.89$ eV is the ionization energy of Cs.

The system (1)–(3) has the following boundary conditions.

At the cathode boundary of the plasma (x = 0) we have

$$j = j_s - \frac{1}{4} qn_k\bar{v}_{ek}e^{-\frac{q\varphi_k}{kT_{ek}}} + j_{ik}, \qquad (5)$$

$$Q_e = j_s\left(\frac{2kT_k}{q} + \varphi_0\right) - \frac{1}{4} n_k\bar{v}_{ek}e^{-\frac{q\varphi_k}{kT_{ek}}}(2kT_{ek} + q\varphi_0)$$

$$-\frac{j_{ik}}{q}[\varepsilon_i + q(\varphi_k - \varphi_0)], \qquad (6)$$

$$T(0) = T_k. \qquad (7)$$

At the anode boundary (x = d) we have

$$j = \frac{1}{4(1-f_0)} qn_a\bar{v}_{ea}e^{-\frac{q\varphi_a}{kT_{ea}}} - j_{ia} \qquad (8)$$

$$Q_e = \frac{1}{4(1-f_1)} n_a\bar{v}_{ea}e^{-\frac{q\varphi_a}{kT_{ea}}} 2kT_{ea} + \frac{j_{ia}}{q}(\varepsilon_i + q\varphi_a), \qquad (9)$$

$$T(d) = T_a. \qquad (10)$$

Here, j_s is the cathode emission, $n_k = n(0)$ and $n_a = n(d)$, $T_{ek} = T_e(0)$ and $T_{ea} = T_e(d)$ are the density and electron temperature at the cathode and anode plasma boundary respectively, T_k and T_a are the cathode and anode temperatures, φ_0 is the voltage drop across the arc (with respect to the anode surface), $\bar{v}_{ek,a} = \sqrt{8kT_{ek,a}/(\pi m_e)}$, and functions $f_0[q\varphi_a/(kT_{ea})]$ and $f_1[q\varphi_a/(kT_{ea})]$ are defined in ref. 3.

If the ionization length $L_i = \sqrt{D_i[1 + (T_e/T)]/[v_e n_a \sigma_0(Te)]}$ is large in comparison with the ion mean free path in the electrode regions, the ion currents to the cathode and anode are given by[4]

$$j_{ik,a} = \frac{qD_i\left(1 + \frac{T_{ek,a}}{T_{k,a}}\right)}{\sqrt{2}L_{ik,a}}. \qquad (11)$$

where D_i is the diffusion coefficient for ions in atoms, and $\sigma_0(T_e)$ is the effective ionization cross section.[5,6]

If the ionization length $L'_i = \bar{v}_a/n\bar{v}_e\sigma_0(T_e)$ is less[1)] than the ion–atom (atom–ion) mean free path the ion currents to the electrodes are given by[7]

$$j_{ik,a} = 0.61q\sqrt{\frac{kT_{ek,a}}{m_i}} n_{k,a}. \qquad (12)$$

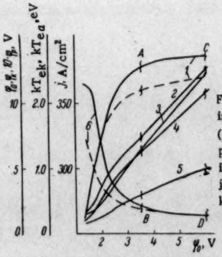

Fig. 1. Voltage–current characteristic of arc (1), T_{ek}(2), T_{ea}(3), φ_k(4), φ_a(5), and φ_p(6). Dashed curves plotted without taking ionization loss into account. d = 0.5 mm, p = 2 torr, $j_s = 409$ A/cm², $kT_k = 0.15$ eV, and $kT_a = 0.08$ eV.

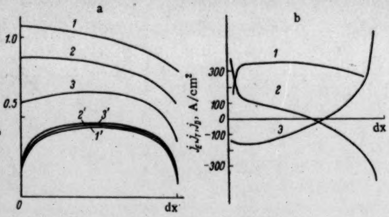

Fig. 2. a) Electron (1, 2, 3) and ion 1', 2', 3') temperatures: j = 357 (1, 1'), 340 (2, 2'), and 310 (3, 3') A/cm². b) Current components in the gap: j_E (1), j_D (2), j_T (3), $j = j_E + j_D + j_T = 320$ A/cm².

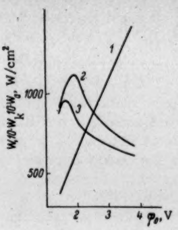

Fig. 3. W(1), W_a(2), and W_k(3).

The results depend on the relationship between the emission current and the random current of plasma electrons $j_r = (q/4)n\bar{v}_e$. The cases $j_s < j_r$ and $j_s > j_r$ are considered below.

3. If $j_s < j_r$, the anode fall retards the electrons moving from the plasma towards the anode so that the arc current does not exceed j_s. The voltage–current characteristic of a planar Cs diode was calculated for this case [d = 0.5 mm, p = 2 torr, j_s = 409 A/cm. In a low-voltage arc in a highly ionized plasma the current j_s increases because of the Schottky effect at the cathode and decreases because of falling ion density near the cathode and decreasing cathode coating. These factors are assumed to compensate each other so that j_s = const]. The voltage–current characteristic is shown in Fig. 1, which also indicates the plasma parameters near the electrode regions. At high currents $T_{ek} \approx T_{ea} \approx q\varphi_0/(2k)$. T_{ek} and T_{ea} increase smoothly with increasing φ_0, φ_k, φ_a, and the voltage drop across the region $\varphi_p = \varphi_a + \varphi_0 - \varphi_k$ decreases.

Figure 2a shows the electron temperature distribution $T_e(x)$ and the temperature distribution for heavy particles T(x) in the gap. The temperature T shows significant variation only in narrow regions near the electrodes. The small variations of T in the main portion of the gas are due to the fact that the heat conductivity of the heavy component is governed by the heat conductivity of ions[8] $\varkappa_i$, which increases rapidly: $\varkappa_i \sim T^{5/2}$. The relatively small change of T_e and T in a completely ionized plasma results in an approximately constant density in the main part of the gap. Significant density gradients appear only in narrow regions near the electrodes.

Figure 2b shows the current components in the gap: $j_E = -u_e n(d\varphi/dx)$, $j_T = -1.7u_e nk(dT_e/dx)$, and $j_D = -qD_e \cdot (dn/dx)$. It is obvious that although all three current components are relatively large, the total current in the main part of the gap $j \approx j_E$. The electric field is nearly constant. However, near the electrodes, where the density gradients (and near the anode also the electron temperature gradient) are high, j differs appreciably from j_E.

4. The principal difference between the present results and those obtained in ref. 1 is the higher electron temperature; this is due to the fact that the energy lost in ionization is a small fraction of the electric power $j\varphi_0$. This result is illustrated in Fig. 3, which shows the ionization loss at the cathode $W_k = (j_{ik}/q)\varepsilon_i$ and anode $W_a = (j_{ia}/q)\varepsilon_i$, and the total power $W = j\varphi_0$. The relatively minor importance of ionization loss is also observed in Fig. 1, where the dashed curves have been plotted neglecting these losses.

Another difference is the nature of variation of the heavy-particle temperature T with increasing φ_0. Whereas for the relatively small currents discussed in ref. 1 T(x) increases with increasing φ_0, in the case discussed here²⁾ T(x) decreases with increasing φ_0.

5. The principal factor which limits the applicability of the discussed approximation[9] is the increase of the Coulomb relaxation length l_ε of the cathode electron beam with the applied voltage φ_0:

$$l_\varepsilon = \frac{1}{2\pi q^4 \lambda} \frac{(q\varphi_k)^2}{n}, \tag{13}$$

where λ is the Coulomb logarithm, and $q\varphi_k$ is the energy of emission electrons accelerated by the cathode voltage fall.

The line AB in Fig. 1 corresponds to the φ_0 for which $l_\varepsilon = d$.

If the energy and momentum relaxation of the cathode beam electrons is provided by Coulomb binary collisions, applicability of the described system requires that $l_\varepsilon < d$. Actually, however, the described conditions cause the excitation of strong oscillations in the cathode region of the plasma, whose excitation length $l_1 \approx r_D(n/n_b)(v_{eT}/v_b) \ll d$. Here, r_D is the Debye radius, n_b and $v_b = \sqrt{2q\varphi_k/m_e}$ are the electron density and velocity in the beam,[10] and $v_{eT} = \sqrt{2kT_e/m_e}$. At a distance from the cathode nearly equal to l_1 the electron velocity distribution function changes, forming a plateau.[11-14] After passing the region of strong oscillations the beam relaxes by binary collisions, as before. However, the relaxation length can change considerably because of the distortion of the distribution function. In particular, assuming that (in accordance with the quasilinear theory) the electron velocity distribution is uniform in the interval from v_{eT} to v_b, the relaxation length L_ε, given by

$$\frac{1}{L_\varepsilon} = \left\langle \frac{\varepsilon}{v\tau_\varepsilon(\varepsilon)} \right\rangle \langle \varepsilon \rangle^{-1} \tag{14}$$

(where τ_ε is the energy relaxation time, and the symbol <> denotes averaging over the distribution function), is

$$L_\varepsilon = \frac{1}{3} \tau_\varepsilon (q\varphi_k) v_{eT}, \tag{15}$$

i.e., noticeably smaller than l_ε. The line CD in Fig. 1

marks the point on the voltage–current characteristics where $L_\varepsilon = d$.

With higher φ_0 and φ_k it is necessary to distinguish between two groups of electrons: fast electrons of the beam and slow randomized plasma electrons. The lack of randomization of fast electrons should, in particular, result in the temperature of slow electrons T_e being significantly lower than $q\varphi_0/2k$, as the energy provided by the electric field is mainly carried out to the anode by the electrons. A T_e lower than that predicted by theory indicates that no fast-electron randomization takes place in the gap.

6. The case $j_r \ll j_s$ can occur at relatively low pressures. In this case the polarity of the anode voltage fall can, in principle, change with increasing φ_0. To analyze such an arc let us consider the case $\varphi_a = 0$.

Assume that the electron temperature is so much higher than the ion temperature that

$$p = n(x)\,kT_e(x). \qquad (16)$$

Using (16) and eliminating $\varphi(x)$ from (1) and (2), we obtain an equation from which $T_e(x)$ can be determined:

$$\Theta_e^{3/2}\left[1.6\,\frac{d}{d\xi}\left(\Theta_e^{5/2}\frac{d\Theta_e}{d\xi}\right) - \frac{5}{2}\frac{d\Theta_e}{d\xi}\right] = -1. \qquad (17)$$

Here, we use the dimensionless quantities $\theta_e = T_e/T_{ea}$ and $\xi = x/L$, where

$$L = \frac{u_e n k T_{ea}}{j} = 194\,\frac{(kT_{ea})^{5/2}}{\lambda j}. \qquad (18)$$

In (18) L is expressed in centimeters, kT_{ea} in electron volts, and j in amperes per square centimeter. The product $u_e n = 1.96\,qn\tau_e/m_e$ (see ref. 8) depends on T_e only and is computed in (18) for $T_e = T_{ea}$. It is convenient to specify the boundary conditions for (17) at the plasma interface with the anode and to integrate the equation beginning at the anode, i.e., in the direction of negative ξ. Let $\xi = 0$ and $x = d$. Then, neglecting the ion current and ionization loss, Eqs. (8) and (9) give

$$\Theta_e(0) = 1,\quad \left.\frac{d\Theta_e}{d\xi}\right|_{\xi=0} = \frac{3}{4}. \qquad (19)$$

The solution of (17) with the boundary conditions (19) is plotted in Fig. 4a. It is seen that there is a critical gap $\xi \approx 0.53$ [or $d_0 = 103\,(kT_{ea})^{5/2}/\lambda j$] at which $\theta_e(\xi)$ vanishes. An arc $\varphi_a = 0$ can hold only for $d < d_0$. Let us now compare the mean free path $l_e = \bar{v}_e\tau_e$ of electrons in a highly ionized plasma with d_0. Finding l_e for $n = n_a$ and $T_e = T_{ea}$, we get $l_e = 125\,(kT_{ea})^{5/2}/\lambda j$, i.e., $l_e \approx d_0$. Thus under the above assumptions it is impossible to form an arc in a dense plasma ($d \gg l_e$) with a zero or accelerating voltage fall at the anode.

Let us now see how the result is affected by accuracy of the boundary conditions at the anode. The second boundary condition in (19) should be written in the general case as $(d\Theta_e/d\xi)|_{\xi=0} = (\beta - \delta)/\alpha$, the factors β and α depending on the electron scattering mechanism (for Coulomb scattering $\beta = 3.2$ and $\alpha = 1.6$), and the factor δ of the electron distribution function at the electrode boundary (in the above we have assumed $\delta = 2$). The function $d_0(\delta)$, plotted from numerical calculations, is shown in Fig. 4b. It is seen that varying δ within reasonable limits does not appreciably change the pattern.

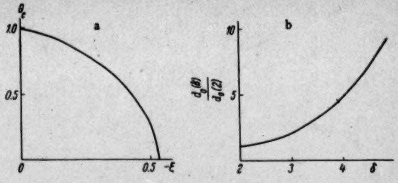

Fig. 4

7. Let us now evaluate the effect of the self magnetic field on the discharge. The interaction of a current j with its self magnetic field B gives rise to a radial pressure gradient which balances the Lorentz force:

$$-\frac{dp(r)}{dr} = \frac{1}{c}\,j(r)\,B(r). \qquad (20)$$

Using the equation

$$\frac{1}{r}\frac{d(rB)}{dr} = \frac{4\pi}{c}\,j, \qquad (21)$$

we get a connection between plasma pressure in the arc averaged over the cross-sectional area $\bar{p} = (2/R^2)\int_0^R p(r)\cdot r\,dr$, the pressure $p_0 = p(R)$, and the magnetic field $B_0 = B(R)$ at the discharge boundary (where R is the discharge radius for $r > R$ and $j = 0$).

$$\bar{p} - p_0 = \frac{B_0^2}{8\pi}. \qquad (22)$$

B_0 is determined by the total arc current I. Assuming that φ and T_e do not vary along the radius, and that the pressure gradient is due to the change in density, neglecting the contribution of ions to pressure, we get from (8)

$$B_0 = \frac{2I}{cR} = \frac{2q\pi R}{c(1-f_0)}\,\frac{\bar{p}}{\sqrt{2\pi m_e kT_{ea}}}\,e^{-\frac{q\varphi_a}{kT_{ea}}}. \qquad (23)$$

Substituting (23) into (22), we have

$$\bar{p} = \frac{1}{2}\left[p_1 - \sqrt{p_1^2 - 4p_0 p_1}\right], \qquad (24)$$

where

$$p_1 = \frac{4(1-f_0)^2 c^2 m_e kT_{ea}}{q^2 R^2}\,e^{\frac{2q\varphi_a}{kT_{ea}}}. \qquad (25)$$

The condition $p_1 \geq 4p_0$ must be obeyed. The condition $p_1 = 4p_0$ gives the maximum discharge radius R_m:

$$R_m = \frac{c}{q}(1-f_0)\sqrt{\frac{m_e kT_{ea}}{p_0}}\,e^{\frac{q\varphi_a}{kT_{ea}}}. \qquad (26)$$

If $R = R_m$, $\bar{p} = (p_1/2) = 2p_0$, i.e., the average arc pressure can be at most twice as high as the gas pressure outside the discharge.

Let us find R_m after the saturation current is removed.

If $j_s < j_r$, the saturation current is $I = \pi R_m^2 j_s$. Eliminating φ_a from (23) and (26), we have

$$R_m = c\sqrt{\frac{2p_0}{\pi}}\frac{1}{j_s}, \tag{27}$$

for p = 2 torr and j_s = 400 A/cm², $R_m \approx 3$ cm, i.e., $R_m \gg d$.

If $j_s \geqslant j_r$, the saturation current is governed by the random current of plasma electrons. If $\varphi_a = 0$ ($f_0 = 1/2$), we have from (26)

$$R_m = \frac{c}{2q}\sqrt{\frac{m_e kT_{ea}}{p_0}} \tag{28}$$

for p = 1 torr, $p_0 = 1$ eV, and $R_m \approx 3 \cdot 10^{-2}$ cm.

Under these conditions the radius R_m is of the same order as the interelectrode distance d, i.e., should such an arc appear, strong self-pinching would be observed.

In conclusion the authors thank G. A. Dyuzhev for discussion.

---

1) If the electron temperature is high enough, a Cs atom evaporated from an electrode can be ionized even before encountering a second atom or ion. The corresponding ionization length L_i' differs from L_i.

2) The energy imparted by electrons to ions in collision[8] is given by $\Delta q_{ei} = (3m_e/m_i)k(T_e - T)(n/\tau_e)$. Since $\tau_e \sim T_e^{3/2}n^{-1}$, and since in a highly ionized plasma $n = p/[k(T_e + T)]$, Δq_{ei} decreases with increasing T_e when the electron temperature is sufficiently high.

Continuous electron acceleration in a gas discharge

G. D. Alkhazov

(Submitted August 24, 1973)
Zh. Tekh. Fiz., 44, 1044-1046 (May 1974)

The possible transition from electron avalanche to continuous acceleration because of the statistical nature of the energy loss is analyzed. On the basis of calculations of the electron energy spectra in Townsend avalanches it is concluded that the electron runaway due to the statistical mechanism begins effectively at a field $E \approx (^1/_2 f)E^*$, where eE^* is the maximum electron energy loss per unit length along the drift path to the anode, and f is the field intensification coefficient near the head of the avalanche.

In strong electric fields the energy imparted to electrons by the field can exceed the energy loss due to inelastic collisions with gas molecules, so that electrons undergo a transition to continuous acceleration, thereby acquiring an energy of the order of eU_0, where U_0 is the applied voltage. It is natural to identify the critical field, i.e., that at which electrons begin acceleration, as the field $E^* = (\gamma/e)(d\varepsilon/dx^{\max})$, where $(d\varepsilon/dx^{\max})$ is the maximum energy loss per unit length of the complete path, and γ is a coefficient equal to the ratio of the average length of the complete path to the distance the electron has moved toward the anode (in strong fields, γ is approximately unity). Fast electrons can appear in gas discharges at fields[1] $E < E^*$, as shown in ref. 2, because electrons are accelerated as a result of the field intensification in the space-charge region. If the electron energy exceeds a certain critical value ε^* in a field $E < E^*$ (Fig. 1), the electrons begin continuous acceleration and acquire an energy of order eU_0. Even if there were no field inhomogeneities, "runaway" electrons could, in principle, appear at $E < E^*$ because of the statistical nature of the energy loss of electrons in a gas. Although the average energy of the avalanche electrons in a field $E < E^*$ is less than ε^*, if the energy lost by an electron is lower than the average over a few mean free paths this electron can acquire an energy greater than ε^* (due to the applied field) and can undergo a transition to continuous acceleration. To get an idea of the importance of the statistical mechanism for accelerating electrons we have now calculated the electron energy distributions for an avalanche in helium moving through a potential difference of $U_0 = 3$ kV.

If we assume that impact ionization is primarily responsible for the growth of the avalanche, and if we neglect space-charge effects, we can find the electron energy distribution on the basis of the model of a one-dimensional avalanche by solving the kinetic equation,

$$\frac{\partial}{\partial x} N(x, \varepsilon) = -\frac{\partial}{\partial \varepsilon} N(x, \varepsilon) eE - n\gamma (Q_\varepsilon^i + Q_\varepsilon^{ex}) N(x, \varepsilon) + \sum_k n\gamma Q_{\varepsilon+eU_k}^{ex}(U_k) N(x, \varepsilon + eU_k) + \int_{eI}^{\varepsilon} n\gamma Q_{\varepsilon+\varepsilon_i}^{i}(\varepsilon_i) N(x, \varepsilon + \varepsilon_i)\, d\varepsilon_i\,, \tag{1}$$

under the initial condition $N(0, \varepsilon) = \delta(\varepsilon)$. Here, $N(x, \varepsilon)d\varepsilon$ is the average number of electrons in an avalanche (which has moved a distance x) which have energies ε in the interval $d\varepsilon$, $Q_\varepsilon^{ex}(U_k)$ is the cross section for the excitation of level k of the helium atom, $Q_\varepsilon^{I}(\varepsilon_i)$ is the differential cross section for the ionization of a helium atom by electrons at energy ε, ε_i is the energy lost in an ionization event, $Q_\varepsilon^{ex} = \sum_k Q_\varepsilon^{ex}(U_k)$ and $Q_\varepsilon^{i} = \int_{eI}^{\frac{\varepsilon+eI}{2}} Q_\varepsilon^{i}(\varepsilon_i)d\varepsilon_i$ are the total excitation and ionization cross sections, I is the ionization potential, and n is the density of helium atoms. In strong fields we can neglect the energy lost in elastic collisions; nevertheless, elastic scattering must be taken into account in our problem. Elastic collisions between electrons and atoms increase the angular spread, i.e., the total distances traveled by the electrons, and thereby increase the probability for energy loss in inelastic collisions. The angular spread of the electrons which results from elastic and inelastic collisions of electrons with atoms is effectively incorporated in Eq. (1) by the coefficient γ, which is larger than unity. Equation (1) is solved by successive iterations.[1)] The ionization and excitation cross sections for the helium atoms are calculated by the semiempirical equations given in ref. 4. Over the range of values of E/E^* considered here the calculated values of the first Townsend coefficient are in good agreement with experiment with $\gamma = \text{const} = 1.4$. The calculated value of E^*/p is[2)] $E^*/p = 7 \cdot 10^4$ V/(cm · atom). Because of the important simplifications used in the model for the shower development (space-charge effects are neglected, elastic scattering is taken into account in a simplified manner, etc.), and because of the uncertainty in the values used for the cross sections, our calculation is of a particularly qualitative nature. Nevertheless, we can conclude on the basis of our results (Fig. 2) that electron acceleration due to the statistical mechanism is possible even when $E = gE^*$, where $g = 0.5$-0.6. Although the relative number

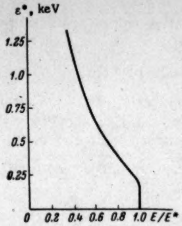

Fig. 1. Critical energy ε^* as a function of the field intensity E. At $\varepsilon > \varepsilon^*$ the increment in the electron energy due to the field exceeds the loss due to inelastic collisions. Here $E^*/p = 7 \cdot 10^4$ V/(cm · atom), where p is the gas pressure.

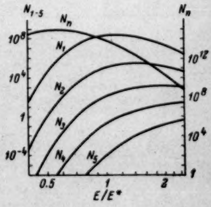

Fig. 2. Results of a numerical solution of Eq. (1) for the case of helium for an applied potential difference of $U_0 = 3$ kV. Here N_n is the total number of electrons formed in the avalanche, and N_{1-5} are the numbers of avalanche electrons having energies in the ranges 0.5-1.0, 1.0-1.5, 1.5-2.0, 2.0-2.5, and 2.5-3.0, respectively.

of electrons which undergo the transition to continuous acceleration is vanishingly small at these fields (only a few electrons "run away"), the appearance of these runaway electrons can alter the development of the discharge significantly: Secondary avalanches appear along the trajectory of a fast electron; the discharge-formation time is reduced; and the discharge can acquire a diffusive or multichannel nature. The calculated total number of electrons in an avalanche (Fig. 2) reaches the large value $N_n \approx 10^{15}$, implying that the calculations are not valid for dense gases. In fact, in dense gases (at atmospheric pressure) the distortion of the field by the space charge causes the growth of the avalanche to deviate from the Townsend law at only $N_n \approx 10^7$, and the avalanche becomes a streamer at $N > 10^8$ in strong fields. Strictly speaking, therefore, these calculations are valid only for low pressures, but it should be noted that fast electrons appear as a result of the acceleration of slow electrons present in the avalanche in an earlier stage of its development, in this case when the avalanche has not yet reached its critical size. Thus taking account of the nonexponential nature of the avalanche growth in this problem has a significant effect on only the total number of electrons; the number of fast electrons is changed only slightly.

When we take account of the field intensification in the space-charge region we find that the minimum field at which fast electrons can appear is reduced to $E = (g/f) \cdot E^*$. According to the calculations of ref. 2, the field-intensification factor f can reach $f = 3$. The x-ray bremsstrahlung detected in ref. 1 in helium discharges at $E \approx 1.5 \cdot 10^4$ V/(cm · atom) is evidence of the appearance of fast electrons in discharges. The appearance of fast electrons at these relatively weak fields ($E \approx 0.2E^*$) can be attributed to the combined effects of the statistical mechanism for electron runaway and the field-intensification effect. A qualitative study of electron runaway in helium discharges was reported in ref. 6, but in those measurements the external field was significantly inhomogeneous. Analogous measurements in homogeneous external fields at various pressures could apparently allow us to distinguish between the contribution of the statistical mechanism for electron runaway and the mechanism involving field intensification near the head of the avalanche.

---

1) The method used is the same as that used in ref. 3.

2) The value $E^*/p = 5 \cdot 10^4$ V/(cm · atom) given in ref. 3 for the case of helium (for the case of no field intensification) is obviously too low, because the authors set $\gamma = 1$.

Accelerators

Inductive energy storage in pulsed accelerators

V. A. Glukhikh, O. A. Gusev, E. G. Komar, and M. P. Svin'in

(Submitted July 23, 1973)
Zh. Tekh. Fiz., 44, 1047-1050 (May 1974)

The outlook for the use of inductive energy-storage banks as pulsed high-voltage sources for direct accelerators is discussed. Electrical circuits are given, and the results of experiments with prototype accelerators are reported.

In recent years, stimulated by the needs of several branches of science and technology for intense charged-particle and x-ray beams, rapid progress has been made in the development of high-current pulsed accelerators. At present, the energy per pulse carried by the particle beam in the most powerful accelerators[1] is as high as 1 MJ at an accelerating voltage of 10^6-10^7 V. Nevertheless, there is a real need for substantial increases in these parameters.

Most high-current accelerators use capacitive storage banks; these more or less determine the geometric dimensions and cost of the installations. Electric fields up to 10^6 V/cm and energy densities up to 0.1 J/cm^3 are achieved in modern oil-filled paper capacitors. In water-filled capacitors, electric fields up to $3 \cdot 10^5$ V/cm and energy densities up to 0.3 J/cm^3 have been achieved for storage times of the order of 10^{-6} sec. Accordingly, capacitive banks for energies of 10^7-10^{10} J are extremely bulky and expensive.

In addition to capacitive banks, however, there are inductive banks. Even at fields on the order of 10^5 Oe, far from the highest possible, the energy density in these banks reaches 40 J/cm^3, i.e., some 150-400 times the energy density which has been reached in an electric field. At the fields of (5-6)$\cdot 10^5$ Oe which have now been achieved in small volumes the energy density reaches more than 1000 J/cm^3.

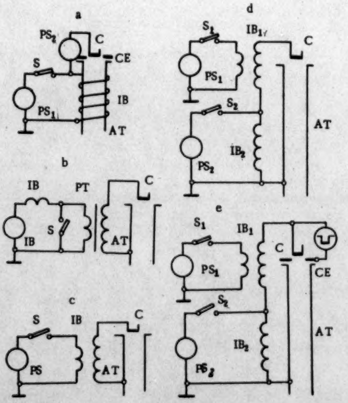

Fig. 1. Schematic circuits of direct-action charged-particle accelerators with inductive storage banks.

It therefore seems worthwhile to evalute the possible use of inductive banks in pulsed charged-particle, e.g., electron, accelerators.

The present authors have offered several suggestions regarding the circuits and construction of direct-action accelerators with inductive banks.

The simplest circuit is that in which the bank is connected directly to the accelerating gap[2] (Fig. 1a). After energy from power supply PS$_1$ has been stored in the inductive bank (IB), switch S cuts off the power supply. The emf of the inductive bank is applied to the gap through accelerating tube AT and cathode C. The energy stored in the bank is expended in accelerating electrons.

The opening of the charging circuit by mechanical or other means can be simplified significantly if the particle beam passes through the accelerating tube before switch S is thrown by PS$_2$ and control electrode CE.

Since the electrons are incident on a grounded collector at the point at which they are used, the electron beam shunts the charging circuit of the bank. If the beam current is made equal to the current in the bank winding, the current passing through switch S vanishes, and the charging circuit can be opened without causing an arc. If the voltage on control electrode CE is then reduced, a voltage of any magnitude can be produced between the bank terminals. Obviously, this voltage will be equal to the product of the bank inductance and the derivative of the electron-beam current. By adjusting this derivative one can shape rectangular pulses or any other accelerating voltage pulses. A fundamental characteristic of an inductive bank is the fact that there is a magnetic field throughout the acceleration process. Under certain conditions, this field can be used for focusing if the solenoid axis and that of the accelerating tube coincide. The beam current at which the beam is focused by the magnetic field of an inductive bank can be found from the familiar equation giving the focusing conditions for a magnetically confined beam.[3] If the focusing field is expressed in terms of the beam current and the parameters of the solenoid by means of B = μNI, where B is the magnetic induction, N is the number of solenoid turns per unit length, and μ is the permeability, the focusing condition is

$$I \geqslant \frac{1}{2\pi\varepsilon\mu^2 q^{3/2} N^2 U^{1/2} r^2 \left(\frac{\Delta r}{r}\right)}.$$

Here, U is the potential corresponding to the particle energy at the beam axis, ε is the dielectric constant, q is the charge-to-mass ratio of the particle, and $\Delta r/r$ is the relative pulsation in the beam edge.

In this accelerator circuit nearly all the energy stored in the bank is expended in accelerating the particles; the only other energy expenditure is that in heating the winding of the bank.

The energy loss is much higher if exploding wires, foils, etc., are used to open the charging circuit of the bank instead of the method suggested above (shunting the switch by the particle beam).

If we neglect the functional dependence of the resistance of the accelerating gap on the applied voltage, and if we assume an exponential behavior of the current in switch S, we find the energy transferred from the bank to the particle beam to be

$$W = W_{\text{in}} \left(1 - \frac{\tau_{\text{b}}}{\tau_{\text{b}} + \tau_{\text{s}}}\right) \text{ for } \tau_{\text{s}} \neq \tau_{\text{b}},$$

$$W = 0.5 W_{\text{in}} \text{ for } \tau_{\text{s}} = \tau_{\text{b}}$$

Here, W_{in} is the energy stored in the bank, and τ_{s} and τ_{b} are the time constants of the switch and beam circuits.

There are other possible circuits for accelerators with inductive banks; for example, the bank can be connected to the accelerating gap through a steel-core step-up transformer (Fig. 1b), or the bank itself can be part of the transformer (Fig. 1c).

Specifying a maximum recovery voltage across the switch, we can find the beam current and efficiency of the energy transfer as functions of the coupling coefficient:

$$I_{\text{b max}} = \frac{k n I_0}{1 + \frac{n^2 r_{\text{b}} \tau_{\text{s}}}{L_{\text{in}}}},$$

$$\eta = \frac{k^2}{1 + \frac{n^2 r_{\text{b}} \tau_{\text{s}}}{L_{\text{in}}}}.$$

Here, k is the coupling coefficient of the transformer windings, n is the ratio of the number of turns in the primary winding to that of the secondary winding, and r_{b} is the equivalent resistance of the accelerating gap.

The beam energy can be increased further by cascading inductive banks (Fig. 1d). After inductive banks IB_1 and IB_2 are charged and the circuit is opened by switch S_1, the current through the secondary winding of IB_1 flows through switch S_2. When the beam current reaches the level of the current in the second winding, the current through switch S_2 drops to zero, facilitating the opening of the circuit of the second bank.

Here, the beam energy is increased by increasing the length of the common discharge of two banks across a single accelerating gap.

If a control electrode is placed in the accelerating gap (Fig. 1e) the advantages of cascading banks can be exploited more fully. In this case, after the circuit of bank IB_2 is opened, the control electrode can be used to adjust the resistance of the accelerating gap, thereby controlling the bank discharge rate and the beam power.

The use of inductive bank pulsed accelerators seems extremely promising.

The most important question here is that of switching the bank current as rapidly as possible. An extremely interesting and promising method is that described above, involving the use of the current carried by the charged-particle beam in the switching.[2] It also seems possible to exploit current instabilities in a plasma, which cause sharp changes in its conductivity.[4]

Experimental accelerators with the circuits in Figs. 1a and 1c have been constructed at the D. V. Efremov Scientific-Research Institute of Electrophysical Apparatus, Leningrad.

The first accelerator is being used to test the conditions for the focusing of the beam by the magnetic field of an inductive bank, the conditions for the formation of rectangular accelerating-voltage pulses, and the switching by means of a controllable charged-particle beam at a recovery voltage of up to 1000 kV.

A field-emission cathode and a high-speed exploding-foil switch are used in the second accelerator. The inductive bank is coaxial with the accelerating tube. An electron beam with a current up to 1 kA, a diameter of 2 cm, and a pulse length of 7 μsec has been obtained at a distance of 0.5 cm from the aperture of the accelerating gap. The voltage across the accelerating gap reaches 300 kV.

Shaping of voltage pulses by discharging an inductive storage bank with a charged-particle beam

O. A. Gusev, E. G. Komar, V. B. Markov, and E. M. Mellekh

D. V. Efremov Scientific-Research Institute of Electrophysical Apparatus, Leningrad

(Submitted July 23, 1973)
Zh. Tekh. Fiz., 44, 1051-1054 (May 1974)

Calculations and experimental data are reported on the conditions for the formation of a rectangular accelerating-voltage pulse in a direct-action charged-particle accelerator in which energy is supplied from an inductive bank.

The use of an inductive energy bank as a high-voltage source for a direct-action accelerator is particularly effective when the intensity of the charged-particle beam can be varied to suit the relation required for shaping a rectangular accelerating-voltage pulse. In this case the charging circuit of the bank can be opened without causing an arc, and the bank can be charged by means of a beam of low-energy charged particles.[1] A necessary condition here is that the beam current be equal to that in the bank.

The limitation on the beam current transported through the accelerating tube and on the bank current makes it necessary to achieve the necessary energy storage by increasing the number of turns in the bank; this leads to an increase in the parasitic capacitance, which affects the current regulation.

Figure 1 shows the equivalent circuit of the regulation of the charged-particle current in an accelerator with an inductive energy bank for the shaping of a flat-topped accelerating-voltage pulse. The transfer impedance of this circuit is

$$h(p)=\frac{U_{\text{acc}}(p)}{i(p)}=\frac{1}{\omega_0}\frac{r+pL}{p^2+2\delta p+g\omega_0},$$

$$\omega_0=\frac{1}{\sqrt{LC}},\quad g=1+\frac{r}{R},\quad \delta=\frac{r}{2L}+\frac{1}{2RC}.$$

The transfer characteristic of the circuit is

$$h(t)=\frac{r}{g}\left[1-\left(\cos\omega t+\frac{\delta}{\omega}\sin\omega t\right)\exp(-\delta t)\right]+\frac{\sin\omega t}{\omega C}\exp(-\delta t),$$

where $\omega = \sqrt{g\omega_0^2 - \delta^2}$; when $r/R \ll 1$, this equation can be simplified to

$$h(t)\approx\frac{\sin\omega t}{\omega C}\exp(-\delta t). \tag{1}$$

From (1) we can determine the amplitude I_1 and length t_r of the input stepped signal required to rapidly charge the parasitic capacitance to the value $U_{\max}$:

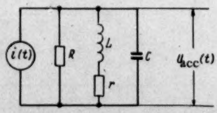

Fig. 1. Equivalent circuit for the shaping of the accelerating-voltage pulse. L) Inductance of bank; r) resistance of the bank; C) total parasitic capacitance of the current regulator and bank; R) dynamic output resistance of the current regulator i(t). I_0 is the initial bank current; and $U_{\text{acc}}(t)$ is the pulsed accelerating voltage.

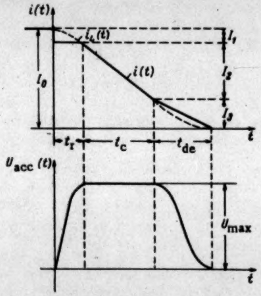

Fig. 2. The functions i(t), $i_L(t)$, and $U_{\text{acc}}(t)$ for r = 0 and R → ∞.

$$I_1=\exp\left[\frac{\delta}{\omega}\operatorname{arc\,tg}\frac{\omega}{\delta}\right]\frac{U_{\max}\sqrt{C}}{\sqrt{L}}, \tag{2}$$

$$t_r=\frac{1}{\omega}\operatorname{arc\,tg}\frac{\omega}{\delta}. \tag{3}$$

It can be shown that the current in the inductive bank is reduced by an amount

$$\Delta i_L=I_1\left[1-\frac{\sqrt{L}}{R\sqrt{C}}\exp\left(-\frac{\delta}{\omega}\operatorname{arc\,tg}\frac{\omega}{\delta}\right)\right]. \tag{4}$$

We see from (2)-(4) that the values of Δi_L and t_r decrease, and that of I_1 increases, as the output resistance of the beam current regulator is reduced.

After an interval $t = t_r$ the accelerating-voltage pulse

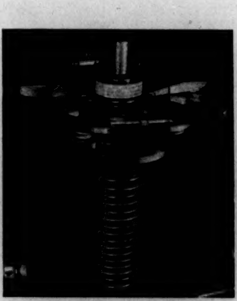

Fig. 3. Inductive storage bank and proton source.

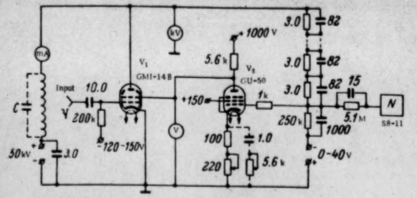

Fig. 4. Schematic of the experimental apparatus.

is given a flat top by cutting off the beam current in a sawtooth fashion from $I_0 - \Delta i_L$ to the value determined from the condition for total extraction of energy from the bank, including the energy stored in its parasitic capacitance, without the return voltage half-wave. The amplitude of this half-wave can be large because of the gain in the accelerating tube. Figure 2 shows the current and voltage for the circuit of Fig. 1 for the conditions $r = 0$ and $R \to \infty$; we see that the energy can be extracted from the inductive bank in a time t_{de} without a change in the voltage polarity when the current is also of sawthooth shape, but not as steep as in the interval t_c. If R is finite, with $r/R \ll 1$, and with the sawtooth law

$$i(t) = \frac{I_3}{t_{de}} t$$

the voltage falls off according to

$$U_{acc}(t) = \frac{I_3}{t_{de}} L + \left(U_{max} - \frac{I_3}{t_{de}} L\right)\left(\cos \omega t + \frac{\delta}{\omega} \sin \omega t\right) \exp(-\delta t), \tag{5}$$

where $t_{de} = \pi/\omega$.

The current in the inductance in this interval varies according to

$$i_L(t) = I_3\left(1 - \frac{t}{t_{de}}\right) - \frac{\sin \omega t}{\omega L}\left(U_{max} - \frac{I_3}{t_{de}} L\right) \exp(-\delta t). \tag{6}$$

Equating (5) and (6) to zero, we find the condition for total extraction of the remaining energy from the bank:

$$I_3 = \frac{U_{max}}{\omega L} \pi \frac{\exp\left(-\frac{\delta\pi}{\omega}\right)}{1 + \exp\left(-\frac{\delta\pi}{\omega}\right)}.$$

As R is reduced, I_3 decreases, and the flat part of the pulse, t_c, becomes longer. Accordingly, a reduction of the output resistance of the regulator for the charged-particle beam current leads to a reduction of the loss of energy stored in the inductive bank associated with the need to charge and discharge the parasitic bank capacitance.

Experimental information on the shaping of high-voltage pulses is obtained in discharges of an inductive bank designed for a 1-MeV proton accelerator with a pulsed beam current up to 1 A. Figure 3 shows the inductive bank and the proton source. The frequency characteristic of the bank has a sharp resonance near 205 Hz; no other resonant frequencies, which could have resulted from the sectioned construction of the bank, are found.

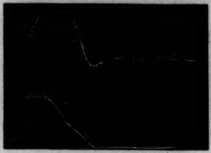

Fig. 5. Oscillograms of the high-voltage (upper curve) and input-signal (lower curve) pulses. The vertical scale for the upper curve is 3.7 kV/div, and the horizontal scale is 5 msec/div.

The inductance of the bank is L = 5270 H, and the resistance is r = 51.4 kΩ. The characteristic impedance of the circuit formed by the inductance and the parasitic capacitance of the bank is on the order of several megohms, so we have constructed the experimental apparatus shown in Fig. 4 in order to simulate the shaping of the accelerating-voltage pulses with an adjustable bank discharge. Here the current regulator is a GMI-14B modulator tube (V_1), whose internal resistance can be increased by introducing positive feedback from the anode of V_1 to the screen grid through the GU-50 (V_2) amplifier cascade.

Figure 5 shows an oscillogram of the high-voltage pulse (upper curve) obtained when the input of the current regulator, which has a high output resistance, is fed the voltage pulse shaped by combining step and sawtooth signals (lower curve). The height of the voltage pulse is 10 kV, and the characteristic times are t_r = 6 msec, t_c = 5.5 msec, and t_{de} = 9 msec. In the interval in which the top of the pulse is shaped the input signal has a variable steepness, to compensate for the nonlinearity of the tube characteristics.

CONCLUSION

1. If an inductive energy bank has a single resonance the required functional dependence of the beam current on the time can be arranged by using simple components: sawtooth and stepped waveforms.

2. Variations in the output resistance of the regulator for the charged-particle beam do not affect these functions; they only change the amplitude and temporal relations.

3. By reducing the output resistance of the beam-current regulator one can reduce the loss of energy stored in the inductive bank due to the charging and discharging of the parasitic bank capacitance.

General

Polarization of a cavity with a thermally deformed active element

I. B. Vitrishchak, L. N. Soms, and A. A. Tarasov

(Submitted June 6, 1973)
Zh. Tekh. Fiz., 44, 1055-1062 (May 1974)

The form of the Jones matrix is found for thermally deformed active laser elements. The polarization states of linear cavities is analyzed for particular cases of practical importance; cavities with active elements in the form of cylinders and rectangular plates. The optical pumping is assumed to be continuous or in periodic pulses. The heat evolution is assumed to be homogeneous and heat is assumed to be removed rapidly from the surface. The cavities also contain various phase plates. The polarization at each point on the cross section of the emitting aperture is shown to be linear. There is an analysis of the compensation for the phase shift between the orthogonal polarizations in reflection from a total-internal-reflection prism. The applicability of the Jones method is discussed.

The Jones matrix method is widely used in calculations of the polarization characteristics of laser cavities with anisotropic elements (phase plates, polarizers, and shifters in various combinations) (see, e.g., refs. 1-3).

In this note we use the Jones method to analyze a cavity with a thermally deformed active element.

When the active element of a solid-state laser is pumped optically an inhomogeneous temperature field is produced, causing thermal stress. When a light beam passes through a stressed active element, the optical path length can be different for the two orthogonal polarizations of the light, which coincide with the directions of the principal stresses σ_1, σ_2 and σ_3 at a given point, if the light propagates along one of them, or in the directions of the quasiprincipal stresses, for an arbitrary propagation direction[4] (Fig. 1).

Accordingly, in the coordinate system x'y', which coincides with the direction of the principal stresses, the Jones matrix for an arbitrary point is

$$A'=\begin{pmatrix}\exp\left(\frac{j\varphi}{2}\right) & 0\\ 0 & \exp\left(-\frac{j\varphi}{2}\right)\end{pmatrix}, \tag{1}$$

where φ is the phase shift between two polarizations when the light passes through a given point along the entire length of the active element.

Transforming to coordinate system xy by means of the familiar equation

$$A=S(-\theta)A'S(\theta),$$

where $S(\theta)$ is the matrix which rotates the coordinate system through an angle θ, we find the Jones matrix for the active element to be[5]

$$A(x,\ y)=\begin{vmatrix}\cos\frac{\varphi(x,\ y)}{2}+j\cos[2\theta(x,\ y)]\sin\frac{\varphi(x,\ y)}{2}, & j\sin[2\theta(x,\ y)]\sin\frac{\varphi(x,\ y)}{2}\\ j\sin[2\theta(x,\ y)]\sin\frac{\varphi(x,\ y)}{2}, & \cos\frac{\varphi(x,\ y)}{2}-j\cos[2\theta(x,\ y)]\sin\frac{\varphi(x,\ y)}{2}\end{vmatrix}. \tag{2}$$

Accordingly, from the polarization standpoint, a thermally deformed active element is a linear phase plate with phase difference and directions of the principal axes which vary over the cross section.

It follows immediately from (1) that the polarizations of the active element at any point coincide with the directions of the principal (or quasiprincipal) stresses at that point; the eigenvalues, whose argument gives the phase shift for the polarizations for passage through such an element, are

$$\lambda_{1,2}=\exp\left(\pm j\frac{\varphi}{2}\right). \tag{3}$$

Analysis of the polarization of cavities containing such an active element and other anisotropic elements reduces to an analysis of the combination of the phase plate plus the anisotropic elements incorporating the coordinate dependence of the phase shift in the active element.

We consider two particular cases of practical importance: a cylindrical active element and an active element in the form of a thin plate (see Fig. 2 and ref. 6). The length of the active element is much larger than the transverse dimensions; the heat evolution is homogeneous throughout the volume of the active element and constant over time (this is the situation in lasers with continuous or pulsed periodic pumping); we assume rapid heat transfer at the lateral surface. The principal stresses at each

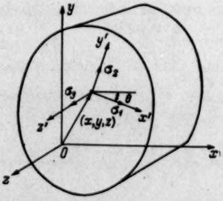

Fig. 1

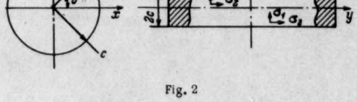

Fig. 2

point of a cylindrical active element are parallel to the axes of a cylindrical coordinate system (the z axis coincides with the cylinder axis); at each point of the plate these are parallel to the x and y axes (except in the boundary regions hatched in Fig. 2, in which edge effects are important; we neglect these regions below).

The temperature distribution is described by the parabolic relation

$$\left.\begin{aligned} T(r) &= T_0 + T_{1c}\left(1-\frac{r^2}{c^2}\right),\\ T(x) &= T_0 + T_{1p}\left(1-\frac{x^2}{c^2}\right), \end{aligned}\right\} \tag{4}$$

where I_{1c} and T_{1p} are the temperature drops between the centers of the cylinder and plate, respectively, and the corresponding surfaces.

The difference between the optical path lengths, ΔP, between the center of the active element and any point for the rays of orthogonal polarizations is

$$\left.\begin{aligned} \Delta P_{r,\theta}(0)-\Delta P_{r,\theta}(r) &= L\left(P\pm\frac{Q}{2}\right)T_{1c}\frac{r^2}{c^2},\\ \Delta P_{x,y}(0)-\Delta P_{x,y}(x) &= L(P\pm Q)\,T_{1p}\frac{x^2}{c^2}, \end{aligned}\right\} \tag{5}$$

Here, P and Q are the thermooptical constants introduced in ref. 7.

At the point under consideration the optical path difference for the rays of these orthogonal polarizations is

$$\left.\begin{aligned} \Delta P_r(r)-\Delta P_\theta(r) &= LT_{1c}Q\frac{r^2}{c^2},\\ \Delta P_x(x)-\Delta P_y(x) &= 2LT_{1p}Q\frac{x^2}{c^2}. \end{aligned}\right\} \tag{6}$$

The phase shift between these rays is given by

$$\left.\begin{aligned} \varphi_c(r) &= 2\pi\frac{LI_{1c}Q}{\lambda}\frac{r^2}{c^2},\\ \varphi_p(x) &= 4\pi\frac{LI_{1p}Q}{\lambda}\frac{x^2}{c^2}. \end{aligned}\right\} \tag{7}$$

The Jones matrix for the cylindrical active element becomes

$$A(r,\theta)=\begin{pmatrix} \cos\frac{\varphi(r)}{2}+j\cos 2\theta\sin\frac{\varphi(r)}{2} & j\sin 2\theta\sin\frac{\varphi(r)}{2}\\ j\sin 2\theta\sin\frac{\varphi(r)}{2}, & \cos\frac{\varphi(r)}{2}-j\cos 2\theta\sin\frac{\varphi(r)}{2} \end{pmatrix}. \tag{8}$$

The corresponding polarizations for the active element are

$$\begin{pmatrix}E_x\\E_y\end{pmatrix}_1=E_0\begin{pmatrix}\cos\theta\\ \sin\theta\end{pmatrix};\quad \begin{pmatrix}E_x\\E_y\end{pmatrix}_2=E_0\begin{pmatrix}\sin\theta\\ -\cos\theta\end{pmatrix}. \tag{9}$$

The Jones matrix for the plate becomes

$$A(x)=\begin{pmatrix}\exp\left(j\frac{\varphi(x)}{2}\right) & 0\\ 0 & \exp\left(-j\frac{\varphi(x)}{2}\right)\end{pmatrix}. \tag{10}$$

The corresponding polarizations of the active element are

$$\begin{pmatrix}E_x\\E_y\end{pmatrix}_1=\begin{pmatrix}1\\0\end{pmatrix};\quad \begin{pmatrix}E_x\\E_y\end{pmatrix}_2=\begin{pmatrix}0\\1\end{pmatrix}. \tag{11}$$

The eigenvalues for both configurations are found from (3):

$$\left.\begin{aligned} \lambda_{1,2} &= \exp\left(\pm j\frac{\varphi_c(r)}{2}\right),\\ \lambda_{1,2} &= \exp\left(\pm j\frac{\varphi_p(x)}{2}\right). \end{aligned}\right\} \tag{12}$$

The arguments $\lambda_{1,2}$ in (12) do not take account of the phase shift resulting from the passage of the light through the active element, which is common to both polarizations; this shift is also a quadratic constant P [see Eq. (5)].

To take this phase shift into account we multiply the right sides of (12) and matrices (8) and (10) by

$$\left.\begin{aligned} &\exp\left(2\pi j\frac{T_{1c}P}{\lambda}\frac{r^2}{c^2}\right),\\ &\exp\left(2\pi j\frac{T_{1p}P}{\lambda}\frac{x^2}{c^2}\right). \end{aligned}\right\} \tag{13}$$

The polarization states are obviously not affected.

The quadratic functional dependences of the phase shift imply that these active elements are equivalent to lenses for each of the polarizations: a spherical lens for the cylinder and a cylindrical lens for the plate.[6]

For the simplest cases of a linear cavity or a ring cavity with an even number of mirrors the polarization is also given by (9) and (11).

We have in fact observed these polarization states experimentally (linear polarization of the radiation of a laser with a plate-shaped active element[6] and transverse electric and transverse magnetic modes $E^{(r)}$ and $E^{(\varphi)}$ in ref. 8).

We now turn to more complicated situations, in which the cavity contains other anisotropic elements in addition to the active element (Fig. 3).

The three variants in Fig. 3 are essentially equivalent and coincide with the variant in Fig. 3B when the phase shift in the phase plate is chosen appropriately. However,

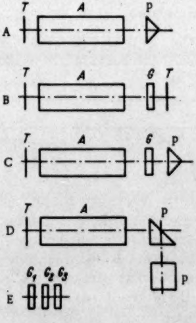

Fig. 3. Optical arrangement of the cavities. The matrices of the anisotropic elements correspond to Eqs. (8), (10) and (14)-(16).

the variant in Fig. 3A merits separate study, since this arrangement is frequently used in Q-spoiled lasers; the arrangement of Fig. 3C, on the other hand, can be useful when it is necessary to compensate for the phase shift at a prism.

The Jones matrices for the elements of the cavity are as follows:[2,3] for a phase plate,

$$G=\begin{pmatrix}\exp\left(j\frac{\psi_g}{2}\right) & 0\\ 0 & \exp\left(-j\frac{\psi_g}{2}\right)\end{pmatrix}; \tag{14}$$

for a prism,

$$\Pi=\begin{pmatrix}\exp\left(j\frac{\psi_p}{2}\right) & 0\\ 0 & \exp\left(-j\frac{\psi_p}{2}\right)\end{pmatrix}; \tag{15}$$

for a mirror,

$$T=\begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix}. \tag{16}$$

In the calculations below we use ψ_p = 82°, corresponding to a refractive index of n = 1.53 for the prism.

The matrices of the cavities are

$$\left.\begin{aligned}D_A&=A\cdot \mathrm{P}\cdot A\cdot T,\\ D_B&=A\cdot G\cdot G\cdot A,\\ D_C&=A\cdot G\cdot \mathrm{P}\cdot T\cdot G\cdot A\end{aligned}\right\} \tag{17}$$

where the subscripts on matrices D correspond to the arrangements in Fig. 3.

It is easy to see that all the matrices in (17) are diagonal for the plate-shaped active element, so the polarization states remain linear, but their directions are along the x and y axes. The eigenvalues of the cavity matrices are equal to the corresponding diagonal terms, and since the elements of matrices (14)-(16) are not functions of the coordinate x, the coordinate dependence of the phase shift of the polarizations of the cavities in Fig. 3 is governed by the same parabolic relation [Eq. (7) with (13)].

For the cylindrical element the components of the cavity have different symmetries, and the question of the polarizations is much more complicated.

We note first that by using the familiar equations[3] for the eigenvalues $\lambda_{1,2}$ and the ratio of the components of the polarizations, E_x and E_y,

$$\left.\begin{aligned}\lambda_{1,2}&=\frac{1}{2}[(D_{11}+D_{22}\pm\sqrt{(D_{11}-D_{22})^2+4D_{12}D_{21}}],\\ \frac{E_x}{E_y}\Big|_{1,2}&=\frac{D_{12}}{\lambda_{1,2}-D_{11}},\end{aligned}\right\} \tag{18}$$

where D_{ik} is the corresponding element of matrix D from (17), we can show that the polarization states of the system of phase plates in Fig. 3E (where $G_1 = G_3$ and where the axes of plate G_2 are rotated through an arbitrary angle with respect to the axes of G_1 and G_3) are linear.

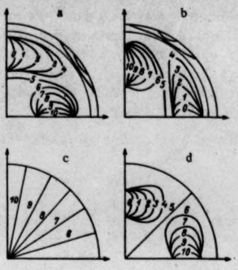

Fig. 4. Distribution of the azimuths of the polarization over the cross section of the cavity. T_{1c} = 23°K, Q = $7\cdot10^{-7}$, L = 8 cm. The contours labeled 0-10 correspond to azimuths from −75 to + 75° at 15° steps.

It follows that for matrix A(x, y) of the most general form, (2), the polarization states of any of the cavities in Figs. 3A-3C are linear, and the only parameter distinguishing these states is the azimuth of the polarization direction.

We use Eqs. (18) to calculate the polarization states of the cavities in Figs. 3A-3D with cylindrical active elements. The results are shown in Figs. 4a-4c as contours of equal azimuth; Fig. 4a shows the azimuth field of one of the polarizations of the cavity in Fig. 3A.

At the center of the cavity, where there is no anisotropy of the active element, the azimuth of the polarization is governed completely by the prism, and it coincides with one of the principal axes of the prism, that running parallel to the x axis, which is itself parallel to an edge of the prism.

We note that there are points at which the contours converge; here there is a compensation for the phase shift in the prism by the phase plate corresponding to the given point of the active element. At these points the cavity is equivalent to an isotropic cavity. The compensation can occur only when the principal axes of the phase plates coincide, so these points lie on lines passing through the center of the active element, parallel and perpendicular to the edge of the prism.

Figure 4b shows the field of azimuths of one of the polarizations of the cavity of Fig. 3B; the phase shift at the plate is chosen to be 41°. Although the phase shift at the plate is 82°, after two passes, like the phase shift at the prism, the field of polarization azimuths is quite different in these cases. The reason is that the right-handed coordinate system is converted into a left-handed system in reflection from the mirror; this does not happen in reflection from the prism, and the mirror is equivalent to a half-wave phase plate in any coordinate system [see (16)]. Accordingly, when the phase shift at the prism is compensated (Fig. 3C) the phase shift between the orthogonal polarizations must be 180° after two passes through the phase plate and the prism, i.e., the phase shift at the plate is

$$\psi_g=\frac{180^\circ-82^\circ}{2}=49^\circ.$$

Figure 4c shows the field of azimuths of one of the polarizations of such a cavity, with this value of ψ_g. We see that the direction of the azimuths corresponds to the mode $E^{(r)}$, i.e., compensation occurs.

On the other hand, when ψ_g is chosen such that the total phase shift vanishes (or is equal to 360°), i.e., when

$$\psi_g = \frac{360^\circ - 82^\circ}{2} = 139^\circ,$$

the picture is quite different (this case can occur when opticomechanical spoilers with rotation-rate doubling are used; Fig. 3D). Figure 4b shows the results calculated for such a cavity; we see that the distribution of polarization over the cavity aperture is quite different from that in the compensation case (Fig. 4b).

We turn now to the range of applicability of the Jones method for calculating the polarization states of anisotropic elements with the coordinate dependence specified above for the phase advance in the cross section of the element.

One condition for the applicability of the Jones method is that the front of the light wave transmitted by the anisotropic element be planar.[3] It is not difficult to show, however, that this requirement is imposed simply so that it is possible to reduce the transformation of the polarization in extended anisotropic elements to the transformation by a certain plane described by the Jones matrix, so that it would not be necessary to follow actual trajectories of the rays through these elements when the wave front is nonplanar.

Obviously this requirement can be lifted if we introduce these trajectories and calculate the transformation of the polarization. As an example we note that the anisotropic device used in ref. 9 to produce $E^{(r)}$ modes (a Galilean telescope into which a calcite plate has been inserted; the optic axis of this plate is parallel to the telescope axis) is described by a matrix like (8); it is simply necessary to take account of the scaling ratio of the coordinate transformation on the different sides of the telescope, which is equal to the magnification of the telescope.

For the thermally deformed active elements with which we are concerned here we can easily derive the condition for which the trajectories discussed above can be neglected and for which the error resulting from the use of the Jones matrices in their simplest form, (8) and (10), is small (Fig. 5).

The phase advance between two polarizations for propagation along the actual trajectory is

$$\varphi_1(r_0) = \frac{1}{L}\int_0^L \varphi(r(r_0, z))\,dz,$$

where $r(r_0, z)$ is the trajectory of the ray which enters the active element at point r_0, propagating parallel to the z axis,[10] and the function $\varphi(r)$ in the integrand is that in (7).

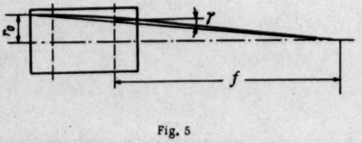

Fig. 5

The phase advance $\varphi_0(r_0)$ in the plane-wave approximation is given by Eqs. (7) with $r = r_0$; matrix (8) can be used when

$$\frac{r}{r_0} \approx 1, \tag{19}$$

$$\frac{\varphi_1(r_0)}{\varphi_0(r_0)} \approx 1. \tag{20}$$

We see from Fig. 5 that

$$1 \geqslant \frac{r}{r_0} \geqslant \frac{r_0 - L\sin\gamma}{r_0} = 1 - \frac{L}{r_0}\sin\gamma.$$

For small γ we have

$$1 \geqslant \frac{r}{r_0} \geqslant 1 - \frac{L}{r_0}\frac{r_0}{f} = 1 - \frac{L}{f},$$

and using (19) we find

$$L \ll f. \tag{21}$$

Similarly, using (7), we find

$$1 \geqslant \frac{\varphi_1(r_0)}{\varphi_0(r_0)} \geqslant \left(1 - \frac{L}{2f}\right)^2 \approx 1 - \frac{L}{f},$$

which is seen to be the same as (21) when (20) is taken into account.

The focal length of the thermal lens of a cylindrical active element of type GLS-2 glass under the conditions assumed in this calculation[10,11] is about 2 m, so that condition (21) is satisfied.

We note in conclusion that the Jones method, which allows us to find the polarization states of cavities containing thermally deformed active elements in a comparatively simple manner, does not give us information about the modes actually excited in such cavities or about their loss.

This information can apparently be found by combining this method with the Fox–Li method[12] for solving diffraction problems. In this case the problem is obviously complicated: instead of solving a single integral equation, it is necessary to solve a system of equations corresponding to an iterative process of the type

$$\mathrm{E}'(\mathbf{r}) = \int K(\mathbf{r}, \mathbf{r}')\,D\mathrm{E}(\mathbf{r}')\,d\mathbf{r},$$

where D is the Jones matrix for the anisotropic cavity.

Gas cooling in transmission of high-power CO_2 laser radiation through the atmosphere

B. F. Gordiets, A. I. Osipov, and R. V. Khokhlov

M. V. Lomonosov Moscow University

(Submitted July 16, 1973)
Zh. Tekh. Fiz., 44, 1063-1069 (May 1974)

The rate of change of the gas temperature in the laser beam path when radiation is transmitted through the atmosphere and the time dependence of the populations of CO_2 and N_2 molecular vibration levels are calculated for a broad range (0.3-10^5 kW/cm^2) of CO_2 laser power densities and altitudes of 0-20 km. The basic parameters of the cooling which can occur immediately following absorption of the radiation are determined. It is shown that for a humid atmosphere there are critical laser power densities which, if exceeded, cause the cooling effect to disappear. For a standard atmosphere these critical power densities range from $2\cdot10^3$-10^5 W/cm^2 (depending on the altitude and atmospheric humidity).

When laser radiation propagates through the atmosphere thermal defocusing occurs due to heating of the gas caused by partial absorption of the radiation and the resulting temperature gradients and refractive index over the beam cross section.[1]

It is shown in ref. 2, however, that when CO_2 laser radiation is transmitted the gas may be cooled, rather than heated, in the initial period following the absorption. This result is due to the fact that the rate of vibrational–translational relaxation of the 10^00 (CO_2) level, which is the lower level for radiative absorption, is large in comparison to the relaxation rate of the populations of the 00^01 upper level and the $\vartheta = 1$ (N_2) molecular vibrational level resonant with it. In this case, absorption of the radiation is associated with energy pumping from the translational degrees of freedom to the 00^01 (CO_2) and $\vartheta = 1$ (N_2) levels, which cools the gas during the initial period. This cooling mechanism is advantageous for transmission of radiation since it is accompanied by thermal self-focusing. In ref. 2, however, the dependence of this effect on laser power density is not considered, although it is important for the selection of the most appropriate conditions for laser energy transfer (for example, in selecting the optimum length of the lasing pulses).

The dependence of cooling effects on laser power density is considered in ref. 3. However, the equations derived in ref. 3 have a limited range of validity and lead to erroneous results for high power densities in a humid atmosphere.

In the present paper we determine the cooling parameters resulting from the transmission of CO_2 laser radiation through the atmosphere for a broad range (0.3-10^5 kW/cm^2) of power densities and altitudes of 0-20 km.

A pure-atmosphere model, i.e., an atmosphere not containing drops of condensed water and other microparticles, is used to solve the problem. In this case one can assume that the CO_2 laser radiation is absorbed only by atmospheric CO_2 (through the $10^00 \rightarrow 00^01$ transition) and water vapor (in the wing of the 6.3 μ absorption band of H_2O).

To determine the time dependence of the gas temperature for CO_2 absorption we begin with the gas-kinetic equations describing vibrational–translational energy exchange in a $CO_2-N_2-O_2-H_2O$ mixture. In the general case this approach requires that one consider a large number of equations for the populations of the lower vibrational states of these molecules. We note that under atmospheric conditions it is improper to base the analysis of CO_2 laser processes on the often-used kinetic model in which different CO_2 vibrational modes have different temperatures, i.e., a local Boltzmann distribution is assumed in each mode. Because of the small amount of CO_2 in the atmosphere the vibrational–vibrational exchange processes which establish a quasiequilibrium are not effective and occur more slowly than, for example, vibrational–translational relaxation. The problem is simplified considerably if it is noted that the following condition always holds for the atmospheric gas temperature T:

$$kT \ll h\nu, \tag{1}$$

where ν is the smallest vibrational frequency in the molecular system under consideration, i.e., the frequency of CO_2 bending vibrations. If (1) is satisfied, all the vibrational partition functions can be set equal to unity and it can be assumed that the population of the 01^00 level is always in equilibrium in the absorption of radiation of any power and that only the populations of the 020, 10^00, and 00^01 levels, responsible for the absorption of the radiation and the population of the first N_2 vibrational level, show any change. This is the case because the negative source of molecules (in our case the radiation converting the molecules from the 10^00 to the 00^01 state) distorts the distribution function only in the energy region $\sim$kT, near the level on which it acts.[4,5] The 01^00 level is separated by $h\nu \gg kT$ from the 02^00 and 10^00 levels.

The problem can be simplified further by noting that the fastest molecular processes under atmospheric conditions are resonant energy exchange between the 10^00 and 02^00 states in CO_2, vibrational exchange between O_2 and H_2O, and vibrational–translational relaxation in H_2O. In this case, it can be assumed that the populations of the 10^00 and 020 (CO_2) levels are always equal (allowing for the statistical weight of the 020 level), and the stored vibrational energy in O_2 and H_2O is in equilibrium; thus, vibrational exchange between O_2 and H_2O and the CO_2 and N_2 molecules only increases the usual vibrational–translational relaxation of the latter two species.

With allowance for the above considerations, the system of gas-kinetic equations describing the vibrational relaxation and accounting for the vibrational–translational energy exchange in the atmosphere in the presence of absorbed CO_2 laser radiation reduces to a system of three linear equations

$$\left.\begin{aligned}\frac{dx_1}{dt}&=-\beta(w+2gP_{10})x_1+\beta wx_2+2\beta gP_{10}x_1^0,\\ \frac{dx_2}{dt}&=wx_1-(w+Q+P_{20})x_2+Qx_3+P_{20}x_2^0,\\ \frac{dx_3}{dt}&=\delta Qx_2-(\delta Q+P_{30})x_3+P_{30}x_3^0.\end{aligned}\right\}\qquad(2)$$

Here, x_1, x_2, and x_3 are the relative populations of the 10^00, 00^01 (CO_2), and $\vartheta = 1$ (N_2) levels; x_1^0, x_2^0, x_3^0 are the equilibrium values of these populations corresponding to a gas temperature T, i.e., $x_1^0 = \exp\{-E_1/T\}$, $x_2^0 = x_3^0 = \exp \cdot \{-E_2/T\}$ [E_1 and E_2 are the energies (in deg) of the 10^00 and 00^01 levels; it is assumed that the energy of an N_2 photon is E_2]; P_{10}, P_{20}, and P_{30} are the probabilities (in sec^{-1}) of collisional quenching of the 01^00, 00^01 (CO_2), and $\vartheta = 1$ (N_2) levels; Q is the probability (in sec^{-1}) of resonant transfer of excitation from 00^01 (CO_2) to the $\vartheta = 1$ (N_2) level; w is the probability (in sec^{-1}) of optical excitation of CO_2 by the laser radiation; g = 3 is the statistical weight of the 020 level; $\beta = (1 + g)^{-1} = 1/4$; $\delta = 3.85 \cdot 10^{-4}$ is the ratio of the total CO_2 concentration to the total N_2 concentration in the atmosphere. In writing (2) it is assumed that collisional relaxation of the 10^00 state occurs through a bending vibration. Spontaneous radiative transitions in CO_2 are not taken into account in (2) because at altitudes of 0-20 km the transition probability is considerably smaller than the probabilities of the collisional processes.

If thermal conductivity and convective heat transfer are neglected, the variation in gas temperature due to the laser radiation is determined by

$$\left.\begin{aligned}&\frac{c_p}{R}N\frac{dT}{dt}=F+\alpha^0_{H_2O}(E_2-E_1)\Phi;\\ &F=N_{CO_2}\Big[E_1 2gP_{10}(x_1-x_1^0)\\ &+E_2P_{20}(x_2-x_2^0)+E_2\frac{P_{30}}{\delta}(x_3-x_3^0)\Big].\end{aligned}\right\}\qquad(3)$$

Here, R is the gas constant, c_p is the specific heat capacity at constant pressure, N and N_{CO_2} are the total number of molecules and the total number of CO_2 molecules per unit volume, F is the energy flux to vibrational degrees of freedom from vibrational relaxation of CO_2 and N_2, Φ is the photon flux in the laser beam, and $\alpha^0_{H_2O}$ is the absorption coefficient of water vapor. It is understood in (3) that due to the rapid rotational relaxation of water vapor saturation effects do not appear for H_2O absorption and that the adsorbed energy is rapidly converted to rotational degrees of freedom. Simple estimates indicate that for altitudes of 0-20 km this assumption is valid for laser power densities $I < 10^{10}$ kW/cm^2.

The radiative photon flux Φ in (3) is related to the probability w of optical excitation of CO_2 by

$$w=\frac{\alpha^0_{CO_2}}{(x_1^0-x_2^0)N_{CO_2}}\Phi,\qquad(4)$$

where $\alpha^0_{CO_2}$ is the absorption coefficient (in cm^{-1}) of atmospheric CO_2 in the absence of saturation effects, i.e., for weak radiative intensities.

We now consider the solution of system (2). Remembering that under atmospheric conditions it is always true that βQ; $2\beta gP_{10} \gg P_{20}/\delta$; P_{30}, we can find the explicit form of the solution for the following case of practical interest.

The negative terms in square brackets in (6), which exceed the other terms during the initial time period, describe the cooling the gas after absorption of the radiation. If the second rapidly damping term in square brackets in (6a) is neglected, the expression for F is the same as that obtained in ref. 2. In this case, such important cooling parameters as the maximum degree of cooling ΔT, the time for attaining this cooling t_{min}, and the time duration of the cooling Δt are determined by the probability P' and the ratio between the CO_2 and H_2O absorption coefficients, i.e., by the atmospheric humidity. It is easy to show from the solution of (3), with (6a), that the maximum degree of cooling ΔT increases linearly with increasing power density I, and t_{min} and Δt are independent of I. We note that the cooling effect itself is possible for atmospheric humidity such that $\alpha^0_{H_2O} < [E_1/(E_2 - E_1)]\alpha^0_{CO_2} = 1.29\alpha^0_{CO_2}$. At sea level this inequality holds for a relative humidity of $\leq$ 50% (at a temperature of 15°C). However, cooling can occur for 100% humidity at altitudes as low as 1.5 km (for a standard-atmosphere temperature).

1. LOW LASER POWER DENSITIES
$w \ll 2gP_{10}$; Q

The above inequality holds in the atmosphere for power densities $I \ll 10^3$ kW/cm^2; 10 kW/cm^2 (for 100% humidity and altitudes of 0 and 18 km, respectively). If we recall that in many cases $Q > 2gP_{10}$ the solution of system (2) is simplified further and becomes

$$\left.\begin{aligned}&x_1\approx x_1^0-\frac{wP'(x_1^0-x_2^0)}{2gP_{10}(\delta w+P')}\\ &+\frac{w}{2gP_{10}}(x_1^0-x_2^0)\Big[\exp\{-2\beta gP_{10}t\}\\ &-\frac{\delta w}{\delta w+P'}\exp\{-(\delta w+P')t\}\Big],\\ &x_2\approx x_3\approx\frac{\delta wx_1^0+P'x_2^0}{\delta w+P'}-\frac{\delta w}{\delta w+P'}(x_1^0-x_2^0)\exp\{-(\delta w+P')t\}.\end{aligned}\right\}\qquad(5)$$

Here and below, $P' = P_{30} + \delta P_{20}$.

By substituting (5) into (3), we find the energy flux F to translational degrees of freedom resulting from CO_2 absorption of laser beam radiation. For the two characteristic cases we have

$$\left.\begin{aligned}&F\approx N_{CO_2}(x_1^0-x_2^0)w[(E_2-E_1)\\ &+E_1\exp\{-2\beta gP_{10}t\}-E_2\exp\{-P't\}]\\ &\text{when }\ \delta W\ll P'\ \text{(a)}\\ &F\approx N_{CO_2}(x_1^0-x_2^0)\Big[\frac{P'}{\delta}(E_2-E_1)\\ &+wE_1(\exp\{-2\beta gP_{10}t\}-\exp\{-\delta wt\})\Big]\\ &\text{when }\ \delta w\gg P'\ \text{(b)}.\end{aligned}\right\}\qquad(6)$$

When $\delta w \gg P'$ one of the saturation mechanisms operates. It follows from (6b) that in the steady state as $t \to \infty$ the energy flux to translational degrees of freedom becomes independent of the laser radiative intensity and is determined by the probability of vibrational deactivation P'/δ. In the transient period, however, at a time $t \leq 1/\delta w$ the flux F is still a function of w. For the present case the cooling parameters ΔT, t_{min}, and Δt are determined for a dry atmosphere by

$$\Delta T \approx -E_1 \frac{R}{c_p}(x_1^0 - x_2^0)\frac{N_{CO_2}}{\delta N}; \qquad (7)$$

$$t_{min} \approx \frac{1}{\delta w}\ln\left[\frac{E_1}{E_2 - E_1}\frac{\delta w}{P'}\right]; \ \Delta t = \frac{E_1}{E_2 - E_1}\frac{1}{P'}.$$

If the atmosphere is humid we obtain

$$\left.\begin{aligned}\Delta T &= \frac{R}{c_p}\frac{N_{CO_2}}{\delta N}(x_1^0 - x_2^0)\left[(E_2 - E_1)\frac{\alpha^0_{H_2O}}{\alpha^0_{CO_2}} - E_1\right];\\ t_{min} &= \frac{1}{\delta w}\ln\left[\frac{\alpha^0_{CO_2}}{\alpha^0_{H_2O}}\frac{E_1}{E_2 - E_1}\right];\\ \Delta t &\doteq \frac{1}{\delta w}\frac{\alpha^0_{CO_2}}{\alpha^0_{H_2O}}\frac{E_1}{E_2 - E_1}[1 - \exp\{-\delta w \Delta t\}].\end{aligned}\right\} \qquad (8)$$

It follows from (7) and (8) that for the indicated saturation mechanism maximum cooling ΔT is independent of the radiative intensity; the time for achieving this cooling is inversely proportional to this intensity. The time duration of cooling Δt is either independent of the intensity [for a dry atmosphere, (7)] or inversely proportional to it [for a humid atmosphere, (8)]. The indicated mechanism has been investigated in detail in ref. 3. It should be noted, however, that the results obtained in ref. 3, just as Eqs. (7) and (8), have a limited range of validity and are invalid for high power densities. Thus, for example, according to ref. 3 and Eqs. (7) and (8), the cooling effect will occur for any power density only if the atmospheric humidity is such that $\alpha^0_{H_2O} < [E_1/(E_2 - E_1)]\alpha^0_{CO_2}$. Actually, the cooling effect can disappear for laser power densities $w > 2gP_{10}; Q$. We consider this case in more detail.

2. HIGH POWER DENSITIES $\omega \gg 2gP_{10}; Q$

For the above relationships between the probabilities the solution of system (2) has the form

$$\left.\begin{aligned}x_1 &\approx x_1^0 - \frac{P'(x_1^0 - x_2^0)}{2\delta gP_{10} + P'} + (x_1^0 - x_2^0)\Big\{\frac{\beta}{1+\beta}\exp[-(1+\beta)wt]\\ &\quad -\left(\frac{\beta}{1+\beta} - \frac{Q}{2gP_{10}+Q}\right)\exp\left[-\frac{\beta}{1+\beta}(Q + 2gP_{10})t\right]\\ &\quad -\frac{Q}{2gP_{10}+Q}\exp\left[-\frac{2\delta gP_{10}Q}{2gP_{10}+Q}t\right]\Big\},\\ x_2 &\approx x_1^0 - (x_1^0 - x_2^0)\Big\{\frac{1}{1+\beta}\exp[-(1+\beta)wt]\\ &\quad +\left(\frac{\beta}{1+\beta} - \frac{Q}{2gP_{10}+Q}\right)\exp\left[-\frac{\beta}{1+\beta}(Q + 2gP_{10})t\right]\\ &\quad +\frac{Q}{2gP_{10}+Q}\exp\left[-\frac{2\delta gP_{10}Q}{2gP_{10}+Q}t\right]\Big\},\\ x_3 &\approx x_1^0 - (x_1^0 - x_2^0)\exp\left\{-\frac{2\delta gP_{10}Q}{2gP_{10}+Q}t\right\}.\end{aligned}\right\} \qquad (9)$$

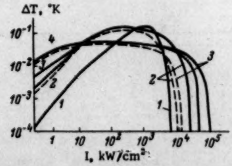

Fig. 1. Maximum cooling ΔT vs. power density I for different altitudes. Here and in Fig. 2, the solid curves represent 30% relative humidity, and the dashed curves 100%; standard atmosphere; H in km: 1) 0; 2) 6; 3) 12; 4) 18.

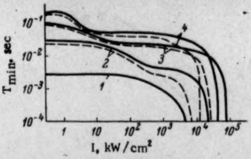

Fig. 2. Time t_{min} for attaining maximum cooling vs power density I for different altitudes.

Substituting (9) into (3) and neglecting the rapidly damping terms with $\exp\{-(1+\beta)wt\}$ and $\exp\{-[\beta/(1+\beta)]\cdot(Q + 2gP_{10})t\}$, we find the energy flux F:

$$F \approx N_{CO_2}(x_1^0 - x_2^0)\left[\frac{P'}{\delta}(E_2 - E_1) - E_1\frac{2gP_{10}Q}{2gP_{10}+Q}\exp\left\{-\frac{2\delta gP_{10}Q}{2gP_{10}+Q}t\right\}\right]. \qquad (10)$$

It follows from (10) that for laser power densities such that $w \gg 2gP_{10}; Q$ the energy flux to translational degrees of freedom from CO_2 absorption of laser radiation no longer depends on the power density over the entire time interval. This may be called the "total" saturation mechanism. Formally, Eq. (10) can be obtained from (6b) by replacing the probability w by the probability $2gP_{10}Q/(2gP_{10} + Q)$. Physically, the conversion from (6a) to (6b) and (10) is due to the presence of bottlenecks for gas heating and cooling. Actually, since the heating rate is limited by the relaxation rate in the 00^01 (CO_2) and $\vartheta = 1$ (N_2) levels (i.e., by the probability P'/δ), with power densities such that $w > P'/\delta$, the probability w in (6a) in the first term, which describes gas heating, is replaced by P'/δ. Similarly, since the cooling rate is limited by the probability of energy conversion from translational degrees of freedom to the 00^01 (CO_2) and $\vartheta = 1$ (N_2) levels (i.e., by the probabilities $2gP_{10}$ and Q), with power densities such that $w > 2gP_{10}; Q$, the term w in (6b) is replaced by $2gP_{10}Q/(2gP_{10} + Q)$. Combining Eqs. (10) and (3), we can find the cooling parameters

$$\Delta T = (E_2 - E_1)\frac{R}{c_p N}\left[\alpha^0_{H_2O}\Phi + (x_1^0 - x_2^0)N_{CO_2}\frac{P'}{\delta}\right]t_{min} - E_1\frac{R}{c_p}(x_1^0 - x_2^0)\frac{N_{CO_2}}{\delta N}\left[1 - \exp\left\{-\frac{2\delta gP_{10}Q}{2gP_{10}+Q}t_{min}\right\}\right];$$

$$t_{min} = \frac{2gP_{10}+Q}{2\delta gP_{10}\cdot Q}\ln\left[\frac{2\delta gP_{10}Q}{(2gP_{10}+Q)}\frac{\alpha^0_{CO_2}E_1}{(P'\alpha^0_{CO_2} + \delta w\alpha^0_{H_2O})(E_2 - E_1)}\right];$$

$$\Delta t = \frac{(x_1^0 - x_2^0)N_{CO_2}E_1}{[\delta\alpha^0_{H_2O}\Phi + (x_1^0 - x_2^0)N_{CO_2}P'](E_2 - E_1)}$$

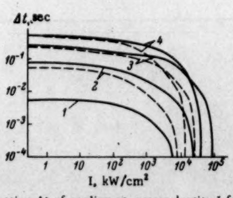

Fig. 3. Time duration Δt of cooling vs power density I for different frequencies.

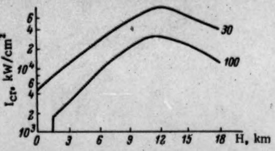

Fig. 4. Critical power density I_{cr} vs. atmospheric altitude for different relative humidities. Standard atmosphere; 30 and 100% humidities.

$$\times\left[1-\exp\left\{-\frac{2\delta gP_{10}Q}{2gP_{10}+Q}\Delta t\right\}\right]. \qquad (11)$$

For a dry atmosphere, ΔT and Δt determined from (11) are close to the values of (7); in contrast to (7), t_{min} does not depend on the radiative intensities and is determined by $2\delta gP_{10}Q/(2gP_{10}+Q)$. For a humid atmosphere, however, when $w > 2gP_{10}$; Q, all three cooling parameters depend on Φ (or I) in a way that is substantially different from that obtained in ref. 3 [see Eq. (8)]. These dependences are given in Figs. 1-3 for a broad range of power densities $0.3\text{-}10^5$ kW/cm² and for different altitudes 0-18 km. It follows from Fig. 1 that for a humidity $\gtrsim$ 30% and power densities $\gtrsim$ 10 kW/cm² the degree of cooling begins to decrease as the power density increases; for power densities $10^4\text{-}10^5$ kW/cm² (depending on the altitude and humidity) the cooling effect disappears. The time t_{min} for attaining maximum cooling (Fig. 2) is independent of the power density or is governed by Eqs. (7) and (8) only for comparatively low power densities ($\leq$ 300, 30, and 10 kW/cm² at altitudes of 6, 12, and 18 km, respectively). The time duration of the cooling for power densities $\gtrsim 10^3$ kW/cm² is not governed by Eqs. (7) and (8), and for a certain power density (determined by the humidity and altitude) it vanishes. The disappearance of cooling in a humid atmosphere comes about because for high power densities, when "total" saturation is attained for CO_2 absorption, the energy flux from translational to vibrational degrees of freedom associated with gas cooling ceases to depend on power density and reaches a maximum [see (10)]. However, the energy flux to translational degrees of freedom, which is induced by water vapor absorption and determines the gas heating, remains proportional to the power density. For this reason there is a certain power density at which gas heating begins to dominate the cooling for the entire time interval $0 < t < \infty$. It is easy to see from (11) that the critical power density I_{cr} at which the cooling effect disappears is determined by

$$w_{cr} = \frac{E_1}{E_2 - E_1}\frac{\alpha^0_{CO_2}}{\alpha^0_{H_2O}}\frac{2gP_{10}Q}{2gP_{10}+Q} - \frac{\alpha^0_{CO_2}}{\alpha^0_{H_2O}}\frac{P'}{\delta}, \qquad (12)$$

where w_{cr} is the critical probability of optical excitation associated with the critical photon flux by Eq. (4). The dependence of the critical power density I_{cr} on altitude for a standard atmosphere is shown in Fig. 4 for relative humidities of 30 and 100%. These power densities are extremely large but they are completely practical experimentally. We note that breakdown of the gas due to CO_2 laser radiation, which may compete with the cooling process, occurs[6,7] at power densities > 10^5 kW/cm², and thus has essentially no effect on the above conclusions.

Equations (7), (8), and (11), along with Fig. 1, indicate that the degree of cooling is small under atmospheric conditions and usually does not exceed ~0.5°K. When radiation propagates in the atmosphere, however, the most important quantity is not the degree of cooling, but the total duration Δt of this process, since during time Δt the propagation of radiation will not be harmed by thermal defocusing of the beam due to the absence of heating in the laser beam path. It is therefore clear that to avoid defocusing the length of the beam pulses must be chosen by starting with Δt.

In conclusion, we note that under laboratory conditions with a dry $CO_2 + N_2$ mixture (with a substantial N_2 excess), preliminary heating of the gas produces cooling in the laser beam path that substantially exceeds the ΔT values obtained in the ordinary atmosphere. Thus, it is easy to see from Eq. (7) that when T = 1000°K (when $x_1 = 0.143$) cooling with $\Delta T = 60$°K can be obtained.

Nonlinear spherical aberrations and thermoelastic stresses in thermal self-focusing

A. A. Vigasin, Yu. A. Gorokhov, A. P. Sukhorukov, and A. M. Khachatryan

M. V. Lomonosov Moscow State University

(Submitted June 25, 1973)
Zh. Tekh. Fiz., 44, 1070-1075 (May 1974)

Experimental and theoretical investigations of thermal self-focusing of the continuum radiation of an argon laser in TF-105 glass are reported. The experimental results are compared quantitatively with an analysis of the effect of thermoelastic stresses on the nonlinear refraction. It is shown that steady-state thermal self-focusing can be described by using the aberration-free approximation up to the focus, applying the aberration correction only in the expression for R_{nl}. The distortion of the Gaussian profile of the laser beam caused by aberrations is investigated.

1. In the propagation of laser radiation through an absorbing medium nonuniform local heating of the medium occurs as a result of dissipation of the electromagnetic energy. The refraction index of the medium changes, leading to thermal self-stress effects [thermal self-focusing or defocusing, depending on the sign of the temperature gradient of the refraction index dn/(dT)], which are most pronounced in beams of high-power cw lasers.

Several papers treat the problem of thermal self-focusing.[1-5] We investigate here the behavior of a self-focusing beam taking account of thermoelastic stresses in the medium and nonlinear spherical aberrations.

The refraction index of an absorbing medium is

$$n(r)=n_0+\frac{dn}{dT}T(r). \tag{1}$$

where T(r) is the steady-state temperature distribution in the medium. However, it must be remembered that the refraction index does not depend only on the absolute temperature increment at a certain point in the medium. Strong temperature gradients produce thermoelastic stresses and these can change the optical characteristics of the medium. Thus, the total temperature-induced change in the refraction index is (see Appendix)

$$\frac{dn}{dT}=\left(\frac{\partial n}{\partial T}\right)_{\sigma=0}+\left(\frac{\partial n}{\partial T}\right)_{TH}$$

$$=\frac{\partial n}{\partial T}+\frac{\alpha n_0^3}{4(1-\nu)}[(p_{11}+p_{12})(1-3\nu)+2p_{12}(1-\nu)]. \tag{2}$$

Since nonlinear refraction accompanying thermal self-stresses is determined by the total derivative of the refraction index with respect to temperature, the effect of thermoelastic stresses can be significant in estimating the self-focusing length, the critical power, etc.

2. An experiment has been performed using an argon laser with an output power of 1 W. The nonlinear medium consists of TF-105 glass with the following characteristics: the length of the specimen, l = 17 cm; the refraction index, n_0 = 1.77; the coefficient of thermal conductivity, $\varkappa = 6.75\cdot 10^{-3}$ W/cm · deg; the relative temperature gradient of the refraction index, $[\partial n/(\partial T)]_{\sigma=0} = 116\cdot 10^{-7}$ deg^{-1}; the linear expansion coefficient, $\alpha = 8.1\cdot 10^{-6}\,\text{deg}^{-1}$; the absorption coefficient, δ = 0.11 cm^{-1}; the constants connected with thermoelastic stresses[6] (see Appendix), ν = 0.25, p_{11} = 0.232, and p_{12} = 0.256. Thus, the total derivative for the glass is $dn/(dT) = 192.10^{-7}\,\text{deg}^{-1}$.

The dispersion resonator of the laser separates the 5145 Å line. An iris is placed inside the laser resonator to isolate the TEM_{00} mode. The beam radius at the exit face of the glass a_0 = 275 μ. After emerging from glass, the light beam strikes the slit of the instrument, which uses an FDK-1 photodiode. The intensity distribution in the self-focusing beam is obtained by moving the instrument across the beam, using a micrometer feed. The beam width at exit from the glass is measured with respect to the level at which the intensity is $1/e^2$ of its maximum value. We thus obtain the diameter of the beam emerging from the specimen as a function of the power incident on the glass. The beam diminishes with increasing power. When the power exceeds a threshold value, the focus of the thermal lens moves inside the specimen, and the beam diameter starts to increase. The beam structure is distorted: Rings appear around the central spot as a consequence of nonlinear aberrations of the thermal lens.

3. The equation for the dimensionless beam width ($f = a(z)/a_0$) describing steady-state thermal self-focusing near the axis of a Gaussian beam (aberration-free approximation) has the following form:[2,7]

$$\frac{d^2f}{dz^2}=-\frac{\delta\exp(-\delta z)}{R_{nl}^{a-f}}+\frac{1}{R_g^2f^3}. \tag{3}$$

Here, $R_g = (ka_0^2)/2$ is the diffraction length of the beam, the quantity

$$R_{nl}^{a-f}=\frac{2n_0\varkappa}{\frac{dn}{dT}I_0}=\frac{\pi n_0\varkappa a_0^2}{\frac{dn}{dT}P_0} \tag{4}$$

characterizes the nonlinear refraction intensity as a function of the intensity I_0 at the axis of a Gaussian beam, a_0 is the radius of this beam at the entrance into the medium, P_0 is the initial power, $\varkappa$ is the thermal conductivity coefficient, and dn/(dT) is the total derivative (2).

The analysis of Eq. (3) is performed on the basis of a computer solution. In particular, this analysis has been performed for the parameters $\tilde{\delta} = \delta R_g = 5$ and $b = \tilde{\delta}(R_g)/(R_{nl}) = 0\text{–}100$, which pertain to the experimental conditions. At the focus, b = 19.5. For these parameters, the dependence $d(P_0)$, shown in Fig. 1 (curve 1), where $d = 2a$, can be obtained from the solution of Eq. (3). The minimum beam contraction for the above parameters can also be obtained from this solution. Calculations for our case yield f_Q = 0.243, which is in good agreement with ex-

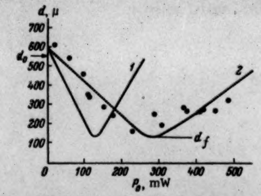

Fig. 1. Diameter of the laser beam at the exit from glass as a function of the power incident to the glass. 1) Aberration-free approximation; 2) with an allowance for aberrations; $d_f = d_0 f_f = 134\ \mu$.

perimental data. However, the general behavior of curve 1 is different from the experimental behavior, and, therefore, the spherical aberrations of a thermal lens must be taken into account in calculating the nonlinear refraction.

4. Nonlinear spherical aberrations are taken into account in the geometric optics approximation (k → ∞) on the basis of the equation for rays[8,9]

$$\frac{d^2 f_r}{dz^2} = -\frac{\delta \exp(-\delta z)}{R_{nl}^{ab}(r_0) f_r}. \qquad (5)$$

Here, $f_r = r(z)/r_0$ is the relative deviation of a ray from the beam axis, r_0 is the initial beam coordinate, and

$$R_{nl}(r_0) = \frac{2n_0\varkappa}{\frac{dn}{dT} \bar{I}(r_0)}, \qquad (6)$$

which characterizes the nonlinear refraction; the latter depends on the mean intensity in the beam tube,

$$\bar{I}(r_0) = \frac{P_0(r_0)}{\pi r_0^2},$$

where $P_0(r_0)$ is the initial power in the beam tube. For a Gaussian beam,

$$\bar{I}(r_0) = I_0 \frac{a_0^2}{2r_0^2}\left(1 - e^{-\frac{2r_0^2}{a_0^2}}\right),$$

where I_0 is the intensity at the axis. Then,

$$R_{nl}(r_0) = \frac{4n_0\varkappa r_0^2}{\frac{dn}{dT} I_0 a_0^2 \left(1 - e^{-\frac{2r_0^2}{a_0^2}}\right)}. \qquad (7)$$

For k → ∞, Eq. (3) is formally identical to Eq. (5), written for a beam tube with $r_0 = a_0$; however, in this case,

$$R_{nl}(a_0) \approx \frac{4.6 n_0\varkappa}{\frac{dn}{dT} I_0} = 2.3\, R_{nl}^{a-f}$$

i.e., if the aberrations are taken into account, the nonlinear refraction is reduced by a factor of approximately 2.3 (see also ref. 10). In Fig. 1, the measured dependence $d(P_0)$ is described adequately by curve 2, obtained by using this correction.

Hence we conclude that steady-state thermal self-focusing can be described by the aberration-free approximation up to the focus, considering the aberration correction only in the expression for R_{nl}.

Nonlinear aberrations must also be taken into account in investigating the beam profile in self-focusing. It has been found experimentally that the Gaussian profile of the beam is distorted; this can be explained by the effect of spherical aberrations. Figure 2 shows the experimental curves characterizing the degree of distortion of the Gaussian profile for different values of the input power. It is evident that, as the beam enters the medium, the Gaussian wings are distorted least, while the rays near the axis experience the greatest contraction.

The intensity distribution at the exit from the nonlinear medium is calculated by using an equation from aberration theory[9]

$$I(r) = \frac{I_0 e^{-\frac{2r_0^2}{a_0^2}} e^{-\delta l}}{f_r^2 + r_0 f_r \frac{df_r}{dr_0}}, \qquad (8)$$

where $f_r = r/r_0$ is the solution of Eq. (5). The functional dependence $f_r(r_0)$ is obtained on the basis of the computer solution of Eq. (5) allowing for the initial beam divergence $df_r/dz|_{z=0} = 1/R$ (under our experimental conditions, this value is $1/R = 6.45 \cdot 10^{-3}\ \mathrm{cm}^{-1}$). The beam profile calculated by means of (8) can be compared with the profile determined experimentally only for low values of the beam power, in which case the geometric optics approximation holds. Figure 2 illustrates the good agreement between experiment and the calculation for 18 and 61 mW (the theoretical and experimental results are indicated by solid and dashed curves, respectively).

Thus, Eq. (5) describes adequately the profile distortion in a Gaussian beam, which is absent if thermal self-focusing is considered in the aberration-free approximation.

APPENDIX

Let us calculate the correction for the refraction index connected with thermoelastic strain in a piezooptic crystal. Assume that the crystal is in the shape of a long cylinder with the radius R and that a narrow laser beam propagates along the z axis of the crystal. Neglecting end effects we assume that the cylinder heated by the laser beam is in a plane strained state. The components of the

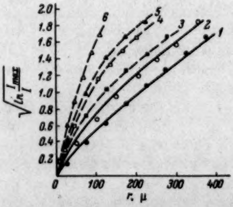

Fig. 2. Distortion of a laser beam with a Gaussian distribution at its entrance into glass. The power incident to glass P is the parameter of the curves: 1) 18; 2) 61; 3) 94; 4) 150; 5) 174; 6) 228 mW.

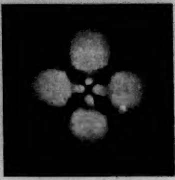

Fig. 3. Characteristic conoscope pattern obtained in a KS-13 glass filter by focusing it in the radiation of an argon laser. The photograph is taken through a microscope, while the filter is placed in crossed polaroids.

stress tensor are then[11]

$$\left.\begin{aligned}\sigma_r &= \frac{\alpha E}{1-\nu}\left[\frac{1}{R^2}\int_0^R T(r)\,r\,dr - \frac{1}{r^2}\int_0^r T(r)\,r\,dr\right],\\ \sigma_\varphi &= \frac{\alpha E}{1-\nu}\left[\frac{1}{R^2}\int_0^R T(r)\,r\,dr + \frac{1}{r^2}\int_0^r T(r)\,r\,dr - T(r)\right],\\ \sigma_z &= \sigma_r + \sigma_\varphi.\end{aligned}\right\} \quad (A.1)$$

Here, α is the linear expansion coefficient, E is Young's modulus, and ν is the Poisson bracket.

The components of σ are related linearly to the components of the elastic strain tensor:

$$\left.\begin{aligned}\varepsilon_r &= \frac{1}{E}[\sigma_r - \nu(\sigma_\varphi + \sigma_z)],\\ \varepsilon_\varphi &= \frac{1}{E}[\sigma_\varphi - \nu(\sigma_r + \sigma_z)],\\ \varepsilon_z &= \frac{1}{E}[\sigma_z - \nu(\sigma_r + \sigma_\varphi)] = \frac{1}{E}(1-\nu)\sigma_z.\end{aligned}\right\} \quad (A.2)$$

If we know the strain tensor we can calculate the permittivity tensor of the medium or the variation in the coefficients of the optical indicatrix[12]

$$\Delta B = \|P\|\hat{E}, \quad (A.3)$$

where $\|P\|$ is the matrix of elastooptical coefficients. The first-order piezooptical effect is also observed in isotropic materials, such as glass. In this case, the matrix $\|P\|$ has the same form as for class-m3m crystals of the cubic system:

$$\|P\| = \begin{vmatrix} p_{11} & p_{12} & p_{12} & 0 & 0 & 0\\ p_{12} & p_{11} & p_{12} & 0 & 0 & 0\\ p_{12} & p_{12} & p_{11} & 0 & 0 & 0\\ 0 & 0 & 0 & p_{44} & 0 & 0\\ 0 & 0 & 0 & 0 & p_{44} & 0\\ 0 & 0 & 0 & 0 & 0 & p_{44}\end{vmatrix}; \quad (A.4)$$

however, its coefficients are related by the expression $2p_{44} = p_{11} - p_{12}$. By substituting (A.4) in (A.3), we find

$$\left.\begin{aligned}\Delta B_r &= p_{11}\varepsilon_r + p_{12}(\varepsilon_\varphi + \varepsilon_z),\\ \Delta B_\varphi &= p_{11}\varepsilon_\varphi + p_{12}(\varepsilon_r + \varepsilon_z).\end{aligned}\right\} \quad (A.5)$$

Small changes in the refraction indices are related to changes in the indicatrix coefficients by the linear expression

$$\Delta n_i = -\frac{\Delta B_i}{2} n_0^3. \quad (A.6)$$

Artificial anisotropy generally arises as a result of thermoelastic stresses in the medium. The laser beam experiences partial depolarization. Figure 3 shows a typical interference pattern, obtained with crossed polaroids in a KS-13 glass filter 5 mm thick, which absorbs completely the argon laser radiation. Similar patterns are observed in other glasses, for instance, UFS-1, PS-13, TS-1, and TS-4.

If we neglect the polarization effects, the mean addition to the refraction index consists of two parts:

$$\Delta n_{\mathrm{me}} = -\frac{1}{4} n_0^3 (\Delta B_r + \Delta B_\varphi) = -\frac{\alpha n_0^3}{4(1-\nu)}[(p_{11} + p_{12})(1-3\nu) + 2p_{12}(1-\nu)]\left[\frac{2}{R^2}\int_0^R T(r)\,r\,dr - T(r)\right]. \quad (A.7)$$

The first term, which is independent of the coordinates, can be significant in nonlinear processes where the synchronism conditions are satisfied. The second term is proportional to the temperature. Therefore, the total nonuniform change in the refraction index is

$$\Delta n = \frac{dn}{dT} T, \quad (A.8)$$

where

$$\frac{dn}{dT} = \left(\frac{\partial n}{\partial T}\right)_{\sigma=0} + \left(\frac{\partial n}{\partial T}\right)_{TH} = \frac{\partial n}{\partial T} + \frac{\alpha n_0^3}{4(1-\nu)}[(p_{11} + p_{12})(1-3\nu) + 2p_{12}(1-\nu)]. \quad (2)$$

Possible electrohydrodynamic effects in electrolytes

E. Z. Gak. É. Kh. Rokhinson, and N. F. Bondarenko

Agrophysical Scientific-Research Institute, Leningrad

(Submitted April 6, 1973; resubmitted September 13, 1973)
Zh. Tekh. Fiz., 44, 1076-1079 (May 1974)

The appearance of a macroscopic space charge in aqueous solutions of electrolytes is discussed. This effect can be used to produce various electrohydrodynamic effects in such solutions. This space charge appears only when limiting diffusion currents flow through the solution.

1. On the basis of arguments regarding the electrical neutrality of electrolytic solutions it is usually assumed that no space charge appears in such solutions except near interfaces, where there is a space-charge density[1] $\rho \neq 0$ in an electrical double layer with thickness of order of 10^2-10^3 Å. Electrohydrodynamic effects, e.g., electroosmosis and electrophoresis occur under the influence of external electric fields in a region with $\rho \neq 0$. Because of the microscopic surface nature of these phenomena, the use of electrohydrodynamic effects in electrolytes has been restricted primarily to capillary–pore systems.

When certain physicochemical conditions prevail in electrolytes electric-charge formations of macroscopic dimensions can appear outside the double layer, expanding the practical usefulness of electrohydrodynamic effects.

We report here a theoretical and experimental study of the effects of alternating electric fields on the space-charge region which arises outside the double layer when an electric current near the limiting strength is passed through a solution. Although the existence of such charge formation has a firm theoretical basis,[2] the absence of convincing experimental results has apparently been responsible for the general neglect of this theory. The magnitude of the charge, the regions in which it exists, and the effect on various heterogeneous processes in electrolytes have not been determined.

2. The idea that a macroscopic space charge can appear outside the double layer is based on the following arguments: When the rate at which ions are furnished determines the rate of a heterogeneous process, i.e., in the region of diffusion and mixed kinetics, a diffusion layer of thickness δ_{diff} is known to appear behind the electrical double layer of thickness δ_{do}; in this diffusion layer the ion density drops from some c to c_0, the density in the bulk electrolyte.

To be definite we consider the case in which the space charge arises in a binary electrolyte and in which there are diffusion limitations at the cathode. In the diffuse part of the double layer the anion concentration is a minimum; anions must accumulate in the diffusion layer adjacent to the electrical double layer, since the movement of cations through the cathode region under the influence of migration mechanisms is considerably more rapid than the movement of anions to the bulk solution by diffusion. Accordingly, in the immediate vicinity of the double layer a negative macroscopic space charge arises with density ρ_{sc} and dimension $\Delta x \gg \delta_{do}$.

In a medium at rest the density ρ_{sc} over a region $x \geq 2$-$3\delta_{do}$ is given by[2]

$$\rho_{sc} = \frac{\varepsilon RT}{4\pi z_2 F}\frac{1}{x^2}, \tag{1}$$

where z_2 is the valence of the anions, R is the Mendeleev–Clapeyron constant, F = 96 kC/g-eq is the Faraday number, T is the absolute temperature, ε is the dielectric constant of the medium, and x is the distance into the electrolyte from the cathode.

The structure of this space-charge formation is similar to that of the diffuse part of the double layer, but the charge ρ_{max} is much lower than that of the double layer.

The dimension of this macroscopic charge formation, Δx, must be a function of the electrolyte concentration: $\Delta x = f(1/\sqrt{c})$. According to an estimate in ref. 5, this dimension is $\Delta x > 10\delta_{do}$ and can reach 10^{-4}-10^{-2} cm at low concentrations. The maximum value of Δx is δ_{diff}.

Using these arguments we can represent the function $\rho = f(x)$ as in Fig. 1, where region I is the double layer (with which we are not concerned here), the space charge increases in region II, for $\delta_{do} \leq x \leq 3\delta_{do}$, and the space charge decreases in region III, in accordance with Eq. (1). The function $\rho(x)$ thus passes through a maximum ρ_{max}, some $(2$-$3)\delta_{do}$ from the cathode.

Let us consider certain consequences of the existence of this macroscopic space-charge formation outside the electrical double layer.

a) This space charge must produce a barrier to the motion of ions toward the cathode; the density ρ_{max} determines the barrier height, and the dimension Δx determines its width. The electric field produced by this charge is $E_{sc} = (dU_{sc})/(dx)$ or, in terms of average values,

$$E_{sc} = \frac{U_{sc}}{\Delta x}. \tag{2}$$

Together with the concentration limitations this electrical barrier is apparently responsible for the formation of limiting currents.

b) The magnitude of the space charge and the region in which it exists are governed largely by the hydrodynamic conditions. An increase in the ion concentration drop dc/dx reduces Δx, but ρ_{max} increases. For ρ_{sc} the following equation has been found:[2]

$$\rho = \frac{\varepsilon}{4\pi}\frac{D_1 - D_2}{z_1 D_1 + z_2 D_2}\frac{RT}{F}\Delta \ln c, \tag{3}$$

where D_1 and D_2 are the cation and anion diffusion coefficients.

We assume that the diffusion limitations cannot be fully lifted even by very rapid mixing. This mixing can be caused by directly perturbing the space charge, e.g., by means of an alternating electric field $E_\sim = E_0 \sin\omega t$, where $\omega = 2\pi f$. The imposition of such a field can lead to hydrodynamic oscillations in the region of the space charge and to deformation of this charge; the result would

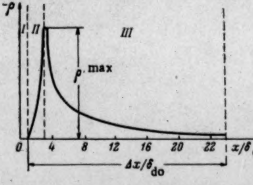

Fig. 1. Space-charge density as a function of the distance to the cathode, $\rho_{sc} = f(x)$. I) Electrical double layer; II) region of increasing space charge formed by anions; III) region in which the space charge falls off with distance from the cathode.

be a partial or complete dissipation of this charge and an increase in the current through the electrolyte. However, this effect of a field can be important only at $E_0 > E_{sc}$.

c) Physical factors should be influential only at current levels near the limiting current in the region in which $\rho_{sc} \neq 0$, i.e., at $x \leq \Delta x$. At currents far from the limiting value, which are thus governed primarily by electrochemical kinetics, an alternating electric field should not have any important effect on the electrode processes.

3. To study these phenomena experimentally we make use of the functional dependence $j_= = f(U_=)$, where $j_=$ is the density of the direct current and $U_=$ is the voltage across the electrochemical cell. Cells of two types are used: an annular electrochemical cell with electrodes 0.6 and 3 cm in radius and 1.5 cm high, and a rectangular cell whose (planar) cathode is 1 cm^2 in area, whose (planar) anode is 6 cm^2 in area, and whose electrodes are 6 cm apart.

To determine the region in which the space charge exists we use a movable electrode through which the liquid can pass freely (a grid electrode); with the annular cell we use a set of grids. We apply an alternating voltage $U_\sim = U_0 \sin \omega t$ between the cathode and the movable electrode, and we apply a constant voltage $U_=$ between the cathode and anode. The corresponding circuits are isolated by the usual circuit methods (RC and LC filters). The frequency of the alternating current is varied from 1 to 10^4 Hz.

The electrolytes are aqueous solutions of $CuSO_4$ and $NiSO_4$ at concentrations ranging from 0.01N to 1N. The electrodes and grids are copper or nickel to avoid chemical polarization of the electrodes.

As expected, the imposition of an alternating electric field lifts the diffusion limitations on the direct electric current through the electrolyte, causing a significant increase in the limiting current; it is in fact possible to displace the entire voltage–current characteristic into the region of electrochemical kinetics. This increase in the limiting current reaches 400–500% at low electrolyte concentrations, increasing with E_0 beyond a certain threshold, i.e., at $E_0 > (5\text{-}10)E_=$ (Fig. 2). From the experimental data we estimate $E_{sc} \approx 20$ V/cm.

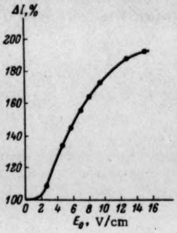

Fig. 2. Increase in the limiting direct current as a function of the amplitude of the applied alternating electric field, $\Delta I = f(E_0)$ for 0.01N $CuSO_4$. The frequency of the applied field is 50 Hz. Here $I = I_{li}(E_0 \neq 0)/I_{li}(E_0 = 0)$, where $I_{li}(E_0 \neq 0)$ and $I_{li}(E_0 = 0)$ are the limiting currents corresponding to $E_0 \neq 0$ and $E_0 = 0$.

As we move the movable grid electrode toward the cathode, to the closest position possible under our experimental conditions ($0.5 \cdot 10^{-2}$ cm), we observe the same effect, a current increase, at progressively lower voltages U_0. The effect is independent of the frequency at frequencies $f \geq 30$ Hz; at lower frequencies (f = 1-20 Hz) there is some increase in the effect. The results obtained with other electrolytes are similar to those shown here.

As expected, in the region in which the current is controlled by electrochemical kinetics, i.e., at currents far from the limiting current, the increase in the direct current does not exceed 10–15%, perhaps due to a change in the structure of the diffuse part of the double layer and to the circumstance that the process can occur under diffusion limitations. This circumstance is apparently responsible for the small changes observed elsewhere in the voltage–current characteristics under the influence of an alternating electric current.[3]

4. These phenomena deserve further study; they may find applications not only in experimental physics and electrochemistry but also in efforts to increase the rates of various heterogeneous processes involving the transport of one or several ion species across an interface when there is a concentration gradient in layers near a wall.

Electron-scanning transformation of the potential distribution on an electrostatic target

V. L. Lentsman
Main Astrophysical Observatory, Academy of Sciences of the USSR, Leningrad
(Submitted June 19, 1973)
Zh. Tekh. Fiz., 44, 1080-1083 (May 1974)

The discharge of the electrostatic targets of television and crt storage devices in scanning by an electron beam whose density is uniform over the target surface is studied. There is a predominant attenuation of the lower spatial frequencies of the spectrum of the electronic image stored on the target. Experimental detection of this effect is reported.

Two basic kinds of electrostatic storage targets are used in television pickup tubes and in crt storage devices: a target formed by a dielectric film held under tension at a certain distance from a fine metal grid (the superorthicon and the izokon) and a target consisting of a metal substrate (signal plate) on which a dielectric film has been deposited (the vidicon, the SEC vidicon, the graphecon, etc.). Images are usually stored, read off, and erased from such targets by scanning with both focused and unfocused beams of electrons with various energies.

The transformations of the electronic images are conveniently described in terms of the mathematical apparatus of scattering functions and spatial frequency characteristics,[1-3] as in optics and photography. In particular, the transformation of the electronic image involved in the transition from the charge-density distribution on the target surface to the potential distribution in the same plane (the "charge-potential" transformation), which largely governs the target resolution, can be characterized by the following frequency characteristics:

For the first type of target,

$$\tau_1(\omega_r)=\frac{d}{\varepsilon_0}\frac{1-e^{-2\omega_r d}}{2\omega_r d}$$

$$\times 2\frac{(\varepsilon_1+1)+(\varepsilon_1-1)e^{-\omega_r\delta}}{(\varepsilon_1+1)^2-(\varepsilon_1-1)^2e^{-2\omega_r\delta}-(\varepsilon_1^2-1)e^{-2\omega_r d}+(\varepsilon_1^2-1)e^{-2\omega_r(d+\delta)}},$$

where d is the distance between the film and the grid, δ is the film thickness, ε_0 is the permittivity of free space, and ε_1 is the dielectric constant of the film material. The coefficient d/ε_0, which governs the value of the frequency characteristic at $\omega_r = 0$, is the reciprocal of the "specific storage capacitance" of the target, $c = \varepsilon_0/d$;

for the second type of target,

$$\tau_1(\omega_r)=\frac{d}{\varepsilon_0\varepsilon_1}\frac{1-e^{-2\omega_r d}}{2\omega_r d}\frac{2\varepsilon_1}{(\varepsilon_1+1)+(\varepsilon_1-1)e^{-2\omega_r d}},$$

where d is the thickness of the dielectric film, and ε_1 is the dielectric constant of the film material.

These frequency characteristics are obtained by integrating the Laplace equation and using the Hankel transform.[2,4] The corresponding scattering functions for the charge-potential transformation, which in this case are the potential distribution due to a point charge, can be found by an inverse Hankel transform.

Let us consider the change in the charge distribution q(x, y, t) and the potential relief V(x, y, t) on such targets in scanning by a beam of electrons whose density is uniform over the target surface. The continuity equation for this case can be written

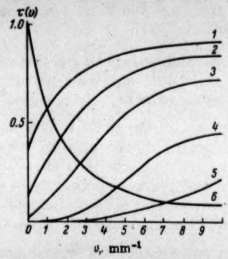

Fig. 1. Frequency characteristics for the transformation of the electronic image on the target. 1-5) For electron irradiation at $j_n b t/c \le 1, 2, 5, 10, 20$, 6) charge-potential transformation for d = 0.1 mm. Here $\nu = \omega_r/2\pi$.

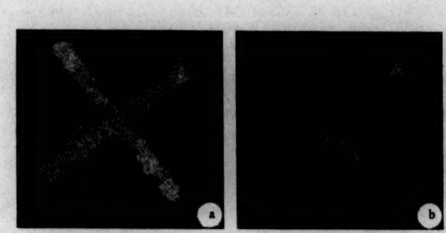

Fig. 2. Images photographed from the screen of a television video monitor.

$$\frac{\partial}{\partial t}q(x, y, t)=j_Q(x, y, t).$$

Here, $j_Q(x, y, t)$ is the instantaneous current-density distribution of the charge; this is governed by the current density of primary electrons and the instantaneous value of the secondary-emission yield, which in turn is a complicated function of the target potential. In certain cases this functional dependence can be approximated as a linear function, e.g., at a low primary-electron energy, in which case the secondary yield is governed by the electron-optics reflection of the primary electrons, or in the fast-electron regime, in which case the average target potential is approximately equal to the collector potential. For these cases the above equation can be written

$$\frac{\partial}{\partial t} q(x, y, t) + j_n \beta V(x, y, t) = 0,$$

where β is a coefficient describing the rate of change in the secondary yield as a function of the target potential. The relation between V(x, y, t) and q(x, y, t) is governed by this charge-potential transformation.

Solving this equation in frequency space through the use of Fourier or Hankel transforms, we can find the frequency characteristic governing the transformation of the spectrum of charge and potential distributions in scanning of the target by an electron beam of uniform density:

$$\tau_2(\omega_r) = \exp\left\{-\frac{j_n \beta t}{c} \tau_1^0(\omega_r)\right\},$$

where $\tau_1^0(\omega_r)$, is the frequency characteristic of the charge-potential transformation, is equal to unity at $\omega_r = 0$.

Curves 1-5 in Fig. 1 show frequency characteristic $\tau_2(\omega_r)$ for five values of the dimensionless parameter $j_n \tau t/c$: 1, 2, 510^0, and 20.

As $\tau_1^0(\omega_r)$ we adopt the frequency characteristic of a target of the first type with d = 0.1 mm (curve 6 in Fig. 1). We see that scanning of the target by a uniform-density electron beam causes a preferential attenuation of the lower spatial frequencies of the spectrum of the electronic image stored on the target. When the current density and scanning time are chosen appropriately, this effect can be exploited to isolate the outlines of objects and fine details in the original image, to correct electron-optics images, to reduce an excessive number of these images, etc. The advantages of two-dimensional transformations of electronic images over the methods basic to signal processing have been pointed out previously.[1,5,6]

Note should be taken of a distinction between this spatial-filtering method and one described previously,[5] based on the combination of electronic images of various signs on the target, one of which (the positive image) is stored in the fast-electron regime, while the other (negative) is stored in the slow-electron regime.

We have carried out an experimental study of this effect with a superorthicon television transmitting tube. The television system in which the tube operates can separate the storage and readout processes and perform various transformations of the electronic images.[6] After the potential distribution is recorded in the usual manner (in the fast-electron regime), the target of the superorthicon is scanned by a beam of slow photoelectrons obtained from the uniform illumination of the photocathode of the tube, whose potential has been changed accordingly. Figure 2 shows the original (a) and transformed (b) images, photographed on the screen of a video monitor. We see the influence of nonlinear effects; in particular, the intensities of the positive and negative excursions at the boundary of the object are not the same.

This transformation of the potential distribution must occur in a wide variety of television and storage tubes even when the target is being scanned by the readout beam, although the discharging of the target under these conditions is of course considerably more complicated. The potential distribution remaining on the target after readout, which corresponds primarily to the outlines of objects and to fine details, is built up from frame to frame during continuous operation of the apparatus, so the resolution of television transmitting tubes at low illumination is significantly improved in the transmission of fixed images. In particular, this mechanism can be used to explain the satisfactory resolution of superorthicons with a large grid–film separation, for which the frequency characteristic of the charge-potential transformation falls off significantly at high spatial frequencies.

Symmetric multielectrode tubular electrostatic lenses

L. G. Glikman, V. M. Kel'man, and M. Sh. Nurmanov
Institute of Nuclear Physics,
Academy of Sciences of the Kazakh SSR, Alma-Ata
(Submitted July 30, 1973)
Zh. Tekh. Fiz., 44, 1084-1087 (May 1974)

Curves are given for determining the cardinal elements and spherical aberration of symmetric multielectrode tubular lenses for three versions of the potential distribution. The electrodes have the same radius, which is equal to the axial dimension. The spherical aberration of the lens drops sharply as the number of electrodes is increased.

The positions of the cardinal elements and the spherical aberration of immersion tubular lenses with electrodes of the same diameter are calculated in refs. 1 and 2. The results show that increasing the number of electrodes reduces the spherical aberration and that, for a given number of electrodes, this aberration is generally a minimum when the lengths of the intermediate electrodes are equal to the radius. In this note we carry out similar calculations for single lenses. Since the spherical aberration is almost always a minimum when the length of the intermediate electrodes, λ, is equal to the radius R (the same for all the electrodes), we report the results for this case alone.

The electrostatic field is calculated from the exact equation given in ref. 1, which is derived under the assumption that the gaps between the electrodes are infinitesimally small. In all cases considered here the number of electrodes N is odd and the field is symmetric with respect to the middle of the lens. We denote by Φ_1 the potential at the extreme electrodes, measured with respect to that at the position at which the charged-particle velocity is zero, and we denote by Φ_c the potential at the central electrode. The electron-optics properties of the lenses are calculated for both $\Phi_c/\Phi_1 > 1$ and $\Phi_c/\Phi_1 < 1$. We consider the following versions of the potential distribution.

1. The ratio of the potentials at two adjacent electrodes in the first half of the lens (between the first and central electrodes) is constant and equal to

$$q = \sqrt[\frac{N+1}{2}]{\frac{\Phi_c}{\Phi_1}}. \tag{1}$$

The potential at the k-th electrode is

$$\Phi_k = \Phi_1 q^{k-1}, \quad k = 1,\ 2,\ \ldots,\ (N+1)/2. \tag{2}$$

The potential in the second half of the lens is determined from the symmetry of the field with respect to the center of the lens.

2. The potential difference between two adjacent electrodes in the first half of the lens is constant and equal to

$$\Delta\Phi = \frac{2(\Phi_c - \Phi_1)}{N-1}. \tag{3}$$

The potential at the k-th electrode is

$$\Phi_k = \Phi_1 + (k-1)\Delta\Phi, \quad k = 1,\ 2,\ \ldots,\ (N+1)/2. \tag{4}$$

The potentials in the second half of the lens are determined from the symmetry condition.

3. The potential distribution is described by

$$\Phi_k = 1 + \frac{m^2}{1 + \left(\frac{z_k - \frac{L}{2}}{d}\right)^2} \tag{5}$$

and

$$\Phi_k = 1 - \frac{m^2}{1 + \left(\frac{z_k - \frac{L}{2}}{d}\right)^2}, \quad k = 1,\ 2,\ \ldots,\ N. \tag{6}$$

Here, m and d are constant, L is the distance between

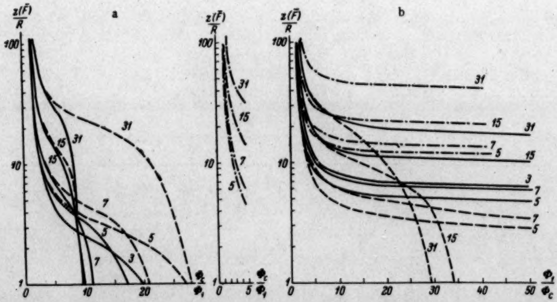

Fig. 1. Coordinates z(F) of the imaginary foci as functions of the ratio of the potentials at the central and extreme electrodes for $\Phi_c/\Phi_1 > 1$ (a) and $\Phi_c/\Phi_1 < 1$ (b).

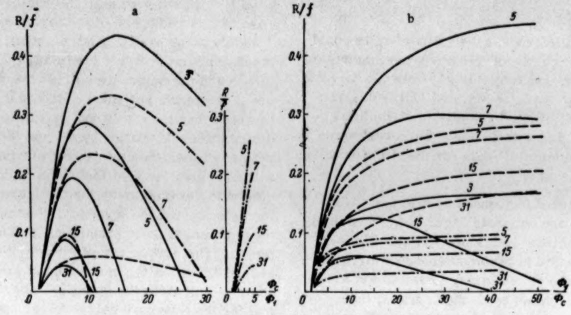

Fig. 2. Diagrams used to determine the focal length for $\Phi_c/\Phi_1 > 1$ (a) and $\Phi_c/\Phi_1 < 1$ (b).

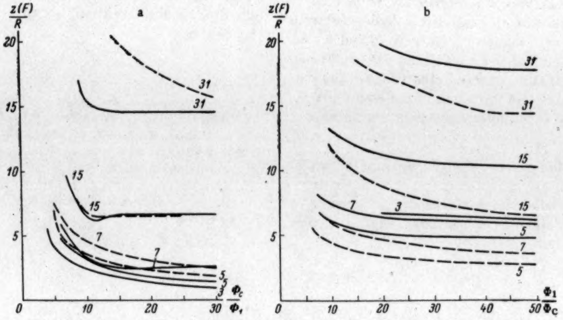

Fig. 3. Coordinates z(F) of the real foci as functions of the ratio of the potentials at the central and extreme electrodes for $\Phi_c/\Phi_1 > 1$ (a) and $\Phi_c/\Phi_1 < 1$ (b).

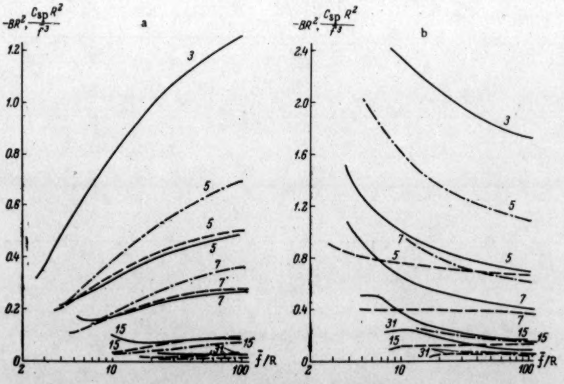

Fig. 4. Diagrams used to determine the spherical aberration coefficient B with the object at infinity and to determine the spherical aberration constant C_{sp} with the object at the real focus for $\Phi_c/\Phi_1 > 1$ (a) and $\Phi_c/\Phi_1 < 1$ (b).

the extreme electrodes, and $z_k = -L/2 + (k-1)\lambda$.

For intermediate electrode k the value of z_k is equal to the coordinate of the center of this electrode, measured along the axis of the system from the gap between the first and second electrodes. As $L/R \rightarrow \infty$ and $\lambda/R \rightarrow 0$, Eqs. (5) and (6) describe bell-shaped potential distributions. The calculations show that with $L/d = 4$ the lens aberrations are nearly a minimum; all data for specific lenses given here refer to this case.

The results calculated for lenses with the specified potential distributions are shown in Figs. 1-4. In each of these diagrams the electron-optics properties of lenses in which the potential ratio between adjacent electrodes is constant in each of the (symmetric) halves of the lens [potential ratio (1)] are shown by dashed curves; those corresponding to the constant potential difference (3) are shown by solid curves; those corresponding to distribution (5), (6) are shown by dot-dashed curves. The curves are labeled with the number of electrodes N. For comparison, these figures show the data for a three-electrode lens, which coincide with the data from refs. 3 and 4. As in ref. 2, it is assumed that the $z = 0$ plane passes through the gap between the first and second electrodes. The calculations are carried out on the basis of the equations given in ref. 5, whose terminology and notation we have adopted here.

Figure 1 shows the positions of the imaginary foci $\overline{F}$ [the coordinates $z(\overline{F})$] as functions of the potential ratio between the central and extreme electrodes. Figure 2 shows diagrams for determining the focal lengths $\bar{f}$. Beyond $N > 3$ an increase in the number of electrodes always results in a reduction of the lens power. The data in Figs. 1 and 2 can be used to find the positions of the principal planes and to construct the image of an object if both the image and the object lie outside the field of the lens. Figure 3 shows the positions of the real foci F for the case in which they lie within the lens field. For the potential distributions described by (5) and (6), and for the range of ratios between the central and extreme electrodes considered here, the real foci lie outside the field and coincide with the imaginary foci. Figure 4 shows diagrams for determining the spherical aberration of lenses, with these potential distributions as a function of the focal length. The curves are plotted for two object positions: at infinity and at the real focus of the lens. For the former case we calculate the spherical aberration coefficient B, and for the latter we calculate the spherical aberration constant C_{sp}. These curves can be used to determine B only when the lens focus lies outside its field. From Fig. 4 we see that increasing the value of N rapidly reduces the spherical aberration, because the size of the lens field increases.

Upper and lower limits on the capacitance of a plane capacitor

R. F. Fikhmanas and P. Sh. Fridberg

(Submitted July 23, 1973)
Zh. Tekh. Fiz., 44, 1088-1090 (May 1974)

1. We consider a plane capacitor formed by two identical, infinitesimally thin, metal plates of arbitrary shape (Fig. 1a); we assign potentials of + 1 and − 1 to the plates.

Since the device is symmetric with respect to the z = h plane, we need only consider the "half" problem: that of a plate, charged to unit potential, above a grounded plane (Fig. 1b). The density of the surface charge σ on the plate D satisfies the integral equation

$$\int_D ds' G(\mathbf{x}, \mathbf{x}')\,\sigma(\mathbf{x}') = \varepsilon, \ \mathbf{x} \in D. \tag{1}$$

Here, $G(\mathbf{r}, \mathbf{r}')$ the Green's function of the Laplace equation for the half-space $z \le h$, satisfies homogeneous Dirichlet boundary conditions, and ε is the dielectric constant of the medium (in international units).

Using (1) and the standard procedure,[1] we find the capacitance

$$C = \frac{1}{2} \int_D ds\,\sigma(\mathbf{x}), \tag{2}$$

in a stationary Schwinger representation:

$$C = \frac{\varepsilon}{2} \max_{\sigma} \frac{\left[\int_D ds\,\sigma(\mathbf{x})\right]^2}{\int_D ds \int_D ds'\,\sigma(\mathbf{x})\,G(\mathbf{x}, \mathbf{x}')\,\sigma(\mathbf{x}')}. \tag{3}$$

Functional (3) can be used to find a lower limit on the capacitance.

An upper limit on the capacitance is known[2] to be given by the Dirichlet integral:

$$C = \frac{\varepsilon}{2} \min_{\varphi} \int_{(z<h)} dv\,|\mathrm{grad}\,\varphi(\mathbf{r})|^2, \quad \varphi|_D = 1. \tag{4}$$

However, the use of variational principle (5) runs into difficulties because of the need to specify the three-dimensional potential distribution $\varphi(\mathbf{r})$.

It is much more convenient to start from the equation

$$\lim_{z\to 0} \frac{\partial}{\partial z} \int_Q ds' \left\{\frac{\partial}{\partial z'} [G(\mathbf{r}, \mathbf{r}') + \Gamma(\mathbf{r}, \mathbf{r}')]\right\}_{z'=0} \varphi(\mathbf{x}') = 0, \ \mathbf{x} \in S; \ \varphi|_D = 1 \tag{5}$$

for the potential $\varphi(\mathbf{x})$ on the continuation S of plate D, (Q = S + D is an infinite plane). Here, Γ and G are the Green's functions for the region $0 \le z \le h$ and satisfy homogeneous Dirichlet boundary conditions. The variational principle based on this equation is

$$C = \frac{\varepsilon}{2} \min_{\varphi} \int_Q ds \int_Q ds'\,\varphi(\mathbf{x})\,K(\mathbf{x}, \mathbf{x}')\,\varphi(\mathbf{x}'), \quad \varphi|_D = 1, \tag{6}$$

where the role of kernel is played by the generalized "admittance"[1)]

$$K(\mathbf{x}, \mathbf{x}') = -\lim_{z\to 0} \frac{\partial}{\partial z} \left\{\frac{\partial}{\partial z'} [G(\mathbf{r}, \mathbf{r}') + \Gamma(\mathbf{r}, \mathbf{r}')]\right\}_{z'=0}. \tag{7}$$

Functional (6) leads to upper estimates on the capacitance in the class of continuous functions having uniformly continuous derivatives along plane Q nearly everywhere, which take on the specified value on the surface of the plate, and which fall off as $x^{-\nu}$ for $x \to \infty$, where $\nu \ge 3$; we denote this class as class F. The actual value of C thus lies on the interval $[C\{\sigma\}, C\{\varphi\}]$, where σ and φ are allowable trial functions.

In contrast with (4), functional (6) now contains information about the geometry of the problem (through the Green's functions of the volumes) and requires specification of only a two-dimensional potential distribution.

2. The most interesting case is that of a circular plate capacitor.

On the basis of physical considerations, Kirchhoff[4] has derived the following asymptotic equation for the capacitance in this case:

$$\frac{1}{4\pi\varepsilon a} C_K = \frac{1}{8\alpha} + \frac{1}{4\pi} \ln \frac{8\pi}{e\alpha}, \quad \alpha \ll 1, \tag{8}$$

where $\alpha = h/a$, and a is the disk radius. The first term of this equation corresponds to the capacitance of a plane capacitor for which edge effects are neglected, and the second, which holds within terms which do not vanish as $\alpha \to 0$, gives the correction for edge effects. Kirchhoff's equation is justified analytically in refs. 5 and 6.

Variational principle (7) has been used[2] with the trial distribution σ = const, i.e., in effect, the Howe method[7] is used to calculate the capacitance of this capacitor.

Noble[8] has refined the results of ref. 2 through the use of the trial function

$$\sigma(x) = A + B\left[1 - \left(\frac{x}{a}\right)^2\right]^{-1/2}. \tag{9}$$

The physical meaning of the second term is obvious: It gives the charge distribution on an isolated disk.

Variational principle (6), formulated in Sec. 1, can be

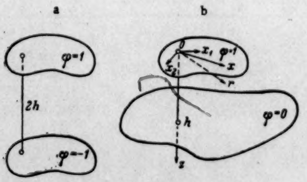

Fig. 1

α	$\frac{1}{4\pi\varepsilon a} C\{\sigma\}$	$\frac{1}{4\pi\varepsilon a} C\{\varphi\}$	$\delta = \frac{C\{\varphi\} - C\{\sigma\}}{C\{\varphi\} + C\{\sigma\}}$

2.0	0.375	0.401	0.032
2.5	0.365	0.394	0.038

used to find an upper limit on the capacitance; when this upper limit is combined with the lower limit, the error of the calculation can be determined.

Using the explicit representation for Green's functions G and Γ in a cylindrical coordinate system and exploiting the axial symmetry of the problem, we find

$$\frac{1}{4\pi\varepsilon} C = \frac{1}{4} \min_{\varphi \in F} \int_0^\infty d\lambda (1 + \operatorname{cth} \lambda h) \left[\int_0^\infty dx\, x J_1(\lambda x) \frac{d\varphi(x)}{dx} \right]^2. \qquad (10)$$

The numerical results found with the trial function[2]

$$\varphi(x) = \begin{cases} 1, & x \in D, \\ \left(\frac{a}{x}\right)^3 \left[1 + A\left(1 - \frac{a^2}{x^2}\right)^{1/2}\right], & x \in S \end{cases} \qquad (11)$$

are shown in Table 1, which also gives the lower limits on the capacitance, which we calculated[3] from the equations of ref. 8.

The calculations show that the plane-capacitor equation has an error certainly larger than 5% even with $\alpha = 0.2$, while the Kirchhoff equation has a corresponding error at $\alpha = 0.02$.

Serini[6] has proposed the following empirical equation for the case of small α:

$$\frac{1}{4\pi\varepsilon a} C_S = \frac{1}{8\alpha} + \frac{1}{\pi}, \quad \alpha \ll 1. \qquad (12)$$

Since the term $1/8\alpha$ is the principal term in the asymptotic behavior as $\alpha \to 0$, while the constant $1/\pi$ is the principal term as $\alpha \to \infty$ (ref. 2), it is interesting to estimate the error of this equation for intermediate values of α; it turns out that over the range $0.05 \leq \alpha \leq 2.5$ we have

$$\left| 1 - \frac{C\{\sigma\} + C\{\varphi\}}{2C_S} \right| < 0.03. \qquad (13)$$

---

[1] Methods for calculating such quantities are examined in ref. 3.

[2] We note that $\varphi(x)$ satisfies the condition at the cut and belongs to class F for any value of the adjustable factor A.

[3] Numerical values of $C\{\sigma\}$ are given in ref. 8 only for α = 0.05, 0.1, 0.2, and 0.4.

Impossibility of shielding against the rf radiation of a thermonuclear reactor with a cold-plasma sheath

A. S. Chikhachev

Moscow Engineering-Physics Institute

(Submitted August 22, 1973)
Zh. Tekh. Fiz., 44, 1090-1091 (May 1974)

The problem of shielding the first wall of a thermonuclear reactor against the highest-frequency part of the radiation of a thermonuclear plasma is analyzed. It is shown that this shielding cannot be achieved with a sheath of cooler plasma because the absorption coefficient α_ω is not a function of the temperature at frequencies $\omega > T_e/\hbar$, where ω is the frequency of the radiation and T_e is the temperature of the cooler plasma.

One of the primary factors preventing prolonged operation of thermonuclear reactors is the intense flux of electromagnetic energy, which destroys the wall.

Let us consider in this connection some estimates giving a qualitative description of the radiation of a reactor plasma in the rf range.

We assume that there are n ions (protons) per cm^3, which are at rest, and we assume that there are an equal number of electrons, moving at a velocity v. We denote by $\sigma_\omega(\varepsilon)d_\omega$ the probability of the emission of a photon with energy $\hbar\omega$ in the frequency range (w, w + $d\omega$) in the collision of an electron with energy ε with an ion at rest. Then the total number of collisions per 1 cm^3 resulting in the emission of energy $\hbar\omega$ is $n^2\sigma_\omega d\omega$, and the total energy radiated in the range $d\omega$ is

$$j_\omega d\omega \simeq \hbar\omega n^2 v\sigma_\omega(\varepsilon)\,d\omega. \tag{1}$$

The bremsstrahlung cross section is given by[1]

$$\sigma_\omega \frac{d\omega}{\varepsilon} = \frac{8}{3}\alpha r_0^2 \frac{d\omega}{\omega}\frac{m}{\varepsilon}\ln\frac{(\sqrt{\varepsilon}+\sqrt{\varepsilon-\omega})^2}{\varepsilon}, \tag{2}$$

where $\alpha = e^2/\hbar c = 1/137$, $r_0 = 2.8\cdot 10^{-13}$ cm is the classical radius, and ε is its energy. We see from Eq. (2) that the emission can, in principle, reach frequencies $\omega \lessdot \varepsilon/\hbar$; the characteristic energy ε here is taken to be electron thermal energy T_e.

An estimate of the rf part of the radiation for the total radiated power per 1 cm^3 yields

$$J \simeq \int^{T_e/\hbar} j_\omega d\omega \simeq \alpha n^2 v_{T_e} r_0^2 mc^2, \tag{3}$$

where ν_{Te} is the velocity of an electron with energy T_e, m is the electron mass, and c is the speed of light.

The radiation pressure, I, is the product of this quantity and the characteristic reactor dimension L. We note that (3) implies an extremely weak functional dependence of this pressure on the temperature. With $L \simeq 100$ cm, $T_e \simeq 50$ keV, and $n \simeq 10^{15}$ cm^{-3} we find I = 100 W/cm^2.

Taking account of the functional dependence on T_e and n, we find

$$\sqrt{\frac{T_e}{50}}\,L \text{ W/cm}^2. \tag{4}$$

Here, n is the number of particles per cubic centimeter, L is the characteristic dimension in meters, and T_e is the temperature in electron volts.

We turn now to the possibility of the absorption of the energy described by (3). The absorption occurs because of scattering processes involving photon absorption.

By definition, the absorption coefficient of the medium is $\alpha_\omega = j_\omega/I_\omega$, where j_ω is given by (1), and $I_\omega = (\hbar\omega^3/8\pi^3c^2)\cdot[\exp(\hbar\omega/T) -]^{-1}$.

It follows from the form of I_ω that the behavior of I_ω differs markedly at $\omega > T_e/\hbar$ and $\omega < T_e/\hbar$; taking account of this circumstance and of the presence of the important Gaunt factor[2] allows us to write a simple qualitative equation for α_ω:

$$a_\omega \simeq n^2 r_0^2\left(\frac{c}{\omega}\right)^2\left[\frac{mc^2}{\max(T_e, \hbar\omega)}\right]^2. \tag{5}$$

If $\hbar\omega \gg T_e$, i.e., if the temperature in some layer near the wall is lower than that corresponding to the radiation energy from the working zone, we can easily find a relation for the characteristic length over which absorption of the radiation can be significant:

$$l_\omega \simeq 10^{19}\left(\frac{\omega}{10^{19}}\right)^{7/3}\left(\frac{10^{18}}{n'}\right)^{2/3} \text{ cm}. \tag{6}$$

Here, ω is the frequency in reciprocal seconds, and n is the density of the cold plasma.

We see that it is unrealistic to try to absorb the rf radiation in a cold-plasma sheath for the conditions corresponding to a thermonuclear reactor, i.e., at $\omega \simeq 10^{19}$ sec^{-1} and $n' \sim 10^{20}$ cm^{-3}. This conclusion can be extended to a moving cold-plasma sheath, in which the radiation would propagate as in vacuum. Absorption is possible if there are more massive ions present. In the working zone of a reactor, however, heavy ions would produce even more radiation, so their presence is extremely undesirable. We are thus left with the possibility of absorption in a wall of a heavy metal, in which resonant transitions of electrons can occur which correspond to photon energies of 50 keV. This conclusion means that most of the load must be carried by the first wall of the reactor.

The author thanks V. M. Smirnov for useful comments.

Absolute decay instability of low-frequency waves in an inhomogeneous plasma

A. D. Piliya and V. I. Fedorov

A. F. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted October 11, 1973)
Zh. Tekh. Fiz., 44, 1092-1093 (May 1974)

Parametric instabilities in a plasma have recently received wide attention in connection with the problem of rf heating and laser initiation of thermonuclear reactions. Since a real plasma is always inhomogeneous it is of interest to consider the effect of this inhomogeneity on the instabilities.

In a weakly inhomogeneous medium whose inhomogeneity is along a single coordinate, the decay conditions for the x components of the wave vectors of parametrically coupled waves can be satisfied only at certain points on the x axis (x is the coordinate along which the plasma parameters vary).[1,2] There is a finite swelling of waves near such points, in contrast with the absolute instability which arises under the corresponding conditions in a homogeneous plasma. If there are turning points, however, an absolute instability can arise for interacting waves even in an inhomogeneous plasma. The reason is that each of the parametrically coupled waves propagating through the interaction region not only interacts with this region but also generates a wave of a different type. A positive-feedback loop arises as a result of this nonlinear transformation and reflection of waves from the turning point in the plasma slab. It turns out that this situation arises whenever there is a point at which a high-frequency wave is cut off.

We assume for simplicity that the characteristic spatial dimension of the pumping field $E_0 = \mathcal{E}_0 e^{-i\omega_0 t}$ is much larger than all other dimensions of interest, so that $E_0 = \text{const}$. In the presence of field $\mathcal{E}_0$, the low-frequency wave $E_3 = f_3(x)\exp\cdot[-i\Omega t + ik_z z]$ $(\Omega \ll \omega_0)$ is parametrically coupled with two high-frequency waves: $E_1 = f_1(x)\exp\cdot[i(\omega_0-\Omega)t + ik_z z]$ and $E_2 = f_2(x)\exp[-i(\omega_0+\Omega)t + ik_z z]$. The equations describing the decay interaction of these waves can be written (e.g., ref. 2)

$$\left.\begin{aligned} f_1'' + k^2(x,\ \omega_0-\Omega)\, f_1 &= \nu_{13} f_3, \\ f_2'' + k^2(x,\ \omega_0+\Omega)\, f_2 &= \nu_{23} f_3, \\ f_3'' + \varkappa^2(\Omega)\, f_3 &= \nu_{31} f_1 + \nu_{32} f_2, \end{aligned}\right\} \tag{1}$$

where $k(x, \omega_0 \pm \Omega)$ and $\varkappa(\Omega)$ are the x components of the wave vectors of the high- and low-frequency waves, respectively, and $\nu_{23} \sim \nu_{13} \sim \mathcal{E}_0$ and $\nu_{31} \sim \nu_{32} \sim \mathcal{E}_0$. Considering a region near the high-frequency turning point whose dimension is small in comparison with the scale of the plasma inhomogeneity, we can write $k^2(x, \omega_0 \pm \Omega) = -\alpha(x \mp x_0)$, $(x_0 \sim \Omega)$ and neglect the function dependence of $\varkappa(\Omega)$ on the coordinate. The dispersion curves for this case are shown in Fig. 1. The arrows show the direction in which energy propagates for the case $dk/(d\omega) > 0$. This direction differs for the high-frequency waves f_1 and f_2 because their frequencies differ in sign. When the group velocity of the high-frequency or low-frequency waves is negative $[dk/(d\omega) < 0]$, the instability appears for the opposite sign of the frequencies $[-\Omega, -(\Omega+\omega_0), \omega_0-\Omega]$.

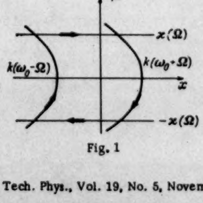

Fig. 1

A resonant decay interaction occurs near the intersections of the curves for $k(x, \omega_0 \pm \Omega)$ and $\varkappa(\Omega)$. If $\varkappa^3\alpha^{-1} \gg 1$, and $\varkappa x_0 \gg 1$ (if the distances between the decay points are large in comparison with the characteristic wavelengths), the interaction in each of the resonant regions proceeds independently of the interactions in the others and is described by the corresponding equations of ref. 3. If there is no absorption, the onset of instability requires that the product of all four "nonlinear-transformation" coefficients (corresponding to the four resonant points) be larger than unity. Using the equations of ref. 3, we can easily write this requirement as

$$4\,\mathrm{sh}^2\,\pi Z \geqslant 1, \tag{2}$$

where $Z = (\nu_{23}\nu_{32} + \nu_{13}\nu_{31})/4\alpha\varkappa$. Furthermore, the semiclassical phase advance over the entire feedback loop (taking into account the phase changes in the resonant regions and at the turning points) must be an integer times 2π:

$$4\varkappa x_0(\Omega) = (2m+1)\pi, \quad m = 0,\ 1,\ 2\ldots. \tag{3}$$

Accordingly, an absolute instability can appear in an inhomogeneous plasma for a certain discrete set of frequencies Ω_m. The instability threshold, given by an equation like (2) is finite, even in the absence of damping. It follows from Eqs. (2) and (3) that m = 0 mode can be the most unstable. In the interaction of plasma and ion-acoustic waves in a plasma without a magnetic field, the threshold pumping field $\mathcal{E}_0'$ for this mode is a minimum at $\Omega \lessapprox \omega_{pi}$, given by

$$\frac{\mathcal{E}_0^2}{4\pi nT} \simeq \frac{r_d^2}{l^2}\sqrt{\frac{m_i}{m_e}}, \tag{4}$$

where n and T are the plasma density and temperature, $l = [1/n|dn/dx|]^{-1}$ is the scale of the plasma inhomogeneity, and r_d is the Debye radius. Here condition (3) leads to the following restriction on l:

$$\frac{l}{r_d} > \sqrt{\frac{m_i}{m_e}}. \tag{5}$$

It should be kept in mind that in the m = 0 case Eqs. (2) and (3), derived in the semiclassical approximation, can be treated as rough approximations. Decay instabilities have been examined for similar conditions by Perkins and Flick,[2] but they take account only of one of the high-frequency waves, therefore reaching the conclusion that there is no absolute instability.

Effect of a high-frequency electric field on the energy loss of a charged particle in a medium

Zh. M. Diasamidze
Tbilisi State University
(Submitted October 5, 1973)
Zh. Tekh. Fiz., 44, 1093-1095 (May 1974)

The energy losses of a charged particle in an alternating electric field moving in an unbounded dielectric are considered. The effect of the external alternating electric field on the energy loss of the particles is investigated for an arbitrary value of the electric field.

The effect of an external alternating electric field on the energy loss of a charged particle moving through a medium (dielectric or a plasma), and when it moves in a dielectric above the boundary of separation of two dielectrics, has been considered in refs. 1-4.

In this paper we consider the energy loss of a charged particle which moves with a constant velocity along the z axis in an unbounded dielectric in the presence of an external high-frequency electric field $\mathbf{E} = \mathbf{E}_0 \sin \omega_0 t$, which is perpendicular to the motion of the particle.

The total energy lost by the particle per unit length of path is given by the well-known relation[5]

$$-\frac{\partial \mathcal{E}}{\partial z} = \frac{e(\mathbf{V}\cdot\mathbf{E})}{V},$$

where the electric field is taken at the particle location.

To determine the electromagnetic field of the particle we use Maxwell's equations with the charge density and the current:

$$\rho = e\delta(x)\,\delta(y - y(t))\,\delta(z - v_0 t),$$
$$\mathbf{j} = \rho\mathbf{V},$$

where

$$\mathbf{V} = \mathbf{V}_0 - \mathbf{V}_\sim \cos \omega_0 t,$$
$$y(t) = y_0 - \frac{v_\sim}{\omega_0} \sin \omega_0 t,$$

and the velocity and trajectory of the particle in the alternating electric field are $V_\sim = eE_0/m\omega_0$, $v_0 = V_{\sim y}$ and $y_0 = 0$, respectively.

The electromagnetic field of a particle which moves along a sinusoidal trajectory can be found in the usual way. Such calculations have been carried out many times (see, for example, refs. 4 and 6). Carrying out the appropriate calculations we obtain the following expression for the total energy loss of the particle of charge e in a field $\mathbf{E} = \mathbf{E}_0 \sin \omega_0 t$, moving in a medium of dielectric constant ε:

$$-\frac{\partial \mathcal{E}}{\partial z} = -\frac{e^2}{2\pi v_0^2}\,\mathrm{Re}\, i$$
$$\times \sum_l \iint \frac{\omega(\varepsilon\beta^2 - 1) J_l^2\left(\frac{k_y v_\sim}{\omega_0}\right)}{\varepsilon\sqrt{\left(\frac{\omega + l\omega_0}{v_0}\right)^2\left(\frac{\omega^2}{(\omega + l\omega_0)^2}\varepsilon\beta^2 - 1\right) - k_y^2}}\, dk_y d\omega$$
$$-\frac{e^2}{8\pi c^2}\frac{v_\sim^2}{v_0^2}\,\mathrm{Re}\, i$$
$$\times \sum_l \iint \frac{\omega J_l\left(\frac{k_y v_\sim}{\omega}\right)\left\{J_l\left(\frac{k_y v_\sim}{\omega_0}\right) + J_{l+2}\left(\frac{k_y v_\sim}{\omega_0}\right)\right\}}{\sqrt{\left(\frac{\omega + (l+1)\omega_0}{v_0}\right)^2\left(\frac{\omega^2}{(\omega + (l+1)\omega_0)^2}\varepsilon\beta^2 - 1\right) - k_y^2}}\, dk_y d\omega$$
$$-\frac{e^2}{8\pi c^2}\frac{v_\sim^2}{v_0^2}\,\mathrm{Re}\, i$$
$$\times \sum_l \iint \frac{\omega J_l\left(\frac{k_y v_\sim}{\omega_0}\right)\left\{J_l\left(\frac{k_y v_\sim}{\omega_0}\right) + J_{l-2}\left(\frac{k_y v_\sim}{\omega_0}\right)\right\}}{\sqrt{\left(\frac{\omega + (l-1)\omega_0}{v_0}\right)^2\left(\frac{\omega^2}{(\omega + (l-1)\omega_0)^2}\varepsilon\beta^2 - 1\right) - k_y^2}}\, dk_y d\omega. \quad (1)$$

Here, the first term with $l = 0$ gives the Cerenkov radiation ($\varepsilon\beta^2 > 1$), with $l \neq 0$ it gives the Doppler radiation with frequency $\omega = |-[l\omega_0/(1 - \beta\sqrt{\varepsilon}\cos\theta)]|$, ($l = \pm 1, \ldots$ $\varepsilon = \mathrm{const}$). The second and third terms for any l make a contribution to the Doppler radiation; for example, with $l = 0$, the next term gives Doppler radiation of frequency $\omega = \omega_0/\beta\sqrt{\varepsilon}\cos\theta - 1$ (the anomalous Doppler effect $\beta\sqrt{\varepsilon}\cos\theta > 1$), and the third term gives Doppler radiation of frequency $\omega = \omega_0/1 - \beta\sqrt{\varepsilon}\cos\theta$ (the normal Doppler effect $\beta\sqrt{\varepsilon}\cos\theta < 1$).

Evaluating (1) for weak alternating electric fields, $|k_y v_\sim|/\omega_0 \ll 1$, and integrating with respect to k_y, we obtain the energy loss of the charge:[4]

$$-\frac{\partial \mathcal{E}}{\partial z} = Q_0 - \frac{e^2}{4v_0^2}\frac{v_\sim^2}{\omega_0^2}\int \omega^3 \frac{(\varepsilon\beta^2 - 1)^2}{\varepsilon}\, d\omega$$
$$+\frac{e^2}{8v_0^4}\frac{v_\sim^2}{\omega_0^2}\int \omega\left\{(\omega + \omega_0)^2\left(\frac{\omega^2}{(\omega + \omega_0)^2}\varepsilon\beta^2 - 1\right)\frac{\varepsilon\beta^2 - 1}{\varepsilon} + 2\beta^2\omega_0^2\right\} d\omega$$
$$+\frac{e^2}{8v_0^4}\frac{v_\sim^2}{\omega_0^2}\int \omega\left\{(\omega - \omega_0)^2\left(\frac{\omega^2}{(\omega - \omega_0)^2}\varepsilon\beta^2 - 1\right)\frac{\varepsilon\beta^2 - 1}{\varepsilon} + 2\beta^2\omega_0^2\right\} d\omega, \quad (2)$$

where

$$Q_0 = \frac{e^2}{v_0^2}\int \frac{\omega(\varepsilon\beta^2 - 1)}{\varepsilon}\, d\omega \quad (3)$$

is the Cerenkov radiation for particle motion in the dielectric with no field. In Eq. (2) we have neglected terms of the order of $v_\sim^4$ and higher.

It is evident from Eq. (2) that the well-known expression for the energy loss by Cerenkov radiation in an unbounded dielectric Q_0, obtained by Tamm and Frank,[7] must be supplemented by terms which are quadratic in the electric field. The first of the terms is an addition to the Cerenkov radiation Q_0 in a weak electric field, and reduces the Cerenkov losses slightly. The last two terms define the Doppler radiation, which increases quadratically with the electric field.

It should be noted that the expression for the energy loss of a charged particle due to Doppler radiation (the normal Doppler effect) for weak electric fields is identical with the expression for the total energy radiated by an electron moving in a medium with refractive index n, obtained by Ginzburg[1] [Eq. (13) of ref. 1] in the dipole approximation. It is easy to show this by calculating the angular distribution of the energy of the normal Doppler radiation per solid angle $d\Omega$, changing in the last term of expression (2) from integration with respect to ω to integration over the angle θ, and using the equation $\omega = \omega_0/1 - \beta\sqrt{\varepsilon}\cos\theta$.

Evaluating (1) for strong alternating electric fields $|k_y v_\sim|/\omega_0 > 1$, and integrating over k_y, as in the previous case we obtain

$$-\frac{\partial \mathscr{E}}{\partial z} = \frac{e^2}{\pi v_0}\frac{\omega_0}{v_\sim}\int \frac{\sqrt{\varepsilon\beta^2 - 1}}{\varepsilon}\sin\left(2\frac{\omega}{\omega_0}\frac{v_\sim}{v_0}\sqrt{\varepsilon\beta^2 - 1}\right)d\omega$$

$$+\frac{e^2}{\pi v_0}\frac{\omega_0}{v_\sim}\sum_{l\neq 0}\int (-1)^l \frac{\omega(\varepsilon\beta^2 - 1)\sin\left(2\frac{\omega + l\omega_0}{\omega_0}\frac{v_\sim}{v_0}\sqrt{\frac{\omega^2}{(\omega + l\omega_0)^2}\varepsilon\beta^2 - 1}\right)}{\varepsilon(\omega + l\omega_0)\sqrt{\frac{\omega^2}{(\omega + l\omega_0)^2}\varepsilon\beta^2 - 1}}\,d\omega.$$

Hence, for strong alternating electric fields the energy loss of a charged particle is inversely proportional to the amplitude of the alternating electric field.

In conclusion we note that maximum radiation is obtained when $|k_y v_\sim|/\omega_0 \sim 1$.

We wish to thank N. L. Tsintsadze for guidance.

Contraction of the positive column of a glow discharge due to the presence of negative ions

L. A. Mikhalev and L. N. Selin

(Submitted May 29, 1973)
Zh. Tekh. Fiz., 44, 1095-1097 (May 1974)

The contracted state of the discharge in a gas containing a small addition of electronegative impurities is investigated. The ionization of the impurity atoms is neglected compared with the ionization of the atoms of the main gas. The model gives a linear relationship between the contraction radius and the radius of the tube. The results show that the contraction of the positive column increases when the density of impurities increases.

It is known from experiment that a gas discharge at medium pressure can contract. The contraction of the positive column may be due to a difference in the temperature of the electrons in the axial region and the peripheral region of the discharge,[1] and a deviation of the electron energy distribution function from a Maxwell distribution at the periphery of the positive column.[2] Another reason may be the fact that the ambipolar diffusion coefficient D_{am} and the recombination coefficient α_r of the electrons is not constant along the radius of the tube.

This point of view has been developed in ref. 3, where the contraction of the positive column of a discharge in electronegative gases is considered.

In the present note we investigate the contracted state of the discharge in a gas which contains a small addition of electronegative impurities.

Consider a plasma layer which is uniform along its length, bounded by plane walls ($x = \pm l$). The plasma is assumed to be neutral, $n_+ = n_e + n_-$, and to be in a nonequilibrium state, $\gamma = T_e/T_+ = T_e/T_- \gg 1$. Here, T_+ and T_- are the temperatures of the positive and negative ions, respectively. The ionization of the impurity atoms is neglected compared with the ionization of the atom of the main gas. The mechanism by which the negative ions are created and destroyed is assumed to be as follows: The negative ions are formed as a result of electron attachment to impurity atoms, and are lost by recombination with positive ions of the main gas and by diffusion to the walls.

With these assumptions the behavior of the particles can be described by the following set of equations:[4]

$$\frac{d}{dx}\left[D_e^a\frac{dn_e}{dx}\right]+(\nu_i-\nu_p)\,n_e=0, \tag{1}$$

$$\frac{d}{dx}\left[D_-^a\frac{dn_-}{dx}\right]+\nu_p n_e-\alpha n_+n_-=0, \tag{2}$$

where

$$D_e^a=b_+T_+\frac{1+\gamma(1+2\varepsilon)}{1+\frac{b_+}{b_e}(1+\varepsilon)+\frac{b_-}{b_e}\varepsilon},\quad D_-^a=D_e^a\frac{1}{\gamma}\frac{b_-}{b_e},\quad \varepsilon=\frac{n_-}{n_e}.$$

We have used the following notation: ν_i is the rate of impact ionization by a single electron, ν_p is the electron attachment rate, α is the ion–ion recombination coefficient, and b_e, b_+ and b_- are the mobilities of the electrons, positive ions, and negative ions respectively.

Assuming that the charges particles recombine completely at the walls, we have the boundary conditions

$$n_e|_\Sigma=n_+|_\Sigma=n_-|_\Sigma=0. \tag{3}$$

In addition, the charged particle distribution must possess axial symmetry, i.e.,

$$\left.\frac{dn_e}{dx}\right|_{x=0}=\left.\frac{dn_-}{dx}\right|_{x=0}=\left.\frac{dn_+}{dx}\right|_{x=0}=0. \tag{4}$$

In view of the fact that $T_+ = T_- \ll T_e$ the diffusion of the negative ions can be neglected. Moreover, in the expression for the diffusion coefficient D_e^a we can, without loss of generality, neglect terms proportional to b_+/b_e and b_-/b_e. This corresponds to the inequality

$$\frac{b_+}{b_e}(1+\varepsilon),\ \frac{b_-}{b_e}\varepsilon\ll 1,$$

which is satisfied even when $\varepsilon \gg 1$.

With these assumptions Eqs. (1) and (2) reduce to the following:

$$\left.\begin{aligned}&\frac{d}{dx}\left[D_e^a\frac{dn_e}{dx}\right]+(\nu_i-\nu_p)\,n_e=0,\\ &\frac{\nu_p}{\alpha n_e}=\varepsilon(\varepsilon+1),\quad D_e^a=b_+T_e(1+2\varepsilon).\end{aligned}\right\} \tag{5}$$

In the case of small ε the radial density distribution of the electrons will be close to a Schottky distribution over a large part of the plasma layer:

$$n_e=n_e(0)\cos\frac{\pi x}{2l},\quad \nu_i-\nu_p=D_e^a\left(\frac{\pi}{2l}\right)^2. \tag{6}$$

The negative ion distribution over the radius will be close to a Π-shaped distribution, $n_- = (\nu_p/\alpha)[1/(1+\varepsilon)]$. Near the walls, in the region $\delta \sim (8/3\pi)l\,[\nu_p/\alpha n_e(0)]$, the negative ion density falls to zero.

Consider the case $\varepsilon \gg 1$ over the whole cross section of the plasma layer. We introduce the following dimensionless variables:

$$y=\sqrt{\frac{n_e}{n_e(0)}},\quad \xi=x\sqrt{\frac{\nu_i-\nu_p}{b_+T_e}\sqrt{\frac{\alpha n_e(0)}{4\nu_p}}}. \tag{7}$$

Equation (5) and the boundary conditions (3) and (4) can then be written in the form

$$2\frac{d^2y}{d\xi^2}+y^2=0,\quad y(\xi(l))=0,\quad y'_\xi(0)=0. \tag{8}$$

The solution of Eq. (8) which satisfies the above boundary conditions can be expressed in terms of the elliptic integral of the first kind (see Fig. 1)

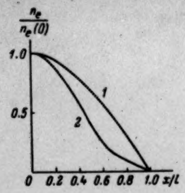

Fig. 1. $n_e/n_e(0)$ as a function of the coordinates. h: 1) 2/3; 2) 0.465.

$$\int_y^1 \frac{dz}{\sqrt{1-z^3}} = \frac{\xi}{\sqrt{3}}. \tag{9}$$

From the boundary conditions $y[\xi(l)] = 0$ we have

$$\frac{\xi(l)}{\sqrt{3}} = l\sqrt{\frac{\nu_i-\nu_p}{3b_+T_e}\sqrt{\frac{an_e(0)}{4\nu_p}}} = \frac{1}{\sqrt[4]{3}}F(\varphi,\ \sin 75°),\quad \cos\varphi = \frac{\sqrt{3}-1}{\sqrt{3}+1}. \tag{10}$$

Here, $F(\varphi, k)$ is the elliptic integral of the first kind.[5]

To estimate the degree of contraction we introduce the parameter $h = l_k/l$, which is equal to the relative half-width of the distribution over the radius. Then, for the Schottky distribution (6) the parameter h = 2/3. We obtain this parameter for the contracted state of the discharge. We have from Eq. (9)

$$\frac{\xi(l_k)}{\sqrt{3}} = l_k\sqrt{\frac{\nu_i-\nu_p}{3b_+T_e}\sqrt{\frac{an_e(0)}{4\nu_p}}} = \frac{1}{\sqrt[4]{3}}F(\varphi_k,\ \sin 75°),$$

$$\cos\varphi_k = \frac{\sqrt{3}-1+\frac{1}{\sqrt{2}}}{\sqrt{3}+1-\frac{1}{\sqrt{2}}}. \tag{11}$$

The parameter h in this case is

$$h = \frac{l_k}{l} = \frac{F(\varphi_k,\ \sin 75°)}{F(\varphi,\ \sin 75°)} = 0.465. \tag{12}$$

The contraction is due to the fact that in the region of the walls the diffusion coefficient D_e^a increases, i.e., the velocity with which the electrons drift to the walls increases.

We note also that the model considered gives a linear relationship between the contraction radius and the radius of the tube.

Current-driven instability in a conducting fluid

A. M. Kovnatskii

M. A. Bonch-Bruevich Leningrad Electrotechnical Communications Institute

(Submitted June 29, 1973)
Zh. Tekh. Fiz., 44, 1097-1098 (May 1974)

Excitation of waves in an inhomogeneous conducting fluid carrying a current in a magnetic field is analyzed. It is shown that instability arises at a critical value of the current.

1. In this paper we consider the excitation of waves in an inhomogeneous medium carrying a current in a magnetic field. It is shown that a current which is sufficiently strong can lead to the excitation of waves which propagate in the medium. The instability condition is

$$j > (ck)(kL)\frac{H_{cr}}{4\pi} \tag{1}$$

when H $\nless$ H$_{cr}$, or

$$j > (ck)\frac{kL}{4\pi}\frac{H_{cr}^2}{H} \tag{2}$$

when H > H$_{cr}$, where j is the current density, c is the velocity of light in vacuum, k is the wave vector, L is the inhomogeneity length, $L^{-1} = |\nabla\eta/\eta|$, $H_{cr} = \eta/\eta_1$ is the critical magnetic field, η and η_1 are the normal and Hall resistances.

2. The equations describing this problem consist of an expression for the electric field

$$\mathbf{E} = \eta\mathbf{j} + \eta_1[\mathbf{j},\mathbf{H}] - \frac{1}{c}[\mathbf{v},\mathbf{H}] \tag{3}$$

and the equation of magnetohydrodynamics.[1] Here, and in what follows, **v** is the hydrodynamic velocity, ρ is the density of the medium and p is the pressure.

The system of equations has been studied by the usual method[1] in the linear approximation. The approximations are as follows: 1) Only the low-frequency case is considered: $\omega \ll \sigma$, where σ is the conductivity; 2) The inhomogeneity is assumed to be weak, $kL \gg 1$; 3) The self magnetic field H_{nat} is neglected as in ref. 2.

3) Suppose that j is directed along the x axis and H along the y axis. The gradient $\nabla\eta$ and the wave vector **k** can lie along any of the axes x, y or z. Out of all the possible orientations between **j**, **H**, $\nabla\eta$ and **k**, excitation is only found for $H \le H_{cr}$ in the following cases.

a) $\nabla\eta$ and **k** are parallel to j. In this case the dispersion equation has the form

$$\omega = -\left(\frac{c^2}{4\pi}\nabla\eta k + \eta_1 cjk\right) + i\left(c\nabla\eta_1 j - \frac{c^2\eta}{4\pi}k^2\right) \tag{4}$$

and H' = H'_z or

$$\omega = (ck)(sk)^2\frac{\left[\frac{c\nabla\eta}{4\pi} + j\left(\eta_1 + 2H^2\frac{\partial\eta_1}{\partial H^2}\right)\right] + ic(sk)^2\left[\frac{ck^2\eta}{4\pi} - \nabla\eta_1 j\right]}{k^2\left(\frac{H^2}{4\pi\rho} + s^2\right)} \tag{5}$$

and H' = H'$_y$ and $\omega \ll$ sk. For the case $\omega \gg$ sk,

$$\omega = -ck\left[\frac{c\nabla\eta}{4\pi} + j\left(\eta_1 + 2H^2\frac{\partial\eta_1}{\partial H^2}\right)\right] - ic\left[\frac{ck^2\eta}{4\pi} - \nabla\eta_1 j\right]. \tag{6}$$

b) $\nabla\eta$ is parallel to the current along the x axis and **k** lies along z. The dispersion equation is now

$$\omega = -\frac{s^2k^2\left\{\left[2c\frac{\partial\eta}{\partial H^2}Hkj + \frac{c^2}{4\pi}H\nabla\eta_1 k\right] - i\left[\frac{k^2c^2}{4\pi}\eta\right]\right\}}{\left(\frac{k^2H^2}{4\pi\rho} + s^2k^2\right) + i\left(\frac{Hkj}{c\rho}\right)}. \tag{7}$$

The instability condition is shown in (1).

c) When H > H$_{cr}$ and **k** ∥ H, $\nabla\eta_1$ ∥ **j**, H ⊥ **j**, the dispersion equation has the form

$$\omega = \frac{ck^2\eta_1 H}{4\pi} + i\left[c\nabla\eta_1 j - \frac{c^2k^2}{4\pi}\eta\right], \tag{8}$$

and the instability condition is given by (2).

4. We now estimate the critical current and the frequency of the excited waves. Excitation occurs if $j \ge j_{cr}$, where

$$j_{cr} = (ck)(kL)\frac{H_{cr}}{4\pi}.$$

with c = $3 \cdot 10^{10}$ cm/sec, k = 1 cm^{-1}, kL ≈ 3, H$_{cr}$ ≃ $3 \cdot 10^4$ Oe, j$_{cr}$ ≃ $3 \cdot 10^4$ A/cm^2.

For the frequency of the excited waves: in case a) $\omega \approx \eta_1 cjk \approx kv_{dr}$, and for $j_{cr} = 3 \cdot 10^4$ A/cm^2, $v_{dr} \approx 10^2$ cm/sec, $\omega \simeq 10^2$ sec^{-1}. For case b) $\omega \simeq (c^2k^2/\sigma) \cdot (H^2/4\pi\rho s^2)kL \approx k^3$ and for the above values $\omega \simeq 10^2$ sec^{-1}. In case c) with H ≃ 10^5 Oe, $j_{cr} \simeq 10^4$ A/cm^2 and n ≃ 10^{22} cm^{-3} (liquid metal), $\omega \sim 10^{-8}$ sec^{-1}, i.e., the instability is almost aperiodic.

Convection in a liquid dielectric in a longitudinal electric field

I. V. Ioffe and N. V. Kalinin

A. F. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted October 29, 1973)
Zh. Tekh. Fiz., 44, 1099-1100 (May 1974)

It is shown that a uniform longitudinal electric field prevents convection; convection is possible only when the liquid is heated from below; in addition there is an upper limit on the critical temperature gradient in addition to the usual lower limit.

The effect of an electric field, parallel to the equilibrium-temperature gradient, on convection in a liquid dielectric has been investigated for nonconducting liquids[1,2] and conducting liquids.[2,3]

In this note we consider convection in a plane layer of a viscous incompressible liquid, situated between horizontal plates ($z = \pm h/2$). The external uniform electric field $\mathbf{E}_0$ is perpendicular to the force of gravity g, and has components $\mathbf{E}_0 = (E_0, 0, 0)$.

It is shown that the applied field prevents convection; convection is possible only when the liquid is heated from below, unlike the results obtained in refs. 1, 2. The set of equations which describes convection in the absence of conductivity, has the form[1,2]

$$\left.\begin{aligned}&\rho\left[\frac{\partial \mathbf{u}}{\partial t}+(\mathbf{u}\nabla)\,\mathbf{u}\right]=-\nabla p+\nu\rho\Delta\mathbf{u}+\mathbf{g}\rho+\mathbf{f}_e,\\&\frac{\partial T}{\partial t}+(\mathbf{u}\nabla)\,T=\chi\Delta T,\ \frac{d\rho}{\partial T}=-\beta\rho,\ \operatorname{div}\mathbf{u}=0,\\&\operatorname{div}(\varepsilon\mathbf{E})=0,\ \ \mathbf{E}=-\nabla\varphi,\ \ \varepsilon=\varepsilon\,(T,\ \rho\,(T)).\end{aligned}\right\}\qquad(1)$$

According to ref. 4

$$\mathbf{f}_e=\frac{1}{8\pi}\left\{\nabla\left[E^2\rho\left(\frac{\partial\varepsilon}{\partial\rho}\right)_T\right]-E^2\nabla\varepsilon\right\}$$

is the electrostriction force. The remaining symbols have the usual meaning.

We reduce the system (1) to dimensionless form, and obtain an equation for the temperature perturbation:

$$\left.\begin{aligned}&\left(\left(\frac{\partial}{\partial t}-\Delta\right)\left(Pr\frac{\partial}{\partial t}-\Delta\right)\Delta^2-R\left(\Delta-RN\frac{\partial^2}{\partial x^2}\right)\Delta_\perp\right)T=0,\\&\Delta_\perp=\Delta-\frac{\partial^2}{\partial z^2},\ \ Pr=\frac{\nu}{\chi},\ \ a=\left(\frac{d}{dT}\ln\varepsilon\right)_0,\end{aligned}\right\}$$

$$N=\frac{1}{4\pi}\frac{\varepsilon a^2E_0^2\chi\nu}{\rho g^2\beta^2h^4},\quad R=\frac{g\beta h^4\nabla T_0}{\nu\chi}$$

is the Rayleigh number.

Equation (2) has the solution $T \sim \exp\{i(k_x x + k_y y) - \omega t\}\,\Theta(z)$. For a layer of liquid with free boundaries (the boundary conditions with respect to z are the same as in the Rayleigh problem) $\Theta \sim \cos k_z z$, $k_z = \pi n$ (see refs. 1, 2, 5). The convection condition has the form $\mathrm{Im}(\omega) = 0$. Then $\mathrm{Re}(\omega) = 0$,

$$\left.\begin{aligned}&k^6+NR^2k_x^2k_\perp^2-\mathrm{R}\,k^2k_\perp^2=0,\\&k^2=k_x^2+k_y^2+k_z^2,\ \ k_\perp=k_x^2+k_y^2.\end{aligned}\right\}\qquad(3)$$

As can be seen from Eqs. (3), when the liquid is heated from above ($R < 0$) convection is impossible.

We write Eqs. (3) in the form

$$NR^2-\frac{1}{b}R+\frac{1}{b}R_0=0,\qquad(4)$$

$b = k_x/k^2$, $R_0 = k^6/k_\perp^2$ is the critical value of the Rayleigh number for ordinary convection.[5]

For $N = 0$, $R = R_0$. Convection is possible if

$$N\leqslant N_m=\frac{1}{4R_0b}=\frac{k_\perp^2}{k_x^2k^4}.\qquad(5)$$

It is evident from Eq. (5) that small values of N stabilize the oscillations with large k_x^2 and small k_y^2; large values of N stabilize oscillations with small k_x^2 and large k_y^2

$$R_{1,2}=\frac{1}{2Nb}\left(1\pm(1-4R_0Nb)^{1/2}\right).\qquad(6)$$

Obviously $R_{1,2} > R_0$, i.e., the applied field inhibits convection. Unlike the case $N = 0$, when the temperature gradient is greater than a certain value and convection always occurs, when $N \neq 0$ the region of instability is limited both from below and from above, $R_1 \leq R \leq R_2$. When $N = N_m$, $R_1 = R_2$ the region degenerates to a point.

The maximum value of the field for which convection occurs is of the order of 1 kV/cm for $h \approx 0.3$ cm.

Infrared nitrogen laser using a transverse discharge

V. F. Tarasenko and Yu. I. Bychkov

Institute of Atmospheric Optics, Siberian Branch, Academy of Sciences of the USSR, Tomsk

(Submitted April 23, 1973)
Zh. Tekh. Fiz., 44, 1100-1101 (May 1974)

Laser action is obtained in molecular nitrogen on the First Positive system using transverse excitation. The optimum pressure is 33 torr and the output pulse is delayed with respect to the exciting pulse by less than 10 nsec. Certain features of transverse excitation are considered.

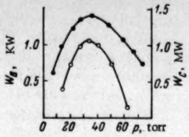

Fig. 1. Plots of output power versus pressure for First Positive (W_B) and Second Positive (W_C) systems of nitrogen.

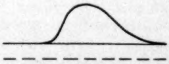

Fig. 2. Shape of output pulse for First Positive system; 8 nsec markers.

Laser action in molecular nitrogen was first obtained[1] in the infrared (0.75-1.2 μ) simultaneously on 30 lines assigned to the First Positive system of the band spectrum of nitrogen. A detailed study of the physical processes is given by Knyazev[2] along with spectral measurements. All known experiments in which laser action has been obtained on the First Positive system of nitrogen have been carried out in tubes in which an axial discharge is maintained at low gas pressures. The output power can be increased by increasing the pressure of the working gas, provided a high electric field can be maintained.

In the present work we investigate the possibility of using transverse excitation to obtain laser action on the First Positive system of nitrogen (the transition $B^3\pi_g \to A^3\Sigma_u^+$). The experimental arrangement is similar to that previously described[3] except that the characteristic impedance of the discharge circuit is 0.07 Ω. The laser chamber is 1 m long and has cross-sectional dimensions 24 × 3 mm. Figure 1 shows a plot of output power versus pressure for the lines of the First Positive system of nitrogen and, for comparison, an analogous plot obtained with the same apparatus for the Second Positive system of nitrogen (transition $C^3\pi_u \to B^3\pi_g$, wavelength λ = 3371 Å). No effort is made to optimize the resonator or the dimensions of the laser chamber. For transverse excitation the output pulse is delayed with respect to the current pulse by less than 10 nsec. There is no difficulty in obtaining laser action simultaneously in the ultraviolet and in the infrared. Figure 2 shows an oscillogram of the output pulse for laser action on the First Positive system of nitrogen. The short duration of the output pulse compared with previous results[1,2,4] is due to the transverse excitation and the high pressure of the working gas in the laser chamber. In systems with a transverse discharge a high electron temperature is maintained only during the switching period, i.e., while the current is building up in the laser chamber. Subsequently, due to the reduction of the voltage across the plasma, the electron energy becomes small and efficient excitation of the B state of molecular nitrogen ceases. The switching time for the transverse-discharge is ~ 10 nsec.

It is known[2] that the rate of change of the population of the upper working level begins to decrease sharply at a certain point as a result of deexcitation of the B state by electrons.

Let us estimate the maximum electron density commencing from which deexcitation by electron impact becomes important for pumping lengths of 10 nsec. The role of radiative decay can be neglected. Then,

$$\dot{N}_B = (N_0 - N_B) n_e \langle \sigma_{0B} v \rangle - N_B n_e \langle \sigma_{BA} v \rangle,$$

where $\langle \sigma_{EA} v \rangle$ is the average, over the electron velocity distribution, of the product of electron velocity v times the effective cross section for deexcitation by electrons of the B state to all lower-lying vibrational levels of the A state; $\langle \sigma_{0B} v \rangle$ is the average of the product of electron velocity times the effective cross section for excitation of the B state from the ground state; N_0 is the initial concentration of nitrogen molecules in the ground state; and n_e is the electron density.

For $\langle \sigma_{0B} v \rangle$ = const, $\langle \sigma_{BA} v \rangle$ = const and $n_e = at$, where a = const and t is time, we find

$$N_B = \frac{N_0 \langle \sigma_{0B} v \rangle}{\langle \sigma_{0B} v \rangle + \langle \sigma_{BA} v \rangle} \{1 - \exp[-0.5 n_e t (\langle \sigma_{0B} v \rangle + \langle \sigma_{BA} v \rangle)]\}.$$

The population of the B state is a maximum when

$$\exp[-0.5 n_e t (\langle \sigma_{0B} v \rangle + \langle \sigma_{BA} v \rangle)].$$

Then, setting $N_B = 0.95\ N_{B\,max}$, we obtain an electron density $n_e \approx 10^{16}$ cm^{-3} at which laser action is limited through deexcitation by electron impact. The values of $\langle \sigma_{0B} v \rangle$ and $\langle \sigma_{BA} v \rangle$ are taken from ref. 4. This value is to be compared with known systems of transverse-discharge excitation, when $n_e \approx 10^{15}$ cm^{-3} and less.[5]

In a nitrogen laser based on the First Positive system the output power can be increased by increasing the electron density, which can be effected by reducing the characteristic impedance of the discharge circuit.

In conclusion, transverse excitation of nitrogen can be used to obtain laser action on the First Positive system at a high optimum pressure and simultaneous laser action in the ultraviolet and the infrared.

Microwave maser with nonrelativistic electrons

A. S. Dement'ev and Yu. G. Pavlenko

M. V. Lomonosov Moscow State University

(Submitted June 18, 1973)
Zh. Tekh. Fiz., 44, 1101-1103 (May 1974)

It is shown by the methods of classical electrodynamics that nonrelativistic electrons moving in an electromagnetic field described by the vector potential A = (0, Hx, 0) and the scalar potential $\Phi = (1/2)(Ax^2 + By^2) - (1/2)(A + B)z^2$ are a source of stimulated emission in the microwave region.

Fundamental to the operation of lasers, masers, and amplifiers is the creation of an inverted population. However, the excited atom or molecule constituting the working medium in such devices delivers an energy equal to just one photon. It is well known that electrons moving in macroscopic electromagnetic fields continuously radiate electromagnetic waves. The reason, in all cases of practical interest, is that the energy of electrons performing a finite motion lies in the region of highly excited energy levels with quantum numbers $n \sim 10^5$. In radiation at submillimeter wavelengths the electron gives up an insignificant amount of energy and remains in an excited state. This has given rise to the concept of a device similar to the maser, but which utilizes electrons moving in periodic trajectories rather than excited atoms and molecules. Such devices are frequently called "electron masers" or "cyclotron-resonance masers".[1] It is also well known that the stimulated emission associated with the motion of electrons in a constant uniform magnetic field is due to relativistic effects. However, in magnetic and electrostatic fields of a certain configuration, stimulated emission occurs even at nonrelativistic electron energies.[2]

In the present work we consider the stimulated emission of nonrelativistic electrons moving in a uniform magnetic field with a vector potential A = (0, Hx, 0) and in an electrostatic field of rhombic symmetry, the potential of which is given by

$$\Phi = \frac{1}{2}(Ax^2 + By^2) - \frac{1}{2}(A + B)z^2, \quad A,\ B > 0. \tag{1}$$

Potential (1) satisfies Laplace's equation $\Delta\Phi = 0$ and can be realized by a suitable configuration of metallic surfaces.

It will be shown below that for fields attainable under laboratory conditions the frequency at which stimulated emission occurs lies in the microwave region and can be tuned by varying the fields.

As the problem is essentially classical, a purely classical approach will be used in the subsequent analysis. Accordingly, to investigate the possibility of stimulated emission we solve the set of equations

$$\left.\begin{aligned} \ddot{x} + \Omega\dot{y} - \Omega_1^2 x &= -\frac{e}{m}E_x(\mathbf{r},\ t), \\ \ddot{y} - \Omega\dot{x} - \Omega_2^2 y &= -\frac{e}{m}E_y(\mathbf{r},\ t), \\ \ddot{z} + \omega_3^2 z &= -\frac{e}{m}E_z(\mathbf{r},\ t). \end{aligned}\right\} \tag{2}$$

Here, m and e are, respectively, the mass and charge of the electron,

$$\Omega = \frac{eH}{mc}, \quad \Omega_1 = \sqrt{\frac{eA}{m}}, \quad \Omega_2 = \sqrt{\frac{eB}{m}}, \quad \omega_3 = \sqrt{\frac{e(A+B)}{m}}, \quad \Omega > \Omega_1 + \Omega_2,$$

and E(r, t) is the field of the wave being amplified.

The initial energies of the particles are assumed to be the same and the initial phases are assumed to be uncorrelated. If the solution of the equations of motion is sought as an expansion in powers of the electron position

$$\mathbf{r} = \mathbf{r}_0 + \mathbf{r}_1 + \ldots, \tag{3}$$

then the instantaneous power of the stimulated emission in the frequency range $d\omega$ and the angular interval do in the direction $\mathbf{n} = (\sin\theta\cos\varphi, \sin\theta\sin\varphi, \cos\theta)$, averaged over the initial phases of the particles and the field, is given by

$$dP^{\text{stim}} = P^{\text{stim}}(t)\frac{V\omega^2}{(2\pi c)^3}\,d\omega\, do,$$

where

$$P^{\text{stim}}(t) = eN\langle\dot{\mathbf{r}}\mathbf{E}(\mathbf{r},\ t)\rangle. \tag{4}$$

Here, N is the number of electrons per unit volume.

In zero order $\mathbf{r}_0$ satisfies a homogeneous set of equations; solving these gives

$$\left.\begin{aligned} x_0 &= R_1\cos(\omega_1 t - \delta_1) + R_2\cos(\omega_2 t - \delta_2), \\ y_0 &= a_1R_1\sin(\omega_1 t - \delta_1) + a_2R_2\sin(\omega_2 t - \delta_2), \\ z_0 &= R_3\cos(\omega_3 t - \delta_3). \end{aligned}\right\} \tag{5}$$

Here

$$\omega_{1,2} = \frac{1}{2}\left(\sqrt{\Omega^2 - (\Omega_1 - \Omega_2)^2} - \sqrt{\Omega^2 - (\Omega_1 + \Omega_2)^2}\right), \quad a_{1,2} = \frac{\omega_{1,2}^2 + \Omega_1^2}{\omega_{1,2}\Omega},$$

and R_i and δ_i are determined by the initial conditions.

It follows from (5) that bounded motion of the electrons is possible only when $\Omega > \Omega_1 + \Omega_2$. For nonrelativistic electron motion we can utilize the dipole approximation. Then, having determined $\mathbf{r}_1$ by variation of parameters, we obtain from (4) for an unpolarized incident wave

$$\begin{aligned} P^{\text{stim}}(t) = \frac{2\pi e^2 N u_{\mathbf{n}_1}(\omega)}{m(\omega_1^2 - \omega_2^2)}\Big\{&[(\omega_2^2 + \Omega_2^2)(1 - n_x^2) \\ &+ (\omega_2^2 + \Omega_1^2)(1 - n_y^2)]\frac{\sin(\omega - \omega_2)t}{\omega - \omega_2} - [(\omega_1^2 + \Omega_2^2)(1 - n_x^2) \\ &+ (\omega_1^2 + \Omega_1^2)(1 - n_y^2)]\frac{\sin(\omega - \omega_1)t}{\omega - \omega_1}\Big\} \\ &- \frac{2\pi e^2 N u_{\mathbf{n}}(\omega)}{m}(1 - n_z^2)\frac{\sin(\omega - \omega_3)t}{\omega - \omega_3}, \end{aligned} \tag{6}$$

where $u_{\mathbf{n}}(\omega)$ is the spectral-angular energy density of the external radiation. It follows from (6) that the incident electromagnetic wave is absorbed at frequencies ω_1 and ω_3 and is amplified at the frequency ω_2.

One is normally interested in the average power of the stimulated emission. If particle collisions constitute the main relaxation factor, the average power is given by[3]

$$P_{\mathrm{av}}^{\mathrm{stim}} = \int_0^\infty P^{\mathrm{stim}}(t) \frac{1}{\tau} \exp\left(-\frac{t}{\tau}\right) dt. \tag{7}$$

If $u_n(\omega)$ is nonzero only in the vicinity of the frequency ω_2, inserting (6) into (7) we have

$$P_{\mathrm{av}}^{\mathrm{stim}} = \frac{2\pi e^2 N u_n(\omega)}{m(\omega_1^2 - \omega_2^2)} [(\omega_2^2 + \Omega_2^2)(1 - \sin^2\theta \cos^2\varphi) + (\omega_2^2 + \Omega_1^2)(1 - \sin^2\theta \sin^2\varphi)] \frac{\tau}{1 + \tau^2(\omega - \omega_2)^2}. \tag{8}$$

It follows from (8) that the gain depends on the azimuthal angle φ and reaches a maximum at resonance ($\omega = \omega_2$). For a magnetic field $5 \cdot 10^4$ Oe and frequencies $\Omega_1 = 0.7\ \Omega$ and $\Omega_2 = 0.1\ \Omega$, we find from (5) that the frequency ω_2 at which amplification occurs satisfies $\omega_2 = 0.1\ \Omega$, which corresponds to a wavelength $\lambda_2 = 2\pi c/\omega_2 = 2.2$ cm. The system can thus be used as a generator of electromagnetic oscillations in the microwave region. Unlike the cyclotron resonance type of maser, which depends upon relativistic effects for its operation, the investigated quasiquantum generator has the advantage of using nonrelativistic electrons. It should be noted that only absorption of the incident electromagnetic wave can occur if the electrons move in a field (1) with A, B < 0. We mention another way of producing fields in which the incident wave can be amplified. To this end a waveguide is located in a homogeneous magnetic field directed along its axis and high-frequency oscillations are excited in it at a frequency much greater than the cyclotron frequency. In this case the electron moves along a smooth trajectory, simultaneously performing small oscillations around it. As shown by Gaponov and Miller[4] the smooth trajectory is formed by the static fields and by an additional force

$$\mathbf{F} = -\nabla U_{\mathrm{eff}}, \quad U_{\mathrm{eff}} = \frac{e^2}{2m} \left\langle \int_0^t \mathbf{E}_\sim^2(\mathbf{r}, t)\, dt \right\rangle,$$

where $\mathbf{E}_\sim$ is the intensity of the high-frequency electric field in the waveguide. It is not hard to see that for certain wave modes the "effective potential energy" U_{eff} has the necessary form. For example, for an electron moving near the axis of a circular waveguide of radius a in the field of a monochromatic H_{1n} wave we have

$$U_{\mathrm{eff}} = -\frac{e^2 |\mathbf{H}_{1n}|^2}{64 m c^2} (x^2 + 3y^2) + \mathrm{const},$$

where H_{1n} is the wave amplitude.

In conclusion we thank Professor A. A. Sokolov for his interest.

Holography of raster objects

Sh. D. Kakichashvili

Institute of Cybernetics, Academy of Sciences of the Georgian SSR, Tbilisi

(Submitted August 2, 1973)
Zh. Tekh. Fiz., 44, 1104-1106 (May 1974)

A theoretical analysis is made of the reference-free holographic recording and reconstruction of objects forming two-dimensional periodic structures composed of identical elements. The analysis is carried out in the Fraunhofer approximation and it shows that virtual and real images are reconstructed from the hologram. A further analysis based on the Fresnel approximation demonstrates the existence of series of reconstructed images formed by the same wave front at multiples of a certain distance in front of and behind the hologram.

It has been shown experimentally that objects in the form of two-dimensional periodic structures composed of identical elements of arbitrary nature can be recorded holographically without a reference wave.[1] The geometrical-optics properties of holograms obtained in this way are discussed theoretically.

If the transparency function of an individual diffracting element is $\xi(x_0, y_0, z_0)$, the transparency function $\Xi(x_0, y_0, z_0)$ of a raster object formed by two-dimensional multiplication of a single element can be written as a Fourier series of the function $\xi(x_0, y_0, z_0)$ in an interval limited by the dimensions of the raster ($x_0, y_0 \le S_0$):

$$\Xi(x_0, y_0, z_0) \approx \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} \exp i2\pi\left(\frac{n}{p_{x_0}} x_0 + \frac{m}{p_{y_0}} y_0\right) C_{n,m}. \tag{1}$$

Here, x_0 and y_0 are the coordinates in the plane of the raster object; p_{x_0} and p_{y_0} are the spatial periods along the x_0 and y_0 axes; $C_{n,m}$ are the Fourier coefficients.

We now use the Fraunhofer approximation in an analysis of the field diffracted by the structure (1). In this approximation the distance to the object located to the left of the origin can be expressed in the form

$$R(x_0, y_0, z_0) \approx -z_0 + \frac{xx_0 + yy_0}{z_0}. \tag{2}$$

In the $z = 0$ plane, where a light-sensitive film is located, the field scattered by the object is

$$\Psi(x, y, t) \approx \frac{i\varkappa}{2\pi z_0} \iint_{S_0} \Xi(x_0, y_0, z_0) \exp i[\omega t - \varkappa R(x_0, y_0, z_0, x, y)]\, dx_0 dy_0$$

$$\approx \frac{iz_0}{2\pi\varkappa} \exp i(\omega f + \varkappa z_0) \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} C_{n,m} \delta\left(\frac{2\pi n z_0}{p_{x_0}\varkappa} - x, \frac{2\pi m z_0}{p_{y_0}\varkappa} - y\right). \tag{3}$$

The light-sensitive film records $(\Psi\Psi^*)\gamma/2$. Selecting $\gamma = 1$ and assuming that $\delta[f(x, y)] = \delta^*[f(x, y)]$, we find that the subsequent illumination of the resultant hologram with a plane-front beam yields (in the same approximation)

$$\Psi'(x', y', z', t) \approx -\frac{z_0}{z'} \exp i(\omega t - \varkappa z')$$

$$\times \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} C_{n,m} \exp i\left(\frac{\varkappa x'}{z'} x + \frac{\varkappa y'}{z'} y\right)$$

$$\times \delta\left(\frac{2\pi n z_0}{p_{x_0}\varkappa} - x, \frac{2\pi m z_0}{p_{y_0}\varkappa} - y\right) \approx -\frac{z_0}{z'} \exp i(\omega t - \varkappa z')$$

$$\times \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} C_{n,m} \exp i2\pi\left(\frac{n z_0}{z' p_{x_0}} x' + \frac{m z_0}{z' p_{y_0}} y'\right), \tag{4}$$

where x', y', and z' are the coordinates of the point of observation.

For distances to the point of observation satisfying the conditions $z' = z_0$ and $z' = -z_0$, it follows from Eq. (4) that

$$\Psi_1'(x', y', z', t) \approx -\exp i(\omega t - \varkappa z_0) \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} C_{n,m} \exp i\,2\pi\left(\frac{nx'}{p_{x_0}} + \frac{my'}{p_{y_0}}\right), \tag{5}$$

$$\Psi_2'(x', y', z', t) \approx \exp i(\omega t - \varkappa z_0) \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} C_{n,m} \exp i2\pi\left(\frac{nx'}{p_{x_0}} + \frac{my'}{p_{y_0}}\right). \tag{6}$$

Therefore, Eqs. (5) and (6) describe, respectively, the virtual and real images of the original raster object, formed by the same wave front in conjugate intervals along the z axis.

We supplement the Fraunhofer analysis by a discussion of the situation in the Fresnel diffraction zone. In this zone the field scattered by objects of the type (1) has interesting singularities first discovered by Talbot[2] and investigated theoretically by Rayleigh.[3] Recently these singularities have attracted the attention of many workers.[4-8]

When a raster object is illuminated with a parallel beam of coherent light, the diffracted field is (in the approximation quadratic in the distance)

$$\Psi(x, y, t) \approx \frac{i\varkappa}{2\pi z'} \exp i\left[\omega t + \varkappa\left(z' + \frac{x'^2 + y'^2}{2z'}\right)\right]$$

$$\times \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} C_{n,m} \iint_{S_0} \exp i\left[\frac{\varkappa(x'^2 + y'^2)}{2z'} + \left(\frac{2\pi n}{p_{x_0}} - \frac{\varkappa x'}{z'}\right) x_0 \right. \tag{7}$$

$$\left. + \left(\frac{2\pi m}{p_{y_0}} - \frac{\varkappa y'}{z'}\right) y_0\right] dx_0 dy_0.$$

Evaluating the integral in the asymptotic approximation ($S_0 \to \pm\infty$), we obtain

$$\Psi(x, y, t) \approx -\exp i(\omega t + \varkappa z') \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} C_{n,m} \exp i2\pi\left(\frac{n}{p_{x_0}} x' + \frac{m}{p_{y_0}} y'\right)$$

$$\times \exp - i2\pi\left(\frac{z'\pi n^2}{p_{x_0}^2 \varkappa} + \frac{z'\pi m^2}{p_{y_0}^2 \varkappa}\right).$$

It follows from Eq. (8) that when the conditions

$$\frac{z'\pi}{p_{x_0}^2 \varkappa} = N, \quad \frac{z'\pi}{p_{y_0}^2 \varkappa} = M \tag{9}$$

are satisfied simultaneously (here, N, M = 0, ± 1, ± 2,

± 3, ...), the third exponential term in Eq. (8) becomes unity irrespective of the value of n and m and the field — with the exception of its phase term $\exp i(\varkappa^2/2\pi)(p_{x_0}^2 + p_{y_0}^2 M)$ — is identical with the field immediately behind the raster object. Obviously, the phase term is not of great significance. Distances in such a self-reproduced image of a raster object can be found by satisfying simultaneously the conditions in Eq. (9). These conditions are compatible only if $p_{x_0} = p_{y_0}$, hence it follows that the required distances must obey

$$z' = \frac{\varkappa p_{x_0}^2 N}{2\pi} + \frac{\varkappa p_{y_0}^2 M}{2\pi}, \tag{10}$$

where the values of M and N are restricted by the conditions in Eq. (9).

Since a reference-free hologram of such an object is also a periodic structure with the same period as the object itself [compare Eqs. (1) and (3)], it follows that at distances specified by Eq. (10) the hologram produces a system of images reproducing the field directly behind the hologram to within the phase factor and also a system of reconstructed images shifted relative to the hologram by the amounts

$$\left.\begin{aligned} z'_{N,M} &= \left(z_0 - \frac{\varkappa p_{x_0}^2 N}{2\pi}\right) + \left(z_0 - \frac{\varkappa p_{y_0}^2 M}{2\pi}\right), \\ z'_{N,M} &= -\left(z_0 - \frac{\varkappa p_{x_0}^2 N}{2\pi}\right) - \left(z_0 - \frac{\varkappa p_{y_0}^2 M}{2\pi}\right) \end{aligned}\right\} \tag{11}$$

respectively, for virtual and real images.

Figure 1 shows schematically a hologram Q, a reconstructed virtual image of a raster object R_1, a reconstructed real image of the object R'_1, a self-reproduced virtual image of the hologram Q_1, a self-reproduced real image of the hologram Q'_1, a reconstructed virtual image of the object R_ν and a self-reproduced virtual image of the hologram Q_ν (ν is the serial number of the image), and a reconstructed real image of the object R'_ν and a self-reproduced real image of the hologram Q'_ν.

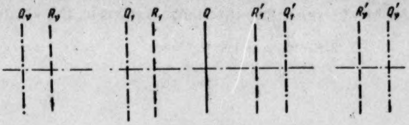

Fig. 1

A reference-free method can also be used in the holographic recording of a coherently emitting object with a spatially restricted spectrum when the formation of a reference wave is for some reason impossible. In this case the beam diffracted by an object must be multiplied by an optical device (see, for example, refs. 7 and 8) which divides the amplitude into a large number of identical spatially periodic cophasal beams of equal amplitudes. Obviously, the total field of such a system of multiplied beams is equivalent to the total field of the light diffracted by the raster object. If the resultant pattern is recorded in a light-sensitive film, the subsequent illumination of this film can be used to reconstruct a multiplied wave front, i.e., a system of multiplied images of the object. Depending on the requirements we can use one of the reconstructed images or we can pass the reconstructed front again through a multiplication system which then synthesizes in the reverse direction the original image of a single object.

NÉM–1T magnetic-discharge pumps in the vacuum system of the I-100 linear accelerator

O. N. Krokhina and K. G. Mirzoev

(Submitted July 16, 1973)
Zh. Tekh. Fiz., 44, 1106-1108 (May 1974)

The characteristics of NÉM-1T titanium pumps after prolonged use in the cavities of a linear accelerator are described. The effective sputtering ratio of the titanium in the cell of the electric-discharge pump is determined from measurements of craters on the cathode plates. Experience gained in the use of these pumps in the linear accelerator is used to determine the failure time, the time over which the vacuum system operates stably at a pressure of (0.5-1)·10^{-6} torr, and the useful lifetime of the pumps under these conditions.

Since magnetic-discharge pumps are increasing in popularity for physical-research apparatus, it is of interest to study the characteristics of these pumps after prolonged operation in the I-100 linear proton accelerator.[1]

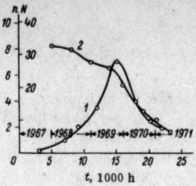

Fig. 1. 1) Number of instances n per 1000 h, in which the cavity pressure surged as a function of the time; 2) number of pumps N which had not been reassembled.

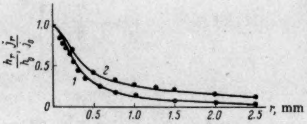

Fig. 2. 1) Characteristic crater profile; 2) distribution of the ion current density with respect to the cathode radius, from ref. 2.

The cavities of the accelerator, with a total volume of 100 m^3, are evacuated by NÉM-1T magnetic-discharge pumps (33 of them) at a pumping rate of 1000 liter/sec at the entrance flange at a pressure of $1 \cdot 10^{-6}$ torr. The basic components in the mass spectrum of the residual gas, measured by an IPDO-1 apparatus at a cavity pressure of (3-5)·10^{-7} torr, are H_2 (36%), N_2 + CO (30%), O_2 (4%), Ar (9%), H_2O (8%), and hydrocarbons (3%).

Most of the pumps operated in the accelerator for an average of 30,000 h, and some operated as long as 35,000 h, without replacement. The pumps operated continuously for 1000-1500 h per cycle. Some of the pumps failed during operation, and the failures were corrected by removing the pumps from the accelerator and reassembling them. A total of 29 pumps were reassembled at various times and tested. A typical cause of failure after prolonged operation is a short circuit in the electrod units due to metallization and splitting of the insulators or as a result of the peeling of films from the electrodes. The average operating time before failure is 8000-9000 h.

The pumps are restored to service by mechanically removing the films from the electrodes and the housing and by replacing the ceramic insulators or cleaning them, by etching in a dilute solution of hydrofluoric acid. After reassembly, the pumps are processed in a vacuum station at 400°C. Measurements of the pumping rate and the limiting vacuum for one of the pumps after 12,000 h of operation in the accelerator without reassembly show that these values are the same as those measured before the pump is installed in the accelerator.

There were several occasions on which the cavity pressure surged sharply for 3-5 min, from $5 \cdot 10^{-7}$ to (0.5-1)·10^{-4} torr, and then returned to its initial value over 25-30 min. The reason could be a brief breakdown in one of the pumps because a titanium film is peeled from the anode, and gas is evolved from this film as it burns. This gas evolution would raise the pressure in the pump and the discharge current, so the absorbed gas, including argon, would be evolved from the cathodes, and the pumping rate would fall off sharply. In some cases so much gas was evolved that the pressure increased throughout the cavity volume, leading to an increase in the discharge current in the other pumps and thus the evolution of gas from them. Because of the large number of pumps and the large cavity volume, the pressure does not exceed $1 \cdot 10^{-4}$ torr; although the pumping rate of the pumps fell off markedly, it remained sufficient to pump out the evolved gas. In some of the pumps an argon instability was observed in the pressure range (1-5)·10^{-5} torr. Figure 1 (curve 1) shows the number of instances of pressure increases per 1000 h of operation as a function of the average operating time of the pumps which had not been reassembled; the number of such pumps is shown by curve 2. Figure 1 shows that essentially no pressure surges are observed before the pumps operate for about 8000 h. Thereafter, the number of surges increases rapidly, and by the end of 1970, when most of the pumps had been cleaned and reassembled, the number of surges was falling approximately in proportion to the number of pumps which had not been cleaned. This behavior shows that the pressure surges in the cavities are initiated by pumps which have been operating for more than 8000-9000 h.

Accordingly, a periodic cleaning of the magnetic-discharge pumps at intervals of 8000-9000 h, for operation at (0.5-1)·10^{-6} torr, can ensure stable operation of the vacuum system.

Since the cathode plates determine the useful lifetime of the pumps, we have studied the craters formed as a result of titanium sputtering. During the reassembly of several pumps, we measure the depths of the craters within ± 0.01 mm at each point. Figure 2 shows the ratio of the crater depth at each point to the depth at the center, h_r/h_0, as a function of the crater radius r (curve 1). Curve 2 shows the distribution of the ion current density j_r/j_0 over the cathode radius,[2] obtained under approximately the same operating conditions. Comparison of these two curves shows that the shape of the craters is related to the ion current distribution; the shape should also be affected by the sputtering of titanium from the opposite cathode and by the incidence angle of the ions, which obviously vary as the shape of the crater changes.

We calculate the amount of sputtered titanium by calculating the crater volumes. Averaging over 10 cells of each of 10 pumps, we find the average rate of titanium sputtering from a single cathode of a cell to be (2 ± 0.5) × 10^{-7} g/h at a cavity pressure of $1 \cdot 10^{-6}$ torr. For each of these pumps we calculate the average pressure in the volume being evacuated over the entire operating history of the pump, and we experimentally determine the functional dependence of the discharge current on the pressure, from which we are able to determine the average ion current to a cathode of the cell within ± 30%. From these results we calculate the effective sputtering ratio for the titanium in a cell of the pump: 0.15 ± 0.04 atom/ion. On the basis of this sputtering ratio, we calculate that several decades would be required for an aperture to grow all the way through a cathode plate 2 mm thick at a pressure of $1 \cdot 10^{6}$ torr.

The authors thank V. G. Rogozinskii for discussion, S. A. Il'evskii for his constant interest in this work, and V. A. Butenko for carrying out the measurements.

Method for studying gas creep along a solid surface

B. M. Markeev

Institute of Problems of Mechanics,
Academy of Sciences of the USSR, Moscow

(Submitted September 24, 1973)
Zh. Tekh. Fiz., 44, 1108-1110 (May 1974)

Many authors have reported on the creep of a gas along a surface (see, e.g., refs. 1-7). Several assumptions have usually been used, but it has been shown[7] that these assumptions, in particular, lead to a discontinuity of the distribution function far from the wall when this function is calculated by the method of half-space moments: a physically meaningless result. Furthermore, the calculation difficulties which arise in the use of this method lead to a situation in which it is possible to analyze creep only of a Maxwellian gas or of a gas whose molecules have a hard-sphere interaction.

In this note we analyze the creep of a gas in a temperature gradient tangential to an infinite wall and in the absence of a gradient, calculating the creep velocities. We make no assumptions regarding the nature of the interaction between gas particles. We seek the particle distribution functions as series expansions in Hermite–Chebyshev polynomials, and we incorporate the boundary conditions into the right-hand side of the kinetic equation by means of sources concentrated at the boundary. The gas molecules in the Knudsen layer at distances on the order of a mean free path from the wall can have a discontinuous distribution function different from the volume function. However, this circumstance is not taken into account in an analysis of the problem on the basis of the moment equations.[3] The method proposed here can be used to take into account the discontinuity of the distribution function in the Knudsen layer.

1. We consider a gas in a temperature gradient tangential to the wall. The origin of our coordinate system is at the surface, the x axis is along the normal to the surface, and the z axis is along the surface. Under the conditions of steady-state flow the distribution function can be determined from a kinetic equation in which the boundary conditions are introduced into the right-hand side in the form of concentrated sources:[8]

$$(\mathbf{v}\nabla) f = J + v_x f(x=0)\,\delta(x), \tag{1.1}$$

where $J = \int d\mathbf{v}_1 d\Omega\sigma(w,\vartheta)\{f'f_1' - ff_1\}w$ is the elastic-collision integral, $\mathbf{w} = \mathbf{v} - \mathbf{v}_1$ is the relative velocity of the colliding particles, ϑ is the scattering angle, $\sigma(w,\vartheta)$ is the differential scattering cross section, and $\delta(x)$ is the Dirac δ function. In the usual manner,[1] we distinguish between molecules moving toward the surface and those moving away from it, i.e., we have $f(\mathbf{v}, \mathbf{r}) = f^+(\mathbf{v}, \mathbf{r})$ for $v_x > 0$ and $f(\mathbf{v}, \mathbf{r}) = f^-(\mathbf{v}, \mathbf{r})$ for $v_x < 0$. We write distribution functions $f^\pm$ over their ranges of definition as series in Hermite–Chebyshev polynomials:

$$f^\pm(\mathbf{v}, \mathbf{r}) = \frac{n}{\pi^{3/2} v_T^3}\exp\left\{-\frac{(v-u_{\pm z})^2}{v_T^2}\right\}\left\{1 - 2\frac{\sigma_{\pm xz}}{2nT}\frac{m}{T}(v-u_\pm)_z v_x - \frac{q_z(v-u_\pm)_z m}{nT}\left[1 - \frac{m(\mathbf{v}-\mathbf{u}_\pm)^2}{5T}\right]\right\}, \tag{1.2}$$

where n is the density, m is the mass, T is the temperature (in energy units), u_z is the average velocity, and q_z is the heat flux. Using the theory of integrals which are functions of parameters,[8] we write the equations for u_z, σ_{xz}, and q_z as follows:

$$\nabla_x \frac{1}{2}(\sigma_+ + \sigma_-)_{xz} = \frac{1}{2}(\sigma_+ + \sigma_-)_{0xz}\,\delta(x), \tag{1.3}$$

$$\mu\nabla_x \frac{1}{2}(u_+ + u_-)_z = \frac{1}{2}(\sigma_+ + \sigma_-)_{xz} + \left[\mu\frac{1}{2}(u_+ + u_-)_{0z} - \frac{2}{5}\nu_1^{-1}\frac{1}{2}(q_+ + q_-)_{0z}\right]\delta(x), \tag{1.4}$$

$$\frac{1}{2}(q_+ + q_-)_z = -\eta\nabla_z T; \tag{1.5}$$

$$\nabla_x \frac{1}{2}(\sigma_+ - \sigma_-)_{xz} = \nu_2 nm\frac{1}{2}(u_+ - u_-)_z + \left(\frac{\nu_3}{v_T^2}\right)\frac{1}{2}(q_+ - q_-)_z + \frac{1}{2}(\sigma_+ - \sigma_-)_{0xz}\,\delta(x), \tag{1.6}$$

$$\frac{2}{5}\nabla_x \frac{1}{2}(q_+ - q_-)_z + nT\nabla_x\frac{1}{2}(u_+ - u_-)_z = \frac{1}{2}(\sigma_+ - \sigma_-)_{xz}\nu_4 + \left(\frac{2}{5}\right)\frac{1}{2}(q_+ - q_-)_{0z}\,\delta(x) + nT\,\frac{1}{2}(u_+ - u_-)_{0z}\,\delta(x), \tag{1.7}$$

$$\frac{T}{m}\nabla_x \frac{1}{2}(\sigma_+ - \sigma_-)_{xz} = \frac{1}{2}nmv_T^2\nu_5\frac{1}{2}(u_+ - u_-)_z + \nu_6\frac{1}{2}(q_+ - q_-)_z + \frac{T}{m}\frac{1}{2}(\sigma_+ - \sigma_-)_{0xz}\,\delta(x). \tag{1.8}$$

The quantities μ, η, ν_1, ν_2, . . . , ν_7 are defined by

$$\left.\begin{aligned}
&\eta = \frac{5}{2}\frac{nT}{m\nu_7};\quad \mu = \frac{nT}{\nu_1};\quad \nu_1 = \frac{3}{10}\Omega^{(2,2)};\\
&\nu_2 = (\Omega^{(1,1)} + 2\tilde{\Omega}^{(1,1)});\quad \nu_3 = -(3\tilde{\Omega}^{(0,0)} - 2\tilde{\Omega}^{(0,1)})\\
&\quad - \left[(\Omega^{(1,1)} + 2\tilde{\Omega}^{(1,1)}) - \frac{2}{5}(\Omega^{(1,2)} + 2\tilde{\Omega}^{(1,2)})\right];\\
&\nu_4 = \left(\frac{3}{4}\tilde{\Omega}^{(0,0)} - \frac{1}{10}\tilde{\Omega}^{(0,2)}\right)\\
&\quad + \frac{1}{2}\left[(\Omega^{(1,1)} + 2\tilde{\Omega}^{(1,1)}) + \frac{3}{10}(\Omega^{(2,2)} + \tilde{\Omega}^{(2,2)})\right];\\
&\nu_5 = \frac{1}{2}\left[\frac{5}{2}(\Omega^{(1,1)} + 2\tilde{\Omega}^{(1,1)}) + (\Omega^{(1,2)} + 2\tilde{\Omega}^{(1,2)})\right];\\
&\nu_6 = -\frac{1}{8}\Omega^{(1,1)} - \frac{1}{5}\Omega^{(2,2)} - \frac{5}{2}\frac{\nu_3}{2};\quad \nu_7 = \frac{2}{5}\Omega^{(2,2)}.
\end{aligned}\right\} \tag{1.9}$$

Here

$$\Omega^{(l,s)} = (8\sqrt{2}/3\sqrt{\pi})\,nv_T\int dg\,d\Omega\sigma(w,\vartheta)(1\quad\cos^l\vartheta)\,g^{2s+3}e^{-g^2},$$

$$\tilde{\Omega}^{(l,s)} = (4\sqrt{2}/3\sqrt{\pi})\,nv_T\int dg\,d\Omega\sigma(w,\vartheta)\cos^l\vartheta\,g^{2s+3}e^{-g^2}.$$

2. We assume that a steady state characterized by a thermal creep velocity and an isothermal creep velocity of the gas with respect to the surface, u_T and u_{cr}, respectively, and by a gradient in the average velocity, $(\nabla_x u)_\infty$, is established in the volume; then we find the following solution for this system of equations

$$\frac{1}{2}(u_+ + u_-)_s = u_\tau + u_{\text{cr}} + (\nabla_x u)_\infty x, \tag{2.1}$$

$$\frac{1}{2}(\sigma_+ + \sigma_-)_{xs} = \mu\nabla_x \frac{1}{2}(u_+ + u_-)_s, \tag{2.2}$$

$$\frac{1}{2}(q_+ + q_-)_s = -\eta\nabla_s T, \tag{2.3}$$

$$\frac{1}{2}(u_+ - u_-)_s = \frac{1}{2}(u_+ - u_-)_{0s} \exp\left\{-\frac{x}{\lambda}\right\}, \tag{2.4}$$

$$\frac{1}{2}(\sigma_+ - \sigma_-)_{xs} = \mu_1\nabla_x \frac{1}{2}(u_+ - u_-)_s, \tag{2.5}$$

$$\frac{1}{2}(q_+ - q_-)_s = -nTS\,\frac{1}{2}(u_+ - u_-)_s, \tag{2.6}$$

where

$$\mu_1 = \frac{nT}{\nu_4}\left[1 - \frac{2}{5}S\right];\ \lambda^{-2} = \frac{nm}{\mu_1}\left[\nu_2 - \frac{1}{2}\nu_3 S\right],$$

$$S = \frac{\nu_5 - \nu_2}{\nu_6 - \frac{1}{2}\nu_3};\quad (\nabla_x u)_\infty = \mu^{-1}\frac{1}{2}(\sigma_+ + \sigma_-)_0,$$

$$u_\tau = \frac{2}{5}\frac{\eta}{\mu\nu_1} = \frac{3}{4}\frac{\mu}{\rho}\nabla \ln T,$$

$$u_{\text{cr}} = (\nu_1\mu)^{-1}\left[\left(\frac{2}{5}\right)\frac{1}{2}(q_+ + q_-)_{0s} + nT\,\frac{1}{2}(u_+ + u_-)_{0s}\right]. \tag{2.7}$$

When $(\nabla_x u)_\infty = u_{\text{cr}} = 0$, Eq. (2.1) takes the simple form

$$(1/2)(u_+ + u_-) = u_\tau. \tag{2.8}$$

Equations (2.4)-(2.6) vanish identically for partial reflection of molecules from the surface. Accordingly, an inhomogeneously heated gas moves along a surface at an average thermal creep velocity $u = u_T$, which is not a function of the distance from the wall. When $(\nabla_x u)_\infty \neq 0$, the creep velocity of the gas, as we see from (2.1)-(2.6), is the sum of the thermal and isothermal creep velocities. The latter, as follows directly from (2.4), is given by the following equation for the case of partial reflection of the molecules from the wall:

$$(\varepsilon/(2-\varepsilon))^2 u_{\text{cr}} = (\nu_4/\nu_1)\,\lambda\,(\nabla_x u)_\infty, \tag{2.9}$$

where ε is the accommodation coefficient. The creep coefficient determined from this equation for the particular case of Maxwell molecules is 1.06, in good agreement with the results, e.g., of ref. 7.

In conclusion we note that the method proposed here has two advantages over that of ref. 2: First, it can be used to analyze creep along a surface by a gas having an arbitrary intermolecular interaction, and the discontinuity of the distribution function near the surface can be taken into account simultaneously. Second, this method does not lead to such physical contradictions as a discontinuity in the distribution function far from the surface.[7]

The author thanks S. P. Bakanov for discussion.

X-ray fluorescence of oxygen in H_2O

L. A. Smirnov

A. A. Zhdanov Leningrad State University

(Submitted April 4, 1973)
Zh. Tekh. Fiz., 44, 1110-1111 (May 1974)

The ratio of the x-ray fluorescence yields in H_2O and O_2 is found; the value of $\omega_K(H_2O)$ is larger than $\omega_K(O_2)$ by a factor of 1.8 ± 0.2. In addition the absolute values of ω_K for oxygen in O_2, CO_2, and H_2O are evaluated: These are 0.0073, 0.0094, and 0.0131 respectively. The maximum error in the determinations is estimated to be 30%.

We have reported previously[1] that the x-ray fluorescence yield of oxygen in CO_2 is 1.3 times that in O_2. We have now used the same procedure to compare these yields in H_2O and O_2. Since the room-temperature density of water vapor is extremely low, the x-ray fluorescence of oxygen is correspondingly extremely weak, amounting to only one third the background intensity. We have therefore carried out about a hundred measurements, to whose results we are able to apply statistical methods to obtain accurate ratios. We find the x-ray fluorescence yield of oxygen in H_2O to be 1.8 ± 0.2 times that in O_2; accordingly, the effect of the chemical binding on the value of ω_K for a light element can be extremely important. Hence, in reporting measurements of ω_K it is mandatory to state the chemical compound in which the element in question is studied.

Altering the experimental procedure slightly, we also determine the absolute values of ω_K for oxygen in H_2O, CO_2, and O_2. Holding constant the parameters of the x-ray tube producing the primary beam, we fill the chamber of the apparatus with oxygen (O_2) and chlorine (as CCl_4) alternately. Measuring the count rates for the x-ray fluorescence of oxygen and chlorine, we are able to find the ratio of the corresponding x-ray fluorescence yields from the obvious relation

$$\frac{N_{Cl}}{N_O}=\frac{n_{Cl}}{n_O}\frac{\omega_K(Cl)}{\omega_K(O_2)}\frac{Q_{Cl}}{Q_O}.$$

Here N_{Cl} and N_O are the count rates for the x-ray fluorescence of chlorine and oxygen, respectively, n_{Cl} and n_O are the numbers of K vacancies produced by the primary radiation per unit time, and Q_{Cl} and Q_O are coefficients which take into account the absorption of the x-ray fluorescence and the efficiency with which it is detected. The coefficients n_{Cl}, n_O, Q_{Cl}, and Q_O are calculated from the dimensions of the apparatus and tabulated absorption coefficients. Then assuming $\omega_K(Cl)$ to be 0.091, according to ref. 2, we find, for oxygen,

$$\omega_K(O_2)=0.0073,$$
$$\omega_K(CO_2)=0.0094,$$
$$\omega_K(H_2O)=0.0131.$$

These results agree with McGuire's calculations[3] for atomic oxygen ($\omega_K = 0.0095$) and with the curve of ref. 4, extrapolated to the light elements. On the other hand, these results are much higher than the data reported in ref. 5; the discrepancy exceeds the maximum possible errors, which can be estimated to be 30% for our data.

Dispersion of the dielectric constant of crystalline KH_2PO_4 near the "soft" mode frequency

V. V. Meriakri, Yu. M. Poplavko, and E. F. Ushatkin

Institute of Radio Engineering and Electronics, Academy of Sciences of the USSR, Moscow

(Submitted June 18, 1973; resubmitted November 16, 1973)
Zh. Tekh. Fiz., 44, 1111-1113 (May 1974)

The dielectric properties of potassium dihydrophosphate are investigated at frequencies 0.3-15 cm^{-1} in the temperature range 80-300°K. The parameters of a dispersion oscillator which describe the dispersion of the dielectric constant of KH_2PO_4 in the paraelectric phase are determined.

Although potassium dihydrophosphate is one of the most studied ferroelectrics, direct measurements of the dispersion of the dielectric constant ε in the vicinity of the Curie point of this crystal have not been performed. The point is that the dispersion of ε in the nonpolar phase of KH_2PO_4 occurs at submillimeter wavelengths, midway between the microwave and infrared regions of the spectrum, and the technology of dielectric measurements of ferroelectrics at such wavelengths is still in the developmental stage.[1]

Investigation of the dispersion of ε near the phase transition is important in connection with the modern dynamical theory of ferroelectricity, which is based on the concept of a "soft" mode of vibration of the crystal lattice. In principle, the vibrational spectra of ferroelectric crystals, from which the character of the temperature dependence of the critical vibration frequency in the vicinity of the phase transition can be determined, can be studied in various ways. In the case of the KH_2PO_4 crystal, however, the damping of the coupled tunnel-phonon vibration (which plays the role of the "soft" mode) proves to be extremely large, precluding observation of a maximum in the scattered light[3,4] as well as in infrared reflection spectra.[5] All these methods only yield an estimate of the frequency and damping of the "soft" model. Accordingly, great importance attaches in crystals of KH_2PO_4 type to direct dielectric measurements in the region of dispersion of ε in a temperature range including the phase transition.

The frequency dependence of the complex dielectric constant of potassium dihydrophosphate along the fourfold axis, $\varepsilon_3 = \varepsilon'_3 - i\varepsilon''_3$, has previously been investigated in the microwave region.[6,7] It was found that in the nonpolar phase ε_3 exhibits no dispersion up to 30 GHz (1 cm^{-1}), although the dielectric losses are observed[7] to increase significantly as the Curie point is approached at millimeter wavelengths, indicating that the dispersion region is not far off. A study of the infrared reflection spectra of KH_2PO_4 crystals[5] has disclosed a low-frequency maximum of ε''_3 at a frequency of 46 cm^{-1} at 300°K, and at 30 cm^{-1} at 200°K. From a comparison of the microwave and infrared data one can expect the dispersion of ε_3 in KH_2PO_4 to occur near the critical temperature in the submillimeter waveband.

The temperature dependence of the transmittance and the reflectivity is measured at submillimeter wavelengths on the apparatus described in ref. 1. The investigated crystal samples are 0.15-0.3 mm thick and 3 cm^2 in area. The error in the measurement of the real and imaginary parts of the dielectric constant at frequencies 7-15 cm^{-1} does not exceed 10%. Microwave experiments are performed in waveguides by the usual method.[7]

Figure 1 shows the temperature variation of ε'_3 and ε''_3 of potassium dihydrophosphate at various frequencies. The temperature variation of ε'_3 at 1 kHz characterizes the properties of the free crystal and is described by the Curie–Weiss law

$$\varepsilon'_3 = \varepsilon'_\infty + C'(T - T_C)^{-1}$$

with parameters C' = 3000°, ε'_∞ = 5.5 and T_C = 123°K. Microwave measurements at 0.3 and 0.8 cm^{-1} yield the parameters describing $\varepsilon'_3(T)$ for a fixed crystal (KH_2PO_4 is piezoelectric above T_C): C = 2600° and Θ = 118°K. The maximum value of $\varepsilon'_3(T)$ at T = T_C reaches 550 ± 30 at microwave frequencies.[7] The onset of dispersion is observed at millimeter wavelengths (2.6 cm^{-1} in the figure). This dispersion is sharply expressed in the submillimeter range: At frequencies 11.3 and 14.6 cm^{-1} the sharp peak in the vicinity of the phase transition is replaced by shallow minima of $\varepsilon'_3(T)$; flat maxima of $\varepsilon'_3(T)$ occur at 170 and 210°K, respectively. Sharp maxima of $\varepsilon'_3(T)$ are conserved only in the ferroelectric phase, where the dispersion frequency of ε_3 is higher than in the nonpolar phase; accordingly, the value of ε'_3 near T_C in the ferroelectric phase is decreased much less than in the paraelectric phase.

The qualitative behavior of the dispersion of $\varepsilon_3(\nu, T)$ in the investigated crystals above T_C = 123°C can be described using a model of a dispersion oscillator with frequency ν_0 and damping γ:

$$\varepsilon_3(\nu, T) = \varepsilon_\infty + \frac{C\nu_0^2}{(T - \Theta)(\nu_0^2 - \nu^2 + i2\gamma\nu)},$$

where $\nu_0 = a(T - \Theta/T)^{1/2}$, in accordance with the dynamical theory of ferroelectricity, which is applicable to KH_2PO_4

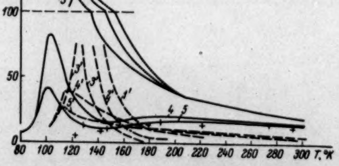

Fig. 1. Plots of ε'_3 (solid curves) and ε''_3 (dashed curves) versus temperature for various frequencies ν, cm^{-1}: 1) $3.3\cdot10^{-7}$ (1 GHz); 2) 0.3; 3) 2.6; 4) 11.3; 5) 14.6. The points denoted by + correspond to calculated values of ε'_3 for a = 85 cm^{-1}, γ = 100 cm^{-1}, ν = 14.6 cm^{-1}.

crystals.[3,8] Far from the Curie point ($T > T_C + 25°$) Eq. (1) gives a good description of the family of curves of the figure for $a = 85$ cm^{-1}, $\gamma = 100$ cm^{-1}, C and Θ as determined above, and $\varepsilon_\infty = 4.5$. Near T_C at submillimeter wavelengths there is a considerable discrepancy between the experimental and calculated data.

The authors are grateful to I. S. Rez and V. G. Vaks for discussion and to V. N. Aleshechkin and A. N. Pashkov for their assistance in preparing the samples.

Formation of molecular ions in an alkali discharge

V. N. Paslen and A. M. Przhonskii

T. G. Shevchenko Kiev State University

(Submitted April 25, 1973)
Zh. Tekh. Fiz., 44, 1113-1115 (May 1974)

The ionic composition of a potassium discharge is measured in the range $p = 7 \cdot 10^{-3}$-$6 \cdot 10^{-2}$ mm Hg and $n_e = 10^9$-10^{11} cm^{-3}. It is shown that the main mechanism for the formation of K_2^+ ions is associative ionization: $2K^*(4P) \rightarrow K_2^+ + e$. The effective cross section for the reaction $q \approx 3 \cdot 10^{-16}$ cm^2.

The results of a mass-spectrometer analysis of the ion composition of a potassium discharge were used in a previous paper[1] to show that at pressures $p \geqslant 0.1$ mm Hg and densities $n_e > 10^{10}$ cm^{-3}, K_2^+ molecular ions are formed mainly as a result of binary ion–molecule collisions of the form

$$K^+ + K_2 \rightarrow K_2^+ + K. \qquad (1)$$

In the present work we present the results of a similar investigation performed at lower pressures $p = 7 \cdot 10^{-3}$-$6 \cdot 10^{-2}$ mm Hg in the density range $n_e = 10^9$-10^{11} cm^{-3} (where increasing n_e causes the electron temperature T_e to decrease monotonically from 10,000 to 4000°K). For these values of p and n_e the recombination of both atomic and diatomic ions takes place mainly at the wall following ambipolar diffusion.

Curves of the ratio J_2/J_1 measured at the mass-spectrometer output (and proportional to the ratio n_2/n_1 of the densities of K_2^+ and K^+ ions in the plasma) as a function of n_e are shown in Fig. 1 for various pressures. Evidently, a) increasing p leads to a growth of n_2/n_1, the growth slowing down significantly for $p > 0.03$ mm Hg; b) increasing n_e reduces n_2/n_1, although the density of diatomic ions n_2 is not decreased, but increases (curve 5'). The latter feature means that at higher n_e the efficiency for the formation of K^+ atomic ions (electron impact ionization) exceeds that of K_2^+ molecular ions.

From a consideration of the balance equation[1] it follows that the above features cannot be explained on the basis of the aforementioned reaction (1). Under the present conditions the governing mechanism for the formation of K_2^+ ions in the plasma appears to be the so-called associative ionization process, with participation of excited atoms. The following reaction of associative ionization is known[2] to be possible in potassium vapor:

$$K + K^{**} \rightarrow K_2^+ + e; \qquad (2)$$

where K is an atom in the ground state and K^{**} is an atom excited to a level no lower than 6P ($\varepsilon^{**} \geq 3.6$ eV). As in cesium vapor,[3,4] another possibility is ionization through the interaction of two potassium atoms excited to the first resonance level:

$$K^* + K^* \rightarrow K_2^+ + e. \qquad (3)$$

Investigations in cesium vapor[5] show that the effective cross section of a reaction of type (3) is about one and a half orders greater than for a reaction of type (2). Estimates made on this basis show that reaction (2) has a negligible effect compared with reaction (3). The balance equation between the rates of formation and disappearance of ions in the plasma must accordingly have the form

$$\frac{1}{2} q u_a n_a^{*2} = \frac{2}{R} \frac{j_{2W}}{e}.$$

In this equation q is the effective cross section of reaction (3), u_a is the mean relative velocity of atoms, n_a^* is the density of potassium atoms in the 4P resonance level, j_{2W} is the diffusion current density of diatomic ions to the side wall (the values of j_{2W} are found from the independently measured values of the total ion current density to the wall $j_W = j_{1W} + j_{2W}$ and $j_{2W}/j_{1W} \approx 1/\sqrt{2}(J_2/J_1)$ [see ref. 1]).

To analyze the balance equation the reversal temperature of the resonance line of potassium is used to determine the values of $n_a^*(4P)$ for the same discharge current $I = 20$ mA at different pressures p (Fig. 2). The curves are correlated; the peaks coincide in the region $p = 0.03$ mm Hg. Further, the data of Fig. 2 imply that $q = 3 \cdot 10^{-16}$ cm^2, which is very close to the effective cross section of the corresponding reaction in cesium vapor[5]

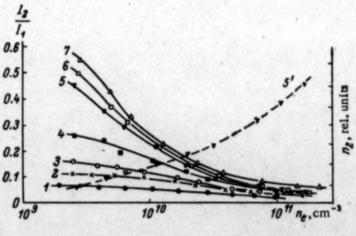

Fig. 1. Vapor pressure p (mm Hg): 1) 0.007; 2) 0.01; 3) 0.015; 4) 0.02; 5) 0.03; 6) 0.04; 7) 0.06; 5' shows n_2 as a function of n_e for p = 0.03 mm Hg.

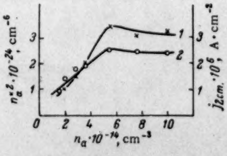

Fig. 2. 1) Graph of $n_a^{*2} = f(n_a)$; 2) graph of $j_{2W} = f(n_a)$. Curves obtained under the same conditions.

($1.1 \cdot 10^{-15}$ cm^2). All this speaks in favor of reaction (3).

We note finally that analogous measurements at pressures $p \sim 0.01$ mm Hg in a cesium plasma lead to a value $q \approx 1.5 \cdot 10^{-15}$ cm^2, which is almost the same as the value measured in ref. 5.

Thus, the formation of diatomic ions in discharge potassium and cesium plasmas in the investigated regimes proceeds mainly through reactions (1) and (3), the latter predominating at low pressures (0.01-0.05 mm Hg) and the former at elevated pressures ($p \geqslant 10^{-1}$ mm Hg).

In conclusion we thank N. D. Morgulis for guidance and A. I. Kravchenko for performing the optical measurements.

Current density of thermionic-field emission into a plasma at moderate fields

I. N. Ostretsov, V. A. Petrosov, A. A. Porotnikov, and B. B. Rodnevich

(Submitted April 20, 1973)
Zh. Tekh. Fiz., 44, 1115-1117 (May 1974)

An analysis is made of the effect on thermionic-field emission at moderate fields of the individual fields of ions which form a nonneutralized space charge near the cathode. An analytic expression is obtained for the electron current density. Taking account of the discrete nature of the charge can increase the emission current significantly.

Guth and Mullin[1,2] have derived approximate analytic expressions for the current density of thermionic-field (T–F) emission into vacuum. Their equation for the case of moderate electric fields E can be written

$$j_{T-F}=AT^2\exp\left(-\frac{e\varphi_0}{kT}+\frac{e\Delta\varphi}{kT}\right)[1+\alpha(T,\ E)], \tag{1}$$

where A is the thermionic-emission constant, e is the electron charge, k is the Boltzmann constant, φ_0 is the work function of the cathode material, and $\Delta\varphi$ is the Schottky correction, which reduces the work function. In the case of a constant field this correction is $\Delta\varphi = \sqrt{e/E}$ The function $\alpha(T, E)$ is small, and is a weak function of E.

When there is a plasma near a hot cathode (e.g., in an arc discharge) the electron current density is usually calculated from Eq. (1) and the field E is determined on the basis of the Langmuir–Mackeown model of the cathode sheath.[3,4] In this model it is assumed that the actually discrete unbalanced space charge in the sheath is smeared into a continuous charge distribution; this simplification can have important effects in calculations for emission processes in several situations: In addition to the average field E there are fluctuations due to the fields of individual ions. Then the field at the cathode is a random quantity, which can take on values from $E_{\min}$ to $E_{\max}$, depending on the arrangement of ions in the sheath, and the work function can, correspondingly, take on values from $\varphi_{\max}$ to $\varphi_{\min}$.

Bauer[5] reported the first attempt to incorporate the effect of the fields of the individual ions on the current density of thermionic field emission, but he used crude assumptions, and his results are valid only for particular cases.

Ostretsov et al.[6] examined the effect of the field of individual ions on thermionic (T) emission; in particular, they derived the distribution function of the correction to the work function due to the discrete nature of the charge distribution in the cathode sheath, and they found the range of this correction:[1)]

$$\left.\begin{aligned} f(x)&=nr_*^3\left(\frac{3.36}{x^{5/2}}-8.23\right)\exp\left[-nr_*^3\left(\frac{2.24}{x^{3/2}}+8.23x+9.58\right)\right],\\ x&=\Delta\varphi\frac{r_*}{e}-0.5,\quad 0\leqslant x\leqslant 0.7.\end{aligned}\right\} \tag{2}$$

Here n is the ion concentration near the cathode surface, $r_* = 1/2\sqrt{e/E}$ is the Schottky distance, x is the dimensionless correction to the work function. When x = 0 the Schottky correction is obtained.

In moderate fields a characteristic feature of T–F emission is the fact that the increase in the electron current density occurs primarily because of a lowering of the potential barrier at the surface of the metal (as in T emission – the Schottky effect), and not because of a narrowing of the barrier, i.e., an increase in its transmission (as in field emission – the tunneling effect). Accordingly, the results of ref. 6 can be extended to this range of T–F emission.

To find the current density for T–F emission, taking account of the effects of the fields of the individual ions (I–T–F emission), we must average $j_{T-F}(x)$ over the distribution $f(x)$:

$$j_{I-T-F}=\int\limits_0^{0.7} j_{T-F}(x)\,f(x)\,dx. \tag{3}$$

Integral (3) cannot be evaluated exactly, so we represent $f(x)$ by a parabola whose vertex is at the maximum, $f(\bar{x})$: $y = f(\bar{x}) - K(x - \bar{x})^2$, where $\bar{x}$ is the coordinate of the maximum of $f(x)$. We find the coefficient K from the normalization condition

$$\int\limits_{\bar{x}-\delta}^{\bar{x}+\delta} y(x)\,dx=1,$$

where $x = \bar{x} + \delta$ and $x = \bar{x} - \delta$ are the points at which the parabola intersects the x axis.

Then

$$f(x)\approx y=f(\bar{x})-\frac{16}{9}f^3(\bar{x})(x-\bar{x})^2. \tag{4}$$

Substituting (4) into (3), we find

$$\left.\begin{aligned} j_{I-T-F}&=AT^2\exp\left(-\frac{e\varphi_0}{kT}+\frac{e\sqrt{eE}}{kT}\right)\\ &[1+\alpha(T,\ E)]\,e^{a\bar{x}}\left(\operatorname{ch}b-\frac{\operatorname{sh}b}{b}\right)\frac{3}{b^2},\\ a&=\frac{e^2}{kTr_*},\quad b=\frac{3a}{4f(\bar{x})}.\end{aligned}\right\} \tag{5}$$

To find $\bar{x}$ we use the approximations

$$\bar{x}=\begin{cases}1.22\,(nr_*^3)^{3/2}, & nr_*^3<0.1,\\ 0.73-0.22\,(nr_*^3)^{-1/2}, & 0.1\leqslant nr_*^3\leqslant 10,\\ 0.7-0.28\,(nr_*^3)^{-1/2}, & 10<nr_*^3.\end{cases} \tag{6}$$

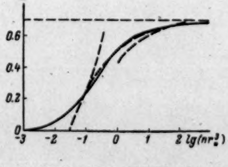

Fig. 1

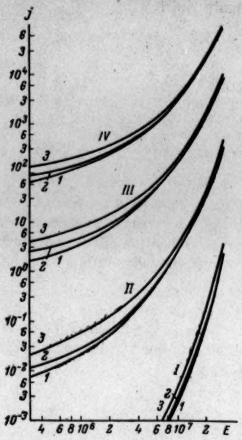

Fig. 2. n, cm^{-3}: 1) 0; 2) 10^{18}; 3) 10^{19}. T (°K): I) 1500; II) 2000; III) 2500; IV) 3000.

Functions (6) are shown in Fig. 1 by the dashed curves; the solid curve shows the exact functional dependence of the coordinate $\overline{x}$ on the parameter nr_*^3, found numerically.

Typical values for I–T–F emission are $nr_*^3 \sim 10^{-1}$. Figure 2 shows functions (5) for various values of T and n; the n = 0 curve corresponds to pure T–F emission. We see that in all cases $j_{I-T-F} > j_{T-F}$. As the temperature is lowered and the density increased this inequality is strengthened.

---

1) The expression in ref. 6 for $f(x)$ is slightly different in form: Eq. (2) differs from it in that $f(x)$ in Eq. (2) vanishes at X = 0.7.

Preservation of semiconductor field-emission cathodes

N. V. Egorov, G. N. Fursei, and M. K. El'Nimr

A. A. Zhdanov Leningrad State University

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 44, 1117-1118 (May 1974)

Direct experiments have shown that irreversible changes in the properties of semiconductor field-emission cathodes, which occur in heating to temperatures exceeding 150°C, are to a considerable degree due to metals which are deposited on the surface of an emitter during the sharpening process in an electrolyte and which alter the conductance of the surface region of the sample.

One of the greatest difficulties in the preparation and use of semiconductor field-emission cathodes is the great change in their properties due to heat treatment. These changes can occur at any stage: during electrolytic etching, in the course of outgassing of a vacuum device with a semiconductor emitter, and as a result of heating of the emitter by its own emission current. Distortions of the field-emission characteristics as a result of heat treatment have been reported for Ge (refs. 1,2), Si (ref. 3), GaAs (ref. 4), In_2S_3 (ref. 5), and other semiconductors.

It has been shown (see, for example, refs. 1-3) that nonlinear voltage—current characteristics can be obtained only if the heat treatment is confined to low temperatures (T ~150°C).

It has been suggested[3] that changes in the properties of semiconductor field emitters may be due to the presence of metal ions which remain following the electrochemical treatment. Solutions of alkalis, hydrofluoric and nitric acids, hydrogen peroxide, and other high-purity etchants are usually contaminated with ions of heavy metals (copper, silver, lead, iron, gold, etc.) in amounts from $1 \cdot 10^{-5}$ to $1 \cdot 10^{-3}$%. This also applies to distilled water, which is used to wash silicon, germanium, and other semiconductors. In the course of etching a semiconductor can absorb impurities present in an etchant. In view of the high ratio of the surface area to the volume of a field emitter, the diffusion of impurities can alter the nature and the degree of doping of the surface region of a semiconductor cathode.

We have investigated this hypothesis in series of experiments in which the concentration of metal impurities captured during etching is reduced by treatment in organic solutions (Trilon B or 2,4-pentadiene).[6] These compounds form stable complexes with copper and similar metal ions in basic solutions and are then easily removed by washing.

The temperature of a sample during vacuum processing lies within the range 150-500°C. After each heat-treatment cycle we record the voltage—current characteristic at a fixed temperature. The recording of the characteristic is preceded by a field-desorption treatment.

It is clear from a comparison of Figs. 1 and 2 that the critical temperature at which the voltage—current characteristic becomes linear, T_{cr}, increases when metals deposited during etching are removed by means of complex-forming agents.

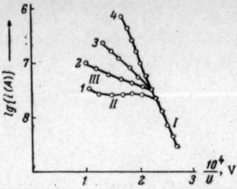

Fig. 1. Illustration of the distortion of the original properties of a silicon field emitter (p-type, ρ = 14 Ω·cm) during heat treatment in the course of vacuum processing of a field-emitting device. T (°C): 1) 150; 2) 250; 3) 300; 4) 350.

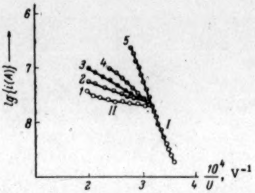

Fig. 2. Voltage—current characteristics of a silicon field emitter (p-type, 14 Ω·cm) recorded after different heat treatments for samples which are etched electrochemically and then treated in solutions forming stable complexes with metal ions. T (°C): 1) 250; 2) 300; 3) 350; 4) 400; 5) 500.

When a sample whose voltage—current characteristic becomes linear is subjected to a second etching, which removes a thin surface layer, the nonlinearity is fully restored. The process is irreversible when the sample is heated to a very high temperature (800-1000°K or above) and this is evidently due to the doping of the whole of the emitter.

Thus, our investigation indicates that the experimentally observed changes in the original properties of a silicon emitter resulting from heat treatments are, to a considerable degree, due to the presence of metal impurities deposited on the surface of the emitter in the course of the electrochemical treatment.

The magnetostatic problem for thin closed shells

I. P. Krasnov

(Submitted August 13, 1973)
Zh. Tekh. Fiz., 44, 1121-1124 (June 1974)

Integral equations are used to solve magnetostatic problems for thin closed shells, limiting cases of the equations are considered, and the relation of these equations to the Dirichlet and Neumann problems and the determination of eddy currents are discussed.

1. In the calculation of the magnetic field created by a thin closed shell of magnetic material with permeability μ located in a medium of permeability μ_1 the following approximate boundary conditions have been proposed[1] on the assumption that the field varies linearly across the thickness of the shell:

$$\left.\begin{aligned}\varphi^+ - \varphi^- &= -\Delta\frac{\mu_1}{\mu}\frac{\partial}{\partial n}\varphi^+,\\ \frac{\partial}{\partial n}\varphi^+ - \frac{\partial}{\partial n}\varphi^- &= \varkappa\Delta\frac{\partial}{\partial n}\varphi^+ + \Delta\frac{\mu}{\mu_1}\operatorname{div}_s\operatorname{grad}_s\varphi^+,\end{aligned}\right\} \qquad (1)$$

where n is the normal to the surface of the shell, div_s and grad_s are the surface divergence and gradient, $\varkappa$ is the curvature of the shell surface,[1)] and Δ is the thickness; the superscripts '+' and '−' denote the limiting values of the scalar magnetic potential φ on the inside and outside of the shell respectively. The fact that the boundary conditions (1) only contain the ratio of the permeabilities means that it is possible to separate the two cases $\mu_1 \ll \mu$ and $\mu_1 \gg \mu$ (the case $\mu_1 \simeq \mu$ is of no particular interest since it can be described simply in terms of a uniformly magnetized shell). The boundary conditions for the two cases are as follows: for $\mu_1 \ll \mu$ (see ref. 2)

$$\left.\begin{aligned}\varphi^+ - \varphi^- &= 0,\\ \frac{\partial}{\partial n}\varphi^+ - \frac{\partial}{\partial n}\varphi^- &= \varkappa\Delta\frac{\partial}{\partial n}\varphi^+ + \frac{\partial}{\partial n}\varphi^-\bigr) + \mu_s\operatorname{div}_s\operatorname{grad}_s\varphi^+,\end{aligned}\right\} \qquad (2)$$

and for $\mu_1 \gg \mu$,

$$\left.\begin{aligned}\frac{\partial}{\partial n}\varphi^+ - \frac{\partial}{\partial n}\varphi^- &= 0,\\ \varphi^+ - \varphi^- &= -\nu_s\frac{\partial}{\partial n}\varphi^+.\end{aligned}\right\} \qquad (3)$$

Here, for simplicity we have written $\mu_s \equiv \Delta\,(\mu/\mu_1)$, $\nu_s \equiv \Delta\,(\mu_1/\mu)$.

The only way of solving the boundary-value problem for the magnetic fields of shells with arbitrary shape is to use numerical or numerical-analytic methods; it is preferable to deal with integral equations. In this paper we given an equivalent formulation of the boundary-value problems (2) and (3) in the form of Fredholm integral equations of the second kind; integral equations equivalent to (2) for a two-dimensional space are considered in ref. 3.

2. In order to obtain integral equations corresponding to (2) and (3) it is convenient to represent the scalar magnetic potential as the sum of the potentials of a primary field φ_0 and a secondary field ψ:

$$\varphi = \varphi_0 + \psi, \qquad (4)$$

and to take as the secondary field the potential of a simple or double layer. It is clear from the properties of these potentials[4] that the first (homogeneous) parts of the boundary conditions (2) and (3) are satisfied if the secondary field in (2) is represented by the potential of a simple layer:

$$\psi(x) = \frac{1}{4\pi}\int_S g(s)\frac{1}{r_{sx}}\,ds, \qquad (5)$$

and in (3) by the potential of a double layer:

$$\psi(x) = \frac{1}{4\pi}\int_S \sigma(s)\frac{\partial}{\partial n_s}\frac{1}{r_{sx}}\,ds; \qquad (6)$$

here, r_{SX} denotes the distance between a points on the surface S of the shell and a point $x = (x_1x_2x_3)$ in space. We now substitute (5) and (6) into the remaining parts of the boundary conditions (2) and (3) respectively and use (4) to obtain singular integral equations which are equivalent to the original problems. Equation (2) is equivalent to

$$\begin{aligned}&g(s_2) - \mu_s\operatorname{div}_s\operatorname{grad}_s\frac{1}{4\pi}\int_S g(s_1)\frac{1}{r_{12}}\,ds_1\\ &-\frac{\varkappa\Delta}{4\pi}\int_S g(s_1)\frac{\partial}{\partial n_2}\frac{1}{r_{12}}\,ds_1 = \mu_s\operatorname{div}_s\operatorname{grad}_s\varphi_0.\end{aligned} \qquad (7)$$

For (3) we have

$$\sigma(s_2) - \nu_s\frac{1}{4\pi}\int_S \sigma(s_1)\frac{\partial}{\partial n_2}\frac{\partial}{\partial n_1}\frac{1}{r_{12}}\,ds_1 = \nu_s\frac{\partial}{\partial n_2}\varphi_0(s_2). \qquad (8)$$

In order to reduce these singular equations to the Fredholm form, we apply to each the integral operation

$$\frac{1}{\pi}\int_S \dots \frac{1}{r_{20}}\,ds_2.$$

We then change the order of integration in the resultant singular integrals in accordance with the commutation relations

$$-\frac{1}{4\pi^2}\int_S\left(\operatorname{div}_s\operatorname{grad}_s\int_S g(s_1)\frac{1}{r_{12}}\,ds_1\right)\frac{1}{r_{20}}\,ds_2$$

$$= g(s_0) + \frac{1}{2\pi}\int_S g(s_1)\,M(s_1s_0)\,ds_1;$$

$$-\frac{1}{4\pi^2}\int_S\left(\int_S \sigma(s_1)\frac{\partial}{\partial n_2}\frac{\partial}{\partial n_1}\frac{1}{r_{12}}\,ds_1\right)\frac{1}{r_{20}}\,ds_2$$

$$= \sigma(s_0) - \frac{1}{2\pi}\int_S \sigma(s_1)\,N(s_1s_0)\,ds_1,$$

$$M(s_1s_0) \equiv \frac{1}{2\pi}\int_S\left(\operatorname{grad}_s\frac{1}{r_{12}},\ \operatorname{grad}_s\frac{1}{r_{20}}\right)ds_2,$$

where

$$N(s_1 s_0) \equiv \frac{1}{2\pi}\int\limits_S \frac{\partial}{\partial n_1}\frac{1}{r_{12}}\frac{\partial}{\partial n_2}\frac{1}{r_{20}}\,ds_2,$$

of which the first can be obtained from the spatial analog of the Poincaré–Bertran equation[5] and the second from Green's theorem for a harmonic function.

Thus Eq. (7) for the boundary condition (2) can be transformed to

$$\mu_s g(s_2) + \frac{1}{2\pi}\int\limits_S g(s_1)\left(\frac{2}{r_{12}} + \mu_s M(s_1 s_2) - \varkappa\Delta P(s_1 s_2)\right) ds_1 = \frac{\mu_s}{\pi}\int\limits_S \operatorname{div}_s \operatorname{grad}_s \varphi_0(s_1)\frac{1}{r_{12}}\,ds_1, \qquad (9)$$

where

$$P(s_1 s_2) \equiv \frac{1}{2\pi}\int\limits_S \frac{1}{r_{20}}\frac{\partial}{\partial n_0}\frac{1}{r_{01}}\,ds_0,$$

and Eq. (8) for (3) to

$$\nu_s \sigma(s_2) + \frac{1}{2\pi}\int\limits_S \sigma(s_1)\left(\frac{2}{r_{12}} - \nu_s N(s_1 s_2)\right) ds_1 = \frac{\nu_s}{\pi}\int\limits_S \frac{\partial}{\partial n}\varphi_0\frac{1}{r_{12}}\,ds_1. \qquad (10)$$

Simple calculations show that the kernels $P(s_1s_2)$ and $N(s_1s_2)$ do not have more than a logarithmic singularity provided that S has a continuous curvature; it can also be shown that $M(s_1s_2)$ then also has a logarithmic singularity.

As a result, Eqs. (9) and (10) are of the Fredholm type (or more exactly, they are integral equations with a weak singularity for which Fredholm's theorem is valid).

We note the relation between the kernels

$$N(s_1 s_2) = \frac{\partial}{\partial n_2}P(s_1 s_2),$$

$$M(s_1 s_2) = \frac{1}{2\pi}\int\limits_S \left(\left[\mathbf{n}_0, \operatorname{grad}\frac{1}{r_{01}}\right]\left[\mathbf{n}_0 - \mathbf{n}_1, \operatorname{grad}\frac{1}{r_{20}}\right]\right) ds_0 - N(s_1 s_2),$$

which shows, in particular, that if S is a plane then P = N = M = 0. If S is a sphere of radius R, then we have

$$M(s_1 s_2) = -\frac{1}{4R^2}K\left(\cos\frac{\vartheta_{12}}{2}\right) = -N(s_1 s_2),$$

where K is the complete elliptical integral of the first kind and ϑ_{12} is the angle between the radii drawn to the points s_1 and s_2.

3. We now consider the limiting cases of (9) and (10). If $\mu_S \to \infty$ in (9), then

$$g(s_2) + \frac{1}{2\pi}\int\limits_S g(s_1) M(s_1 s_2)\,ds_1 = \frac{1}{\pi}\int\limits_S \operatorname{div}_s \operatorname{grad}_s \varphi_0\frac{1}{r_{12}}\,ds_1. \qquad (11)$$

This Fredholm equation can be considered as an integral equation for the solution of the Dirichlet problem

$$\psi|_s = -\varphi_0(s)$$

by means of a simple layer potential (the usual formulation of the Dirichlet problem by means of the potential of a simple layer leads to an equation of the first kind with a weak singularity). Similarly, Eq. (11) can be considered as an integral equation for the solution of the Poisson problem on the surface S:

$$\operatorname{div}_s \operatorname{grad}_s \psi = F\ (\equiv -\operatorname{div}_s \operatorname{grad}_s \varphi_0),$$

which occurs in the determination of eddy currents in thin shells.[6] If $\nu_S \to \infty$ in (10), then

$$\sigma(s_2) - \frac{1}{2\pi}\int\limits_S \sigma(s_1) N(s_1 s_2)\,ds_1 = \frac{1}{\pi}\int\limits_S \frac{\partial}{\partial n_1}\varphi_0(s_1)\frac{1}{r_{12}}\,ds_1. \qquad (12)$$

This equation can be considered as an integral equation for the solution by means of a double-layer potential of the Neuman problem

$$\frac{\partial}{\partial n}\psi|_s = -\frac{\partial}{\partial n_s}\varphi_0(s),$$

which is usually solved with the use of a single-layer potential.

The integral equations (9) and (10) and their limiting cases have been verified by the example of a surface S in the form of a spheriod; an analytical solution is obtained by expanding 1/r in a series of orthogonal functions on this surface and the solution identical to that given in ref. 1. Analytical solutions of (9) and (10) exist in cases in which separation of variables is possible for the boundary-value problems (2) and (3), but the advantage in using these equations appears when numerical methods are used for shells of arbitrary shape.

We note in conclusion that (2) and (3) are related in the two-dimensional case when $\varkappa\Delta \ll 1$. This follows the fact that the solutions of (2) and (3) are then the real and imaginary parts of a function of a complex variable; if g(s) is the density of the simple-layer potential with which (2) is solved and δ(s) is the density of the double-layer potential for solving (3), then

$$g(s) = \frac{d}{ds}\sigma(s).$$

Thus the methods suggested in ref. 3 for solving (2) are also suitable for solving (3). In the three-dimensional case, the relation between (2) and (3) no longer holds.

---

1) If u and v are orthogonal coordinates on the surface of the shell and h_u and h_v are the corresponding Lamé coefficients, then

$$\varkappa = \frac{1}{h_u h_v}\frac{\partial}{\partial n}(h_u h_v).$$

Microwave propagation in a low-loss dielectric

L. É. Rikenglaz

G. V. Plekhanov Leningrad Mining Institute

(Submitted September 4, 1973)
Zh. Tekh. Fiz., 44, 1125-1128 (June 1974)

The self-consistent problem of determining the electric and temperature fields in a semiinfinite dielectric is solved in the adiabatic approximation for the case of a plane wave at normal incidence; the parameters of the medium are arbitrary functions of temperature.

In this note the problem of determining the electric and temperature fields in a semiinfinite low-loss dielectric is solved in the adiabatic approximation for the case of normal incidence of a plane wave [$\sim\exp(i\omega t)$]. The parameters of the medium are arbitrary functions of temperature. The problem has been solved earlier[1] for the case in which the damping coefficient is a linear function of temperature and all other parameters are constants.

Since the characteristic heating time and the relaxation times of the electrical parameters of the medium are much greater than the oscillation period, the electric field in the medium can be written in the form

$$E(x,\ t)=y(x,\ t)\exp(i\omega t)\quad(x>0),\tag{1}$$

where y(x, t) is a slowly varying function of time that satisfies the equation

$$\frac{d^2y}{dx^2}+k_0^2\varepsilon(x,\ t)\,y=0,\tag{2}$$

in which the time is a parameter. Here, k_0 is the wave number in vacuum, and $\varepsilon = \varepsilon' - i\varepsilon''$ is the complex dielectric constant of the medium.

In the isothermal case the field penetration depth in a low-loss medium

$$h=\frac{2}{k_0\varepsilon'\operatorname{tg}\delta}\quad\left(\operatorname{tg}\delta=\frac{\varepsilon''}{\varepsilon'}\right)$$

is considerably greater than the wavelength in the medium. Since the temperature of the medium and the dielectric constant ε vary on a space scale of order h, the WKB method can be used to solve Eq. (2).

Neglecting the reflected wave, we have

$$y=D\frac{\varepsilon^{1/4}(0,\ t)}{\varepsilon^{1/4}(x,\ t)}\exp\left[-k_0\int\limits_0^x\varepsilon^{1/2}(x',\ t)\,dx'\right].\tag{3}$$

Using the continuity of the field vectors at the dielectric boundary x = 0, we find

$$y=\frac{2D_0}{1+\varepsilon^{1/2}(0,\ t)}\,\frac{\varepsilon^{1/4}(0,\ t)}{\varepsilon^{1/4}(x,\ t)}\exp\left[-k_0\int\limits_0^x\varepsilon^{1/2}(x',\ t)\,dx'\right],\tag{4}$$

where D_0 is the electric field of the incident wave.

The density of heat sources in the medium q(x, t) is

$$q(x,\ t)=0.5\omega\varepsilon_0\varepsilon'\operatorname{tg}\delta\,|E|^2=SD_{\rm en}(t)\,\alpha(x,t)\exp\left[-\int\limits_0^x\alpha(x't)\,dx'\right],\tag{5}$$

where S is the electromagnetic energy flux density, $D_{\rm en}(t) = 4\varepsilon'(0,\ t)[1+\varepsilon'^{1/2}(0,\ t)]^{-2}$ is the energy transmission coefficient, and $\alpha(x,\ t) = k_0\sqrt{\varepsilon'(x,\ t)}\tan\delta$ is twice the isothermal damping coefficient.

In the adiabatic approximation the heat-conduction equation assumes the form

$$c(T)\rho(T)\frac{\partial T}{\partial t}=SD_{\rm en}(t)\,\alpha(x,\ t)\exp\left[-\int\limits_0^x\alpha(x',\ t)\,dx'\right]\tag{6}$$

with the initial and boundary conditions

$$T(0,\ x)=T(t,\ \infty)=T_0.\tag{7}$$

If the experimental or theoretical temperature of the heat capacity c, density ρ, and complex dielectric constant ε of the medium are known, Eq. (6) is a nonlinear integrodifferential equation for the temperature. The explicit dependence of the temperature on the time and coordinate has been determined for the special case[1]

$$\alpha=\alpha_0+\gamma(T-T_0);\quad c=\text{const},\quad \rho=\text{const},\quad \varepsilon'=\text{const}.$$

We now solve Eq. (6) in the general case. We first determine the temperature at the boundary of the medium. At x = 0 we have

$$c\{T(0,\ t)\}\,\rho\{T(0,\ t)\}\,\frac{\partial T(0,\ t)}{\partial t}=SD_{\rm en}\{T(0,\ t)\}\,\alpha\{T(0,\ t)\},\tag{8}$$

so that

$$t=\int\limits_{T_0}^{T}\frac{c(T)\,\rho(T)\,dT}{SD_{\rm en}(T)\,\alpha(T)}.\tag{9}$$

The integral can be evaluated numerically for known temperature dependences of the parameters of the medium, making it possible to determine the temperature T(0, t) at the boundary of the medium and the energy transmission coefficient $D_{\rm en}(t)$.

When T(0, t) and $D_{\rm en}(t)$ are known it is possible to find T(x, t). We replace the time t by the new variable Q:

$$Q=S\int\limits_0^t D_{\rm en}(t)\,dt;\quad \frac{\partial Q}{\partial t}=SD_{\rm en}(t).\tag{10}$$

The meaning of the new variable is obvious; Q is the energy transferred across unit area in time t.

Using Eq. (10), we transform Eq. (6):

$$\frac{c(T)\,\rho(T)}{\alpha(T)}\,\frac{\partial T}{\partial Q}=\exp\left[-\int\limits_0^x\alpha(x',\ Q)\,dx'\right];$$

$$T(0,\ x)=T(Q,\ \infty)=T_0.\tag{11}$$

We define the new function H(Q, x) by the equation

$$H(Q,\ x)=\int\limits_{T_0}^{T}\frac{c(T)\,\rho(T)}{\alpha(T)}\,dT;\quad \frac{dH}{dT}=\frac{c(T)\,\rho(T)}{\alpha(T)}\tag{12}$$

and assume that $\alpha\{T(Q,x)\}$ can be expressed as $\alpha\{H(Q,x)\}$.

Substituting Eq. (12) into (11), we obtain

$$\frac{\partial H}{\partial Q}=\exp\left[-\int_0^x \alpha(x',\,Q)\,dx'\right]H(0,\,x)=H(Q,\,\infty)=0. \quad (13)$$

We differentiate Eq. (13) with respect to x:

$$\frac{\partial^2 H}{\partial x\partial Q}=-\alpha(H)\exp\left[-\int_0^x \alpha(x',\,Q)\,dx'\right]=-\alpha(H)\frac{\partial H}{\partial Q}. \quad (14)$$

Relation (14) can be written in the alternative form

$$\frac{\partial}{\partial Q}\left(\frac{\partial H}{\partial x}+\int_0^H \alpha(H)\,dH\right)=0,$$

so that

$$\frac{\partial H}{\partial x}+\int_0^H \alpha(H)\,dH=f(x), \quad (15)$$

where $f(x)$ is an arbitrary function.

For Q = 0 we have $H(0,\,x) = \partial H(0,\,x)/\partial x = 0$. Therefor, $f(x) = 0$, and Eq. (15) assumes the form of an equation with variables separable:

$$\partial x=-\frac{\partial H}{\int_0^H \alpha(H)\,dH}. \quad (16)$$

Integrating this relation, we find

$$x=\int_{H(Q,\,x)}^{H(Q,\,0)}\frac{dH'}{\int_0^{H'}\alpha(H'')\,dH''}. \quad (17)$$

Making a change of variables in this relation according to Eq. (12), we obtain the following implicit solution of the problem:

$$x=\int_{T(x,\,t)}^{T_s}\frac{c(T'')\rho(T'')\,dT''}{\alpha(T')\int_{T_0}^{T'} c(T'')\rho(T'')\,dT''}. \quad (18)$$

For the important case in which the density and heat capacity are constant Eq. (18) is greatly simplified:

$$x=\int_{T(x,\,T)}^{T(0,\,t)}\frac{dT'}{\alpha(T')(T'-T_0)}. \quad (19)$$

Equation (19) can be integrated analytically in many important cases; in any case it can be integrated numerically.

We now estimate the range of validity of the underlying assumptions. The adiabaticity conditions require that

$$c\rho\frac{\partial T}{\partial t}\gg\lambda\left|\frac{\partial^2 T}{\partial x^2}\right|, \quad (20)$$

where λ is the thermal conductivity of the medium.

Using Eqs. (8) and (19) we find that (20) holds for (x,t) satisfying the relation

$$\frac{SD_{\mathrm{en}}(t)}{T(0,\,t)-T_0}\gg a^2\left[\alpha(T)+(T-T_0)\frac{d\alpha}{dT}\right], \quad (21)$$

where $a^2 = \lambda/c\rho$ is the thermal diffusivity of the medium.

Maximum current of a beam with finite phase volume

G. I. Trubnikov and V. S. Kuznetsov

D. V. Efremov Scientific-Research Institute of Electrophysical Apparatus, Leningrad

(Submitted April 17, 1973)
Zh. Tekh. Fiz., 44, 1129-1132 (June 1974)

A universal curve giving the conditions for maximum current of an axisymmetric beam with finite phase volume is derived. This curve is the boundary of the region in which solutions for the beam envelope exist. Use of this curve to design a beam-transport channel is illustrated.

The familiar maximum-current problem is encountered in one form or another in many electronic devices and charged-particle accelerators.[1-3]

In the drift region this problem consists of determining the maximum current which can be transported through the drift tube in the absence of focusing fields. Formulated differently, it consists of determining the minimum number of lenses required in a drift tube of given length and bore to transport a given beam.

This problem has been solved previously only for one particular case: that in which the beam particles have zero thermal-velocity spread. In many cases, however, particularly in ion-beam calculations, this spread is important; frequently it is the decisive factor in beam spreading.[4] In this note we solve this problem for high-current beams, taking account of the thermal spread, which is characterized by the value of the beam emittance.

SOLUTION OF THE MAXIMUM-CURRENT PROBLEM

The spreading of an axisymmetric beam in an equipotential space is described by[4]

$$\frac{d^2r}{dz^2}-\frac{E^2}{r^3}-\frac{K}{r}=0. \qquad (1)$$

Here, r is the beam radius (envelope), z is the longitudinal coordinate, E is the beam emittance, and

$$K=\frac{e(1-\beta^2)^{3/2}}{2\pi\varepsilon_0 m_0 c^3\beta^3}I$$

is the Coulomb factor, where β is the relative longitudinal particle velocity and I is the beam current.

Integrating Eq. (1) twice, we find an integral equation relating z and r for initial conditions r_0 and r_0':

$$z=\int\limits_{r_0}^{r}\frac{dr}{\sqrt{E^2\left(\frac{1}{r_0^2}-\frac{1}{r^2}\right)+2K\ln\frac{r}{r_0}}}. \qquad (2)$$

The solution of Eq. (1) is symmetric with respect to the plane in which $r_0' = 0$; without any loss of generality we can then analyze the beam spreading with the initial conditions $r = r_0$ and $r_0' = 0$, where r_0 is now the beam radius at the crossover point:

$$z=\int\limits_{r_0}^{r}\frac{dr}{\sqrt{E^2\left(\frac{1}{r_0^2}-\frac{1}{r^2}\right)+2K\ln\frac{r}{r_0}+r_0'^2}}. \qquad (3)$$

We note that $E = r_0\alpha_0$ at the crossover point, where α_0 is the maximum inclination angle of a particle trajectory, a measure of the thermal spread.

To find the maximum distance the beam can propagate for a fixed maximum radius r as function of r_0, we differentiate (3) parametrically with respect to r_0 and equate the derivative to zero, using the new variable $x = r/r_0$; we find

$$\int\limits_{1}^{x}\frac{\partial}{\partial r_0}\left(\frac{r_0}{\sqrt{\frac{E}{r_0^2}\left(1-\frac{1}{x^2}\right)+2K\ln x}}\right)dx = \frac{x}{r_0}\,\frac{r_0}{\sqrt{\frac{E}{r_0^2}\left(1-\frac{1}{x^2}\right)+2K\ln x}}. \qquad (4)$$

Differentiating the integrand and introducing $2Kr_0^2/E^2 = A$, we find

$$\int\limits_{1}^{x}\frac{dx}{\sqrt{1-\frac{1}{x^2}+A\ln x}}+\int\limits_{1}^{x}\frac{\left(1-\frac{1}{x^2}\right)dx}{\left[1-\frac{1}{x^2}+A\ln x\right]^{3/2}}=\frac{x}{\sqrt{1-\frac{1}{x^2}+A\ln x}}. \qquad (5)$$

The solution of Eq. (5) is the quantity $x = x^*$, which

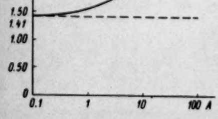

Fig. 1. The relative radius x* as a function of the parameter A for a maximum current.

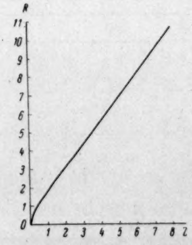

Fig. 2. The universal curve; here Z = z(K/E) and R = r($\sqrt{K/E}$).

is a function of the parameter A and which governs the condition for the maximum current. Figure 1 shows the functional dependence of x^* on A obtained through a numerical solution of Eq. (5).

At $A = 0$ Eq. (5) has the analytic solution $x^* = \sqrt{2}$; this case corresponds to a negligibly small Coulomb factor. As A is allowed to increase without bound, x^* asymptotically approaches the value 2.35, corresponding to the known solution of this problem for the case of a negligibly small thermal spread.

Integrating (3) up to the value x^* which we have found, we can find a functional relation between z and r, corresponding to the condition for maximum current.

Introducing the coordinates $R = r(\sqrt{K}/E)$ and $Z = z(K/E)$, we find a universal curve, which is the solution of our problem (Fig. 2).

PHYSICAL MEANING OF THE UNIVERSAL CURVE

For fixed values of E and K, the universal curve gives a functional relation between z and r which corresponds to the maximum current. For a given length of the drift tube, L, we can set $z = L/2$ and find the minimum tube radius r required to transport a beam with the parameters K and E.

The universal curve is the envelope of the family of all beam envelopes which can be obtained by solving Eq. (1) for $r_0' = 0$ and for various values of r_0. The beam envelopes fill the entire region above the universal curve; each envelope intersects each other envelope and is tangent to the universal curve at one point.

The fact that the envelopes intersect means that a crossover can be achieved at a given z by two methods by specifying the convergence angles to be equal to the derivatives of the envelopes at the intersection. The points lying on the universal curve correspond to the unique solution of this problem. The universal curve is thus the boundary of the definition region of the function specified by Eq. (1).

Since the universal curve is tangent to the envelopes, the angle of incidence of the beam at maximum current can be found from the derivative of this curve. The corresponding value of r_0 can be found from the curve in Fig. 1. Accordingly, we can determine all the basic beam parameters – the beam radius, its incidence angle (these two parameters unambigously determine the lens power), and the beam radius at the crossover point – without resorting to a solution of Eq. (1).

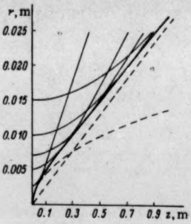

Fig. 3. Universal curve, degenerate curves, and beam envelopes for the case K = 0.0008 and E = 0.0001.

In the case of a small thermal spread, the universal curve degenerates into the straight line

$$r = \sqrt{2K \ln 2.35}\, z, \tag{6}$$

and in the case of a small Coulomb factor it becomes the parabola

$$r = \sqrt{2Ez}. \tag{7}$$

Figure 3 shows the universal curve for a 750-keV proton carrying a current of 0.4 A and having an emittance of 10^{-4} m · rad. The light curves show the beam envelopes, and the dashed curves show line (6) and parabola (7).

The authors thank E. K. Chistov for assistance in the computer calculation.

Symmetry of high-frequency plasma motions

A. A. Zhmudskii and V. B. Taranov

Institute of Nuclear Research,
Academy of Sciences of the Ukrainian SSR, Kiev

(Submitted July 17, 1973; resubmitted October 18, 1973)
Zh. Tekh. Fiz., 44, 1133-1136 (June 1974)

The high-frequency motion of a plasma is analyzed on the basis of the one-dimensional single-fluid model taking account of the finite electron temperature. The symmetry of the equations is analyzed by the theory of continuous transformation groups. Since the equations are invariant under a transformation to a coordinate system oscillating at the plasma frequency, equations for generalizing the solutions can be derived. In particular, generalization of traveling-wave solutions leads to new solutions in which the phase as a linear function of the time is supplemented by a term which oscillates at the plasma frequency and in which the velocity and electric field are supplemented by terms which result from the noninertial nature of the oscillating coordinate system.

The single-fluid model is usually used in the analysis of the high-frequency motion of a plasma. Several exact solutions of the nonlinear equations of the one-dimensional single-fluid model are derived in refs. 1-4, primarily traveling-wave time-independent solutions. In addition, a general solution has been found for these equations, written in Lagrange variables, for the case of a cold plasma.[1-3] Below we analyze the equations of the one-dimensional single-fluid model, taking account of the finite electron temperature, in a more general manner; specifically, we use a group method,[5] which leads to new exact solutions representing traveling waves in the coordinate system oscillating at the plasma frequency, and which leads to equations for generalizing these solutions. Taking account of the pressure alters the symmetry of the equations and, thus, the nature of the exact solutions.

1. We consider the one-dimensional, high-frequency motion of a plasma with electron temperature T, neglecting the ion motion ($n_i = n_0 = \text{const}$, $v_i = 0$). Adopting the standard notation, we introduce the dimensionless variables

$$\left.\begin{aligned} &t^* = \omega_p t, \quad x^* = \omega_p \sqrt{\frac{m}{T}}\,x, \quad n^* = \frac{n}{n_0}, \\ &v^* = \sqrt{\frac{m}{T}}\,v_e, \quad E^* = \frac{E}{\sqrt{4\pi n_0 T}}, \quad p^* = \frac{p}{n_0 T}, \end{aligned}\right\} \tag{1}$$

where

$$\omega_p = \sqrt{\frac{4\pi e^2 n_0}{m}}.$$

The system of equations for the electron component in the absence of a magnetic field is (we omit the asterisks below) is

$$\left.\begin{aligned} &\frac{\partial v}{\partial t} + \frac{\partial v}{\partial x} + f(n)\frac{\partial n}{\partial x} + E = 0, \\ &\frac{\partial n}{\partial t} + v\frac{\partial n}{\partial x} + n\frac{\partial v}{\partial x} = 0, \\ &\frac{\partial E}{\partial x} = 1 - n, \end{aligned}\right\} \tag{2}$$

where $f(n) = (1/n)(dp/dn)$ and where $n > 0$.

System (2) must be solved with the boundary condition

$$\left(\frac{\partial E}{\partial t} - nv\right)\Big|_{x=x_0} = 0, \tag{3}$$

where x_0 is an arbitrary fixed constant.

2. Analysis of the symmetry of Eqs. (2), whose results are given in Sec. 3 of this paper, shows that with $f(n) \neq 0$ we can find two types of solutions:

a) Self-similar solutions,

$$\left.\begin{aligned} &E = \frac{\alpha x \cos t}{1 + \alpha \cos t}, \quad v = \frac{-\alpha x \sin t}{1 + \alpha \cos t}, \\ &n = \frac{1}{1 + \alpha \cos t}, \quad |\alpha| < 1. \end{aligned}\right\} \tag{4}$$

For these solutions $\partial n/\partial x = 0$, i.e., they can easily be derived from the general solution of the cold-plasma equations (see, e.g., ref. 3).

b) Solutions of the type (the dot denotes differentiation with respect to t)

$$\left.\begin{aligned} &v(x, t) = v(\xi) + \dot{F}(t), \\ &E(x, t) = E(\xi) - \ddot{F}(t), \\ &n(x, t) = n(\xi), \end{aligned}\right\} \tag{5}$$

where $\xi = x - F(t)$, and F(t) is a function whose specific form is found below with the help of condition (3).

From (2) we find a system of equations for the functions v, E, and n of ξ (the prime denotes differentiation with respect to ξ):

$$\left.\begin{aligned} &vv' + f(n)n' + E = 0, \\ &(nv)' = 0, \\ &E' = 1 - n. \end{aligned}\right\} \tag{6}$$

The second equation in (6) yields

$$nv = -u_0 = \text{const}. \tag{7}$$

Using condition (3) along with (6) and (7), we find a specific equation for the function F(t):

$$F(t) = F_0 + u_0 t + (\dot{F}_0 - u_0)\sin t + \ddot{F}_0(1 - \cos t). \tag{8}$$

where F_0, $\dot{F}_0$, and $\ddot{F}_0$ are constants.

Using the equations in sec. 3 to generalize the solutions, we can distinguish among solutions (5) certain un-

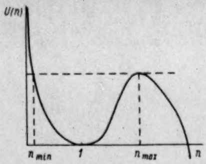

Fig. 1

usual solutions like

$$\left.\begin{aligned} v &= v(\xi) + u_0, \\ E &= E(\xi), \\ n &= n(\xi), \end{aligned}\right\} \qquad (9)$$

where $\xi = x - u_0 t$. Solutions of this type are traveling waves with a phase velocity u_0. New solutions can be generated from (9) by means of the generalization equations in Sec. 3.

Equations (6) and (7) allow the energy integral

$$W = \frac{1}{2} E^2 + \frac{1}{2} u_0^2 \left(\frac{1}{n} - 1\right)^2 + \int_1^n \left(\frac{1}{n} - 1\right) dp. \qquad (10)$$

Equations (7) and (10) give $v(\xi)$ and $E(\xi)$ as functions of $n(\xi)$; using the third equation in (6) we can then reduce the problem to quadratures. Exact traveling-wave solutions for the case $p = (1/3) n^3$ have been found previously.[4]

Using integral (10) we can analyze qualitatively the behavior of the solutions for an arbitrary functional dependence of p on n. We treat the function

$$U(n) = \frac{1}{2} u_0^2 \left(\frac{1}{n} - 1\right)^2 + \int_1^n \left(\frac{1}{n} - 1\right) dp \qquad (11)$$

as a "potential energy."

With $n = 1 + \varepsilon$, where $|\varepsilon| \ll 1$ we have

$$U(1+\varepsilon) \approx \frac{1}{2}\left(u_0^2 - \left.\frac{dp}{dn}\right|_{n=1}\right)\varepsilon^2. \qquad (12)$$

Since this model is applicable when the wave phase velocity u_0 is much larger than the electron thermal velocity $dp/dn|_{n=1}$, we see that U (n) has a minimum at n = 1.

Figure 1 shows the nature of the function U(n) for the case $p = (1/\gamma) n^\gamma$.

The function U(n) has a maximum at the point $n_{\max} = |u_0|^{2/(\gamma+1)}$. For $W < U(n_{\max})$, the solutions are periodic in ξ; for $W > U(n_{\max})$ we find the multistream motion analyzed in refs. 1 and 2. When $W = U(n_{\max})$, the solution is a soliton solution.

3. Here we list the results of a group analysis[5] of the symmetry of Eqs. (2).

With an arbitrary function $f(n)$, system (2) permits an infinite-dimensional transformation group with the infinitesimal operator

$$X = C_1 \frac{\partial}{\partial t} + F(t)\frac{\partial}{\partial x} + \dot{F}(t)\frac{\partial}{\partial v} - \ddot{F}(t)\frac{\partial}{\partial E}, \qquad (13)$$

where C_1 is a constant, and F(t) is an arbitrary function of t. The symmetry of (13) is markedly nonlinear, i.e., linearized equations (2) do not permit transformations (13).

In the case $f(n) = 0$ the group is more comprehensive; the operator

$$Y = x\frac{\partial}{\partial x} + v\frac{\partial}{\partial v} + E\frac{\partial}{\partial E} \qquad (14)$$

is added.

Because of the symmetry of (14) the phase velocity of the wave turns out to be an unimportant parameter in this case; in the linear theory, this corresponds to the fact that the dispersion relation is independent of the wave vector k.

Group (13) contains a subgroup which effects a mutual interchange of the solutions of system (2) with condition (3); this subgroup is found from (13) by setting

$$F(t) = A\cos t + B\sin t + C, \qquad (15)$$

where A, B, and C are constants.

Finite transformations of this subgroup yield the following equations for generalizing the solutions of system (2) with condition (3).

If $v = \varphi(x, t)$, $E = \chi(x, t)$, $n = \psi(x, t)$ is some solution of (2) which satisfies (3); then the functions

$$\left.\begin{aligned} v &= \varphi(\bar{x}, \bar{t}) - R\sin(t-\theta), \\ E &= \chi(\bar{x}, \bar{t}) + R\cos(t-\theta), \\ n &= \psi(\bar{x}, \bar{t}) \end{aligned}\right\} \qquad (16)$$

are also solutions of (2) which satisfy (3). Here

$$\bar{t} = t + a,$$
$$\bar{x} = x + b - R\cos(t-\theta),$$

and a, b, R, and θ are arbitrary constants.

A simple illustration of the use of Eqs. (16) is to generalize the trivial solution E = 0, v = 0, n = 1, from which we find

$$\left.\begin{aligned} E &= R\cos(t-\theta), \\ v &= -R\sin(t-\theta), \\ n &= 1, \end{aligned}\right\} \qquad (17)$$

i.e., a plasma wave with $\lambda \to \infty$.

We note in conclusion that solutions (9) can be generalized by means of Eqs. (16); in particular, this holds for the solutions found in ref. 4 and for any other solutions of system (2) which satisfy condition (3).

The authors thank V. N. Oraevskii for guidance.

Aperiodic instability in a plasma gap with external feedback

A. N. Igritskii

Moscow Engineering-Physics Institute

(Submitted July 12, 1973)
Zh. Tekh. Fiz., 44, 1137-1142 (June 1974)

A complete numerical solution is found for the dispersion relation for nonlinear aperiodic electrostatic waves in a homogeneous plasma gap. The nonlinear instability of the stable solutions with an adiabatic change in the boundary conditions is discussed. The nonlinear growth rate is much larger than the linear growth rate. The sensitivity of the growth rate to C and R elements in the external feedback circuit is analyzed.

INTRODUCTION

When an electron beam passes through a system with electrodes on which an external feedback circuit maintains specified boundary conditions an electrostatic instability can be excited.[1-3] This instability limits the current that can be carried by a neutralized electron beam. In the case of nonrelativistic beams this current is only a few times larger than the limiting current in vacuum, which is limited by the space charge of the beam. The problem of limiting currents and the stability of relativistic electron beams in plasmas have been analyzed in detail.[4] The instability can be suppressed by introducing a suitable feedback circuit.[5] The effect of feedback on the wave spectrum of a plasma in a limited volume (generalized boundary conditions) is analyzed in ref. 6. The instability in a one-dimensional plasma-filled gap is treated only in the linear approximation in refs. 1-3. The stability of nonlinear, steady-state potential distributions in such a system is analyzed qualitatively in ref. 7 for arbitrary initial distribution functions of the emitted electrons and ions. The nonlinear theory of the instability of a monoenergetic electron beam in a system with electrodes is treated in ref. 8, where certain particular growth rates are determined. The effects associated with the introduction of an arbitrary external feedback circuit, the equivalent circuit of the plasma-filled gap at frequencies low in comparison with the plasma frequency, and the end result of the nonlinear evolution are analyzed in ref. 9.

In this work we discuss a numerical solution of the dispersion relation for a nonlinear aperiodic electrostatic instability in a one-dimensional plasma-filled gap; the nonlinear instability of the stable solutions with an adiabatic change in the boundary conditions is also described. The nonlinear growth rates are shown to be much larger than the growth rates of the linear theory. The effect of an external feedback circuit (an RC circuit) on the growth rates is analyzed qualitatively.

1. The nonlinear dispersion relation for the electrostatic mode[7,9]

$$\left.\begin{aligned}\varphi(\xi)&=\varepsilon\sin\psi\left(1-\frac{\varepsilon}{2}\sin\psi\right),\\ \psi&=\xi+\varepsilon(1-\cos\psi)\end{aligned}\right\}\qquad(1)$$

is[8,9]

$$F(\xi,\ \psi\,|\,z)\equiv\xi-\frac{\psi}{1+z^2}+\frac{2z}{(1+z^2)^2}-\frac{e^{-z\psi}}{(1+z^2)^2}\left[(z^2-1)\sin\psi+2z\cos\psi\right]=0,\qquad(2)$$

where $\xi = L/r_d$; $\varepsilon = (eE_0r_d)/(mv_0^2)$; $\varphi = (e\varphi_L)/(mv_0^2)$; $r_d = v_0[(4\pi e^2n_0)/m]^{-1/2}$, L is the distance between the electrodes between which a constant potential difference φ_L is maintained, E_0 is the steady-state value of the electric field at the emitter, and v_0 and n_0 are the initial velocity and density of the electron beam. Here, n_0 is the density of the homogeneous, fixed ion background. The small perturbations of steady-state distribution (1) are given by ~ exp(zt), with $z = \gamma + i\omega$.

The equation

$$|\operatorname{Im}F(\xi,\ \psi\,|\,\gamma\pm i)|=\int_0^{\psi}(\psi-\alpha)\sin^2\alpha\, e^{-\gamma\alpha}d\alpha=0$$

has no solutions for any finite γ; we can thus write (2) in the equivalent form

$$P_4(\xi,\ \psi\,|\,z)=e^{-z\psi}Q_2(\xi,\ \psi\,|\,z),\qquad(3)$$

where

$$\begin{aligned}P_4&\equiv\xi z^4+(2\xi-\psi)z^2+2z+\xi-\psi,\\ Q_2&\equiv(z^2-1)\sin\psi+2z\cos\psi.\end{aligned}$$

Dispersion relation (3) has a special branch of solutions corresponding to an aperiodic instability $\omega = 0$, $\gamma \neq 0$, with the asymptotic value

$$\gamma_{as}=-\operatorname{ctg}\left(\frac{\psi-k\pi}{2}\right).\qquad(4)$$

which is independent of ε. Furthermore, at points $\psi_{01} = 2\operatorname{arc\,cot}\varepsilon$ and $\psi_{02} = 2k\pi$ there are solutions with $\gamma = 0$. Treating small deviations of the growth rate from the value $\gamma = 0$, setting $\psi = \psi_{0i} + \lambda$, where $|\lambda| \ll \psi_{0i}$ (i = 1, 2), and expanding (3) in powers of the deviations γ and λ, we find

$$a_{10}\lambda+a_{01}\gamma+a_{11}\gamma\lambda+a_{20}\lambda^2+a_{02}\gamma^2=0,\qquad(5)$$

where

$$\left.\begin{aligned}a_{10}&=\cos\psi-\varepsilon\sin\psi,\\ a_{01}&=-\psi\sin\psi+2(1-\cos\psi),\\ a_{11}&=\sin\psi-\psi\cos\psi,\\ a_{20}&=-\frac{1}{2}(\varepsilon\cos\psi+\sin\psi),\\ a_{02}&=\frac{1}{2}\psi^2\sin\psi+\psi(1+2\cos\psi)-3\psi.\end{aligned}\right\}\qquad(5')$$

From (5) we find

$$\gamma=\frac{1+\varepsilon^2}{1-\frac{\varepsilon\psi}{2}}\frac{\lambda}{4}-\frac{1}{(a_{01})^2}\left[a_{20}a_{01}+a_{11}+\frac{a_{02}}{a_{01}}\right]\lambda^2+O(\lambda^3) \tag{6a}$$

for $\psi = \psi_{01}$, and

$$\gamma=\pm\sqrt{-\lambda/3\psi}+\frac{1}{9}\lambda+O(\lambda^{3/2}) \tag{6b}$$

for $\psi = \psi_{02}$, with $\lambda \leq 0$.

When $\psi = \psi_{02}$ the complex frequency is

$$\left.\begin{aligned}\omega&=\pm\frac{1}{\sqrt{3\psi}}\lambda^{1/2}\pm\frac{1}{\sqrt{3\psi}}\left(\frac{7}{108}\psi+\frac{\varepsilon}{4}+\frac{1}{3\psi}\right)\lambda^{3/2}+O(\lambda^{5/2}),\\ \gamma&=\frac{1}{9}\lambda-\frac{2}{27}\left(\frac{\psi}{3}+\frac{2}{\psi}\right)\lambda^2+O(\lambda^3);\ \lambda>0.\end{aligned}\right\} \tag{7}$$

Equation (7) shows that the points $\xi = \psi = 2k\pi$ are not boundary points separating the unstable from the stable regions, as was previously assumed.[7] In fact, when the sign of λ is changed, i.e., when the points $\xi = 2k\pi$ are passed, we find another branch, with $\omega \neq 0$ and $\gamma > 0$; in other words, the solution remains unstable, but quasiperiodic growing solutions appear, since $|\omega| \gg \gamma$. At the same points, $\xi = 2k\pi$, the solutions of the equation are also unstable and, for small perturbations, are of the form const·t. Thus, each solution of Eq. (3) has a quasiperiod of 2π in the sense that the solutions are qualitatively similar at these intervals. Furthermore, at the points $\xi = 2k\pi$ $(k \geq 1)$, solutions with $|\omega| \gg \gamma$ and $\gamma > 0$ are generated, at least near these points.

Figure 1 shows the complete numerical solution of the equation for the aperiodic instability for the limiting nonlinearity cases $\varepsilon = 0$ and ± 1. Let us discuss certain features of these $\gamma = \gamma(\xi)$ curves.

With $\psi = 2\,\text{arc cot}\,\varepsilon$ it follows from (6) that in the case $\varepsilon > 0$ there is always some ψ such that the coefficient of λ becomes negative: $(2-\varepsilon\psi)^{-1} < 0$. The result is the typically nonlinear functional dependence of the growth rate on the external parameters ξ (Fig. 2). This behavior of γ corresponds to the collapse of the stable solutions: By adiabatically changing n_0 and holding L = const, i.e., by changing $\xi \sim \sqrt{n_0}$, we find that there is an electron flux density $n_0 = n_{0\,cr}$ which cannot be exceeded without the rapid onset of instability. This effect cannot be observed in a real system, since a continuous transition to the unstable region is possible even at lower values of n_0. This conclusion follows from the circumstance that the collapse requires that the condition $\varepsilon\psi > 2$ be satisfied, while the first value $\psi \equiv 2\,\text{arc cot}\,\varepsilon$ does not satisfy this condition. Accordingly, collapse can occur only beyond a Debye length. It is not difficult to evaluate γ at the collapse point directly from (3): Assuming $\gamma > 0$ and $1/\psi \ll \gamma \ll 1$, we find

$$\gamma\approx\sqrt{\frac{\varepsilon(1-\cos\psi)}{\xi}}=\sqrt{\frac{2\varepsilon}{\varepsilon^2+1}}\,\xi^{-1/2}. \tag{8}$$

Analysis of Eq. (3) and Fig. 1 reveals two markedly different solution regions, $|z| \gg 1$ and $|z| \ll 1$. At $|z| \gg 1$, the plasma properties of the system become inconsequential, and only the stable vacuum properties are manifest; here, $\gamma < 0$ and the nonlinearity has a weak influence on the values of γ in this region. In region $|z| \ll 1$, we can distinguish between the two subregions $|z\psi| \ll 1$ and $|z\psi| \gg 1$: The first corresponds to a quasisteady-state change in the boundary conditions, for which the transit time of the particles through the system is much shorter than the characteristic time for this change in boundary conditions. The steady-state potential distributions transform continuously into the distributions which are most similar to the steady-state distributions.

Generally speaking, the second subregion can exist only when $\psi \gg 1$, at least beyond a Debye length. This subregion also corresponds to a critical change in the boundary conditions, but here the plasma sheath is so large that the signal cannot pass through it. The part of the plasma-filled gap nearest the emitter – the part through which the signal carrying information about the change in the boundary conditions has already passed – displays plasma properties, while the rest of the system is equivalent to a vacuum gap. At $\varepsilon > 0$ a large part of each plasma period is unstable with respect to the feedback chosen, while at $\varepsilon < 0$ we have the opposite situation. Accordingly, at $\varepsilon > 0$ those periods through which the signal has already propagated are unstable on the average and they amplify the signal more, the larger ε. In the case of pronounced nonlinearity ($|\varepsilon| \sim 1$) and a large plasma sheath, the instability predominates. This behavior is seen in the collapse regions, where $\gamma \sim 1/\sqrt{\psi}$ and where $\varepsilon\psi > 2$. A general manifestation of the nonlinearity is the appearance in the aperiodic instability of growth rates $\gamma \sim 1/\sqrt{\psi} > 0$, while as $|\varepsilon| \to 0$ we have $\max\gamma \sim 1/\psi$. Hence

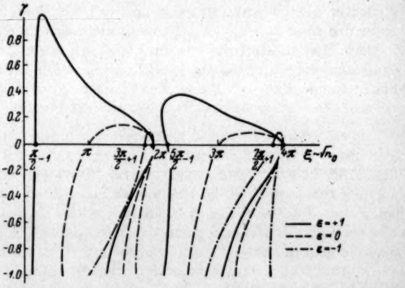

Fig. 1. Growth rate of the aperiodic instability γ/ω_0, as a function of the parameter $\xi\ [n_0/(mv_0^2/4\pi e^2L^2)]^{1/2}$ for the limiting cases of the nonlinearity: $\varepsilon = eE_0r_d/mv_0^2 = 0, \pm 1$.

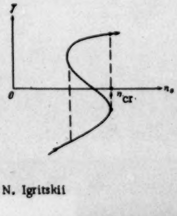

Fig. 2. Behavior of the growth rate for the aperiodic instability near the critical density (qualitative).

$\gamma_{\text{non}} \gg \gamma_{\text{lin}}$, and the nonlinear effects not only do not confine the growing instability; they even amplify it.

2. If we introduce a complex impedance

$$Z_{\text{fb}}(z)=\frac{1}{C}+Rz \tag{9}$$

in the feedback circuit, we can rewrite dispersion relation (3) as

$$F(\xi,\ \psi\,|\,z)+\frac{1}{C}+Rz=0. \tag{10}$$

The solutions z of this equation for $\omega = 0$ have the same asymptotic behavior as before [Eq. (4)]. The values of ψ_{01} and ψ_{02} corresponding to the value $\gamma = 0$ are now given by the equation

$$\sin\psi-\varepsilon(1-\cos\psi)+\frac{1}{C}=0. \tag{11}$$

It follows that with

$$\frac{1}{C}>\varepsilon+\sqrt{1+\varepsilon^2} \tag{12}$$

there are no values with $\gamma = 0$ in the aperiodic branch; by virtue of the continuity of the solution, all the values of γ are negative. This choice of C thus stabilizes the system with respect to perturbations with $\omega = 0$. This result cannot be extended to arbitrary z. Using $Z_{\text{fb}} = 1/C$ and (3), we rewrite (10) as

$$P_4\left(\xi+\frac{1}{C},\ \psi\,|\,z\right)=e^{-\varepsilon\psi}Q_2(\xi,\ \psi\,|\,z). \tag{13}$$

Apply Rouché's theorem to (13), we find that in the right half-plane ($\gamma > 0$) we have

$$\left|\left(\xi+\frac{1}{C}\right)(\omega^2-1)+\psi\right|>|\sin\psi|, \tag{14}$$

if this inequality holds at the $\gamma = 0$ axis even under condition (12). We conclude that the number of roots of Eq. (13) in the right half-plane is equal to the number of roots of the polynomial $P_4[\xi+(1/C),\ \psi|z)$ in this region, i.e., two, as is easily seen. The oscillatory instability with $\omega \neq 0$ is thus retained, so that additional elements must be used in the feedback circuit to make the system quasisteady-state.

To illustrate the consequence of a passive resistance R, we assume it to be large; then (6) becomes

$$\gamma\approx\begin{cases}\left(R+\dfrac{4-2\varepsilon\psi}{\varepsilon^2+1}\right)^{-1}\lambda; & \psi=\psi_{01},\\ -\dfrac{1}{R}\lambda; & \psi=\psi_{02}.\end{cases} \tag{15}$$

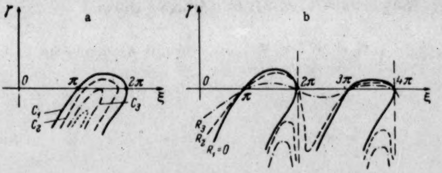

Fig. 3. Effect of capacitive feedback (a) and of a passive resistance (b) on the functional dependence of the growth rate on ξ (qualitative). a) $C_1 = \infty$; $C_3 < C_2 < C_1$; b) $0 = R_1 < R_2 < R_3$.

Figure 3a gives a qualitative idea of the effect of capacitive feedback and of a passive resistance R.

CONCLUSION

1. Numerical and approximate analytic solutions show that in the case of a pronounced nonlinearity the stable solutions collapse into the unstable region, after the first period.

2. The growth rates of the linear theory are increased when the nonlinearity is taken into account. Accordingly, nonlinear effects do not suppress a growing instability; on the contrary, they amplify it.

3. At the points $\xi = 2k\pi$ which are also unstable, small perturbations grow in proportion to the time. Furthermore, a quasiperiodic instability is generated at them under the condition $k \geq 1$ with $|\omega| \gg \gamma$ and $\gamma > 0$.

4. The introduction of small capacitances into the external feedback circuit makes the system completely stable with respect to aperiodic perturbations.

In conclusion the author thanks V. M. Smirnov for useful comments and fruitful discussion.

Magnetodrift waves in a finite-β plasma

N. M. Ryzhov, V. L. Sizonenko, V. A. Suprunenko, E. A. Sukhomlin, and Yu. V. Gutarev

(Submitted July 30, 1973)
Zh. Tekh. Fiz., 44, 1143-1150 (June 1974)

The low-frequency magnetodrift instability is studied in the finite-β plasma of an electrodeless induction discharge (a theta pinch). The instability is of a kinetic nature ($\omega \ll k_z v_{Te}$) and results from a mechanism that thermalizes the electrons accelerated by the induction electric field. The peak magnetic field of the waves is comparable to the main magnetic field.

INTRODUCTION

The excitation of electrostatic drift waves in a collisionless, low-β plasma ($\beta \equiv 8\pi n_0 T/H_z^2 \ll 1$) has been studied in detail (see, e.g., refs. 1 and 2 and the literature cited there). In a finite-β plasma ($\beta \geqslant 1$), on the other hand, it has been shown theoretically[3,4] that Alfvén and magnetosonic drift waves can also be excited; these waves, which are electromagnetic, have been called "magnetodrift waves." Although experiments on the excitation of drift waves in a finite-β plasma are of considerable interest in connection with several practical applications, they have received little attention.

We report here a study of magnetodrift waves in the plasma of an electrodeless induction discharge (a theta pinch). We show that the drift waves observed in the finite-β plasma have magnetic-field oscillations of a high amplitude, comparable to the main magnetic field.

EXPERIMENTAL PROCEDURE

A pulsed magnetic field with H_z up to 34 kOe is produced by discharging a 16-kJ capacitor bank into a single-turn coil 8 cm in diameter and 32 cm long. The half-period is 5.6 μsec.

The plasma is produced in a ceramic tube 150 cm long, with an inside diameter of 6.5 cm, filled with hydrogen at a pressure between 1 and 20 torr. Figure 1 shows the overall arrangement of the apparatus with the diagnostic devices. The geometric dimensions of the apparatus are chosen to provide minimum curvature of the magnetic lines of force in the working region and thus to prevent the possible excitation of the ordinary hydromagnetic instability, which has been studied in detail by many workers. In these experiments the condition

$$\frac{R}{a} > \left(\frac{a}{\rho_{Bi}}\right)^2$$

is satisfied easily, ensuring that there will be no hydromagnetic instability[2] (Fig. 2). Here R is the radius of curvature of the magnetic lines of force in the working part of the discharge, a is the plasma radius, and ρ_{Bi} is the ion gyroradius.

Figure 3 shows oscillograms of the magnetic field obtained by a magnetic probe for two cases: 1) The probe is in the central part of the discharge, where the magnetic field is homogeneous and where the hydromagnetic instability cannot be excited (curve 1 in Fig. 3); 2) the probe is near the edge of the coil, where the magnetic lines of force are highly curved (curve 2 in Fig. 3).

The low-frequency oscillations of the magnetic field observed on these two oscillograms clearly differ in shape and amplitude. We assume that in the region of high curvature the oscillations of the magnetic field are due to the excitation of the hydromagnetic instability at the ends of the discharge, while in the central part of the discharge we assume nonhydromagnetic instability, whose amplitude is of the order of the vacuum magnetic field at $\beta \sim 1$. Below, we identify this wave branch as corresponding to a magnetodrift wave of the magnetosonic type.

EXPERIMENTAL RESULTS

Curve 1 in Fig. 4 shows clearly that this low-frequency instability is excited only at a certain time t, at which completely definite relations have been established among the discharge parameters.

Analysis of the electron temperature as measured by the x-ray probes[5] (curve 3 in Fig. 4) and of the superthermal microwave emission from the discharge near the upper hybrid frequency (curve 2 in Fig. 4) shows that a high-frequency instability due to electron acceleration by the induction electric field of the theta pinch is excited in the plasma at time t, before the low-frequency magnetodrift instability is excited. This instability, which

causes rapid turbulent heating of the plasma electrons in the central part of the discharge, is known[6] to be of a resonance nature and is excited when one of the even harmonics of the electron gyrofrequency lies near the upper hybrid frequency, $n\omega_{Be} = \sqrt{\omega_{pe}^2 + \omega_{Be}^2}$.

The thermalization of the accelerated electrons and the nearly instantaneous turbulent plasma heating in the central part of the discharge provide conditions suitable for the excitation of a low-frequency magnetodrift wave.

In these experiments, the plasma electron temperature reaches several keV at a plasma density of $10^{14}\,\text{cm}^{-3}$, corresponding to an equilibrium value $\beta_p \simeq 0.5$ [here $\beta_p \equiv 8\pi n_0(0)T_e(0)/H_z^2(a)$] before the low-frequency instability is excited. It should be noted that the ions remain essentially cold.

The diamagnetic effect related to this heating causes a pronounced radial gradient of the magnetic field (curve 1 in Fig. 5). Curve 2 in Fig. 5 shows the radial profile of the magnetic field 1 μsec after the excitation of the high-frequency starting instability, at which time the low-frequency instability has been excited. We see a wave structure whose half-wavelength is of the order of the magnetic field gradient. The corresponding radial wave vector k_r is

$$k_r = \frac{2\pi}{\lambda_r} \sim \frac{1}{H_z}\frac{\partial H_z}{\partial r} \simeq 1.7\ \text{cm}^{-1}.$$

Curve 3 in Fig. 5 shows the amplitude of this wave along the radius of the plasma column; this instability develops primarily in the central part of the discharge, where the electron heating is most pronounced (curve 4 in Fig. 5).

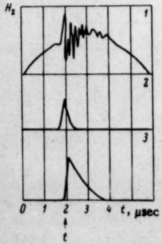

Fig. 4. 1) Oscillogram of the magnetic field; 2) microwave emission from the plasma at 8 mm; 3) signal from the x-ray probe.

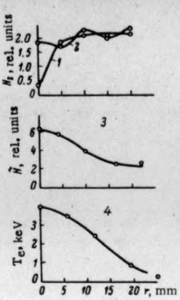

Fig. 5. Radial distribution of: 1) the magnetic field, before the excitation of the magnetodrift instability; 2) longitudinal magnetic field 1 μsec after the excitation of the magnetodrift instability; 3) amplitude of the magnetodrift waves; 4) electron temperature.

Figure 6 shows the amplitude and frequency of the low-frequency magnetodrift waves as functions of the initial hydrogen pressure. The bell-shaped functional dependence of the electron temperature on the initial pressure is due to the resonance properties of the initial high-frequency instability.[6] An important result of these experiments is the similarity of the functional dependences of all these quantities. On the basis of this similarity we conclude that the parameters of the low-frequency instability have the monotonic functional dependence on the electron temperature shown in Fig. 7.

A distinctive feature of this instability is the presence of a wave structure along the magnetic field ($k_z \neq 0$). The curves in part 1 of Fig. 8 are oscillograms of the signals from magnetic probes located 24 cm apart along the magnetic field. On the basis of a correlation analysis of these signals we can plot the phase of the first temporal harmonic of these waves along the axis of the system (curve 2 in Fig. 8). The wavelength found in this manner is 70 cm, i.e., the half-wavelength is roughly half the length of the coil. We find the corresponding value $k_z = 2\pi/\lambda_z \approx 0.1$. Over the interval of the phase measurements there is no appreciable axial gradient of the magnetic field before the waves appear (Fig. 2). The corresponding values for the second temporal harmonic are $\lambda_z = 35$ cm and $k_z \approx 0.2$ (curve 3 in Fig. 8).

The azimuthal structure of the instability is studied by means of three magnetic probes at various azimuthal positions and at equal distances from the center of the plasma. Figure 9 shows the wave phase as a function of the azimuthal angle.

This instability can be pictured as a cylindrical mag-

netic tube with radius of the order of the dimension of the hot part of the plasma column, slightly bent in the radial direction and rotating around the geometric axis of the system at an angular velocity of the order of 10^7 sec^{-1}.

THEORY OF MAGNETODRIFT WAVES IN A FINITE-β PLASMA

Mikhailovskii and Fridman[4] have analyzed the excitation of magnetosonic drift waves in a finite-β plasma. We use their results to describe a possible mechanism for the excitation of the waves in these experiments. For this purpose, however, we require an analysis, more detailed than that of ref. 4, of the magnetodrift waves in a plasma with $T_e \gg T_i$, whose frequencies ω and wave vectors **k** satisfy

$$\omega \ll \omega_{Bi}, \quad k_\perp v_{Ti} \ll \omega_{Bi}, \quad k_z v_{Ti} \ll \omega \ll k_z v_{Te}. \tag{1}$$

Turning to this analysis, we start from the dispersion relation for unstable waves in the local approximation [Eq. (2.10) of ref. 4]:

$$k^2 \varepsilon_0 \left(\frac{k^2c^2}{\omega^2} - \varepsilon_2\right) + \alpha_2^2 = 0, \tag{2}$$

where ε_0, ε_2, and α_2 are determined with the help of inequalities (1):

$$\varepsilon_0 = \frac{\omega_{pi}^2}{\omega_{Bi}^2} - \frac{\omega_{pi}^2}{\omega^2}\cos^2\theta + \frac{\omega_{pi}^2(\varkappa_n - \varkappa_B)}{k_\perp \omega \omega_{Bi}}$$
$$+ \frac{\omega_{pe}^2}{k^2 v_{Te}^2}\left[1 + i\sqrt{\frac{\pi}{2}}\frac{\omega}{k_z v_{Te}}\left(1 - \frac{\omega_n}{\omega} + \frac{\omega_T}{2\omega}\right)\right],$$
$$\varepsilon_2 = -2\frac{k_\perp^2 v_{Ti}^2}{\omega_{Bi}^2}\frac{\omega_{pi}^2}{\omega^2} + i\sqrt{2\pi}\frac{\omega_{pe}^2}{\omega k_z v_{Te}}\frac{k_\perp^2 v_{Te}^2}{\omega_{Be}^2}\left(1 - \frac{\omega_n}{\omega} - \frac{3\omega_T}{2\omega}\right),$$
$$\alpha_2 = -\frac{k_\perp \omega_{pe}^2}{\omega \omega_{Be}}\left[1 + i\sqrt{\frac{\pi}{2}}\frac{\omega}{k_z v_{Te}}\left(1 - \frac{\omega_n}{\omega} - \frac{\omega_T}{2\omega}\right)\right].$$

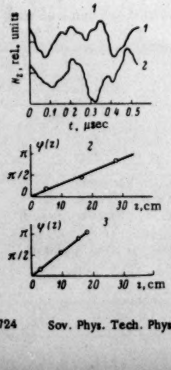

Fig. 8. Correlation analysis of the magnetodrift waves. 1) Magnetodrift waves according to probes 24 cm apart along the axis of the system, in the homogeneous part of the magnetic field; 2) profile of the phase of the standing wave along the axis, for the first temporal harmonic of the wave; 3) the same, for the second harmonic.

Here θ is the angle between **k** and H_z ($\cos\theta \equiv k_z/k \ll 1$), $\omega_{p\alpha} \equiv \sqrt{4\pi e_\alpha^2 n_0/m_\alpha}$ is the plasma frequency, $\omega_{B\alpha} \equiv e_\alpha H_z/m_\alpha c$ is the gyrofrequency of particles of species α (α = e,i; $e_e = -e_i < 0$), $\varkappa_{n,T,B} \equiv \mathrm{grad}\ln(n_0, T_e, H_z)$, and $\omega_{n,T} \equiv k_\perp T_e/(m_e\omega_{Be})\varkappa_{n,T}$.

We also use the equation $\varkappa_B = -(1/2)\beta(\varkappa_n + \varkappa_T)$, which follows from the pressure-balance equation $H_z^2/8\pi + n_0 + n_0T_e$ = const.

Using the condition $T_i \ll T_e$ and neglecting terms containing T_i in (2), we convert Eq. (2) to

$$\left[1 + \frac{k_\perp^2 v_s^2}{\omega_{Bi}^2} - \frac{k_z^2 v_s^2}{\omega^2} - \frac{\omega_n}{\omega}\left(1 - \frac{\varkappa_B}{\varkappa_n}\right) + i\sqrt{\frac{\pi}{2}}\frac{\omega}{k_z v_{Te}}\left(1 - \frac{\omega_n}{\omega} + \frac{\omega_T}{2\omega}\right)\right]$$
$$\times\left[1 - i\sqrt{\frac{\pi}{2}}\frac{\omega}{k_z v_{Te}}\beta\left(1 - \frac{\omega_n}{\omega} - \frac{3\omega_T}{2\omega}\right)\right]$$
$$+ \frac{\beta}{2}\left[1 + i\sqrt{\frac{\pi}{2}}\frac{\omega}{k_z v_{Te}}\left(1 - \frac{\omega_n}{\omega} - \frac{\omega_T}{2\omega}\right)\right]^2 = 0,$$
$$v_s \equiv \sqrt{\frac{T_e}{m_i}}. \tag{3}$$

Now, assuming the imaginary terms $\sim i(\omega/k_z v_{Te})$ in (3) to be small, we find that Eq. (3) has the two solutions $\omega = \omega_{1,2} + i\gamma_{1,2}$ ($|\gamma_{1,2}| \ll |\omega_{1,2}|$), where

$$\omega_{1,2} = \frac{1}{2}\omega_n\left(1 - \frac{\varkappa_B}{\varkappa_n}\right)\left(1 + \frac{\beta}{2} + \frac{k_\perp^2 v_s^2}{\omega_{Bi}^2}\right)^{-1}$$
$$\times\left\{1 \pm \left[1 + 4\frac{k_z^2 v_s^2}{\omega_n^2}\left(1 - \frac{\varkappa_B}{\varkappa_n}\right)^{-2}\left(1 + \frac{\beta}{2} + \frac{k_\perp^2 v_s^2}{\omega_{Bi}^2}\right)\right]^{1/2}\right\},$$
$$\gamma_{1,2} = -\sqrt{\frac{\pi}{8}}\frac{\omega_{1,2}^2}{k_z v_{Te}}\left(1 + \frac{\beta}{2} + \frac{k_\perp^2 v_s^2}{\omega_{Bi}^2}\right)^{-1}\left\{1 \pm \left[1 + 4\frac{k_z^2 v_s^2}{\omega_n^2}\left(1 - \frac{\varkappa_B}{\varkappa_n}\right)^{-2}\right.\right.$$
$$\left.\left.\times\left(1 + \frac{\beta}{2} + \frac{k_\perp^2 v_s^2}{\omega_{Bi}^2}\right)\right]^{-1/2}\right\}^{-1}\left[\left(1 + \beta + \frac{1}{2}\beta^2\right)\left(1 - \frac{\omega_n}{\omega_{1,2}}\right)\right.$$
$$\left. + \frac{\omega_T}{2\omega_{1,2}}\left(1 - \beta - \frac{3}{2}\beta^2\right)\right]. \tag{4}$$

The wave branch with frequency ω_1 in a low-β plasma ($\beta \to 0$, $\varkappa_B/\varkappa_n \to 0$) was first studied by Rudakov and Sagdeev,[7] who neglected the ion inertia ($k_\perp^2 v_s^2/\omega_{Bi}^2 \to 0$); Kadomtsev and Timofeev[8] took inertia into account.

It follows from (4) that the growth rate γ_1 increases with decreasing k_z, and under the condition

$$4\frac{k_z^2 v_s^2}{\omega_n^2}\left(1 - \frac{\varkappa_B}{\varkappa_n}\right)^{-2}\left(1 + \frac{1}{2}\beta + \frac{k_\perp^2 v_s^2}{\omega_{Bi}^2}\right) \ll 1$$

it is

$$\gamma_1 = \frac{1}{4}\sqrt{\frac{\pi}{2}\frac{m_e}{m_i}}\frac{\varkappa_n^2 v_s}{k_z}\frac{k_\perp^2 v_s^2}{\omega_{Bi}^2}\left(1 - \frac{\varkappa_B}{\varkappa_n}\right)\left(1 + \frac{1}{2}\beta + \frac{k_\perp^2 v_s^2}{\omega_{Bi}^2}\right)^{-3}$$
$$\times\left[\left(1 + \beta + \frac{1}{2}\beta^2\right)\left(\frac{\varkappa_B}{\varkappa_n} + \frac{1}{2}\beta + \frac{k_\perp^2 v_s^2}{\omega_{Bi}^2}\right)\right.$$
$$\left. + \frac{\varkappa_T}{2\varkappa_n}\left(\frac{3}{2}\beta^2 + \beta - 1\right)\left(1 + \frac{1}{2}\beta + \frac{k_\perp^2 v_s^2}{\omega_{Bi}^2}\right)\right]. \tag{5}$$

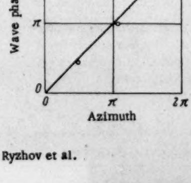

Fig. 9. Azimuthal profile of the phase of the magnetodrift wave for the first temporal harmonic.

The growth rate reaches a maximum at $k_\perp = k_0$, where k_0 is determined from

$$\left(\frac{k_0^2v_s^2}{\omega_{Bi}^2}\right)^2\left[1+\beta+\frac{1}{2}\beta^2+\frac{\varkappa_T}{2\varkappa_n}\left(\frac{3}{2}\beta^2+\beta-1\right)\right]-2\frac{k_0^2v_s^2}{\omega_{Bi}^2}\left(1-\frac{\varkappa_B}{\varkappa_n}\right)$$
$$\times\left(1+\beta+\frac{1}{2}\beta^2\right)-\left[\left(1+\frac{\beta}{2}\right)\left(1+\beta+\frac{1}{2}\beta^2\right)\left(\frac{\beta}{2}+\frac{\varkappa_B}{\varkappa_n}\right)\right.$$
$$\left.+\frac{\varkappa_T}{2\varkappa_n}\left(1+\frac{\beta}{2}\right)^2\left(\frac{3}{2}\beta^2+\beta-1\right)\right]=0. \tag{6}$$

When $\beta \gg 1$ and $\varkappa_n/\varkappa_T \sim 1$, we find $1 - \varkappa_B/\varkappa_n \approx \beta/2(1 + \varkappa_T/\varkappa_n)$, $k_0^2 = \beta(\omega_{Bi}^2/2v_s^2)p$, where

$$\left.\begin{aligned} p &\equiv \left(1+\frac{\varkappa_T}{\varkappa_n}\right)\left(1+\frac{3\varkappa_T}{2\varkappa_n}\right)^{-1}\\ &\times\left[1+\sqrt{1+\frac{\varkappa_T}{2\varkappa_n}\left(1+\frac{3\varkappa_T}{2\varkappa_n}\right)\left(1+\frac{\varkappa_T}{\varkappa_n}\right)^{-2}}\right],\\ \max\gamma_1 &= \sqrt{\frac{\pi}{8}\frac{m_e}{m_i}\frac{\varkappa_n^2v_s}{k_z}\frac{\beta^2}{4}\left(1+\frac{\varkappa_T}{\varkappa_n}\right)\frac{p}{(1+p)^3}\left[p+\frac{\varkappa_T}{2\varkappa_n}(1+3p)\right]},\\ \omega_1 &= -\varkappa_n v_s\sqrt{\frac{\beta}{2}\left(1+\frac{\varkappa_T}{\varkappa_n}\right)\frac{\sqrt{p}}{(1+p)}}. \end{aligned}\right\} \tag{7}$$

The second wave branch is easily seen to reach a maximum growth rate at

$$k_\perp \sim \frac{\omega_{Bi}}{v_s}\sqrt{1+\frac{1}{2}\beta},\quad k_z \sim \varkappa_n\sqrt{1+\frac{1}{2}\beta}, \tag{8}$$

and this growth rate is

$$\gamma_2 \sim |\varkappa_n| v_s\left(1+\frac{1}{2}\beta\right)^{3/2}\sqrt{\frac{m_e}{m_i}},\quad \omega_2 \sim \omega_n \sim \varkappa_n v_s\sqrt{1+\frac{1}{2}\beta}. \tag{9}$$

Obviously, only the first wave branch should be excited in our experiments, since the growth rate of the second branch is too small ($\gamma_2 \lessdot 10^6$ sec$^{-1} \ll \max\gamma_1$). The minimum values of k_z which can be used in (5) and (7) are governed by the length of the apparatus ($\min k_z \sim L^{-1}$), so that waves whose longitudinal wavelength is of the order of the length of the plasma column should be excited first. The conditions $\omega/k_zv_{Te} \ll 1$, $k_z^2v_s^2/\omega_n^2 \ll 1$ hold for these wavelengths. On the other hand, the condition $\gamma_1/\omega_1 \sim \sqrt{m_e/m_i\varkappa_n}L\beta^{2/3} \ll 1$ may not hold in the present experiments, since $\varkappa_nL \sim L/a \approx 10$ and since the local value of $\beta(r)$ at the center of the plasma is large: $\beta(0) \approx 5$–10. In this case Eq. (3) is also invalid, since the condition $\omega_{Me} \ll k_zv_{Te}$, no longer holds [here $\omega_{Me} = \varkappa_B k_\perp T_e/(m_e\omega_{Be})$ is the magnetodrift frequency, which appears in the resonant denominators $\omega - k_zv_z - \varepsilon\omega_{Me}$ of the dielectric tensor derived in ref. 4]. Since solutions (5), (7) constitute a limiting case of some more general solution of the dispersion relation, which also describes instabilities in the range $\omega_{Me} \sim k_zv_{Te}$, by extrapolating (5) and (7) to this range we find that in the present experiments magnetodrift waves with

$$\gamma \sim \omega \sim |\varkappa_n| v_s,\quad k_\perp \sim \frac{\omega_{Bi}}{v_s},\quad k_z \sim \frac{1}{L} \tag{10}$$

can be excited.

Estimates (10) agree with the experimental data: The wave growth is nearly aperiodic ($\gamma \sim \omega$), the wave frequency is a function of the temperature and a weak function of the amplitude of the external magnetic field, and the frequencies and wavelengths in (10) agree in order-of-magnitude terms with the experimental results. More precise agreement cannot be expected because the transverse wavelengths and the electron gyroradii are comparable to the radius of the plasma, so that the local approximation is not valid.

CONCLUSION

The instability in the present experiments is an electromagnetic wave whose frequency is much lower than the ion gyrofrequency, whose transverse wavelength is of the order of the plasma radius, whose longitudinal half-wavelength is of the order of the length of the homogeneous part of the magnetic field along the length of the coil, and whose azimuthal length is $2\pi a$. The amplitude of this instability has been shown experimentally to increase with increasing plasma electron temperature and to reach a large value after rapid turbulent plasma heating due to a high-frequency starting instability.

On the basis of this evidence we conclude that this instability is a branch of magnetodrift waves which are a natural continuation of electrostatic drift waves into the region of finite β.

The large wave amplitude observed indicates that this instability should strongly influence the plasma dynamics in a theta pinch.

The authors thank K. N. Stepanov for useful discussion of this work.

Zh. Tekh. Fiz., 44, 1151-1160 (June 1974)

Electron oscillations in a plasma sheath in a strong longitudinal magnetic field are investigated. The model of a thin plasma sheath is substantiated, and solutions of the simple wave type are found and analyzed. The wave interaction in a thin plasma sheath is solved exactly. Simple asymptotic expressions are derived from the exact equations for a number of cases of practical importance.

1. INTRODUCTION

It is well known that wave interaction in a nonlinear medium, in a plasma in particular, produces combination frequencies; the spectrum changes in the course of wave propagation. The evolution of the spectrum has been studied theoretically and experimentally.[1–6]

Wave interaction is normally described by asymptotic methods,[7,8] which make it possible, in the case of a small nonlinearity, to reduce the problem to a system of approximate (truncated) equations for the amplitudes of the interacting waves. The solution of the approximate system yields the spectrum of combination frequencies and its evolution, at least in the initial stage of the interaction process. This approach is acceptable for a weakly turbulent plasma, in which case the phases of the waves are random variables. In situations where the phases can be regarded as deterministic, however, the indicated approximation becomes inapplicable for large times or coordinates. In this case, as in the case of large initial amplitudes, a rigorous analysis is needed to describe the evolution of the waves. This situation arises, in particular, in the investigation of simple waves.

We have shown previously[9] that simple-wave solutions occur in the study of a thin plasma sheath in a strong longitudinal magnetic field. The wave-interaction problem reduces to the solution of a transcendental equation describing a simple wave excited by sinusoidal oscillations.

In the present work an exact solution is obtained for the problem of the oscillation spectrum at any point z of a thin plasma sheath. Simple asymptotic representations are found for several cases of practical importance. The resulting expressions describe the familiar steepening of the simple wave front. The latter effect accompanies the generation of harmonics and combination-frequency oscillations. For small amplitudes and short distances the expression describing the oscillation spectrum agrees with the result obtained by the method of truncated equations.[4] The well-known Bessel–Fubini equation follows from the same relation when only one wave is excited in the sheath.[10,11]

Simple waves in a thin plasma sheath are investigated below; an exact solution is found for any distance from the point z = 0 at which oscillations are excited at frequencies ω_1 and ω_2. Calculations yielding a number of useful asymptotic expressions are described.

2. WAVES IN A THIN PLASMA SHEATH

Consider a cold plasma sheath of thickness 2d located symmetrically about the plane x = 0 in the space between two conducting planes x = ±D at zero potential. The system is assumed to be homogeneous in the y direction. A magnetic field strong enough to permit only longitudinal motions of the electrons is applied in the z direction. The density n_0 of the unperturbed plasma is assumed to be constant throughout the sheath.

The electron oscillations in the sheath are described by the equations

$$\frac{\partial v}{\partial t}+v\frac{\partial v}{\partial z}=\frac{e}{m}\frac{\partial \varphi}{\partial z}, \tag{1}$$

$$\frac{\partial n}{\partial t}+\frac{\partial}{\partial z}(nv)=0, \tag{2}$$

$$\frac{\partial^2\varphi}{\partial x^2}+\frac{\partial^2\varphi}{\partial z^2}=\begin{cases}4\pi e(n-n_0), & |x|<d,\\ 0, & d<|x|<D,\end{cases} \tag{3}$$

in which conventional notation is used.

Taking account of the symmetry of the problem and transforming to dimensionless variables $\eta = x/D$ and $\zeta = z/L$, where L is the characteristic scale of the perturbation in the z direction (wavelength), we write the potential φ as a series:

$$\varphi_1=\sum_{n=0}^{\infty}\frac{\partial^{2n}\varphi(\eta,\zeta)}{\partial\eta^{2n}}\bigg|_{\eta=0}\frac{\eta^{2n}}{(2n)!},\quad |\eta|\leqslant\eta_d\equiv\frac{d}{D},$$

$$\varphi_2=\sum_{n=0}^{\infty}\frac{\partial^{n}\varphi(\eta,\zeta)}{\partial\eta^{n}}\bigg|_{\eta=\eta_d}\frac{(\eta-\eta_d)^{n}}{n!},\quad \eta_d\leqslant\eta\leqslant 1.$$

According to the Laplace equation

$$\frac{\partial^2\varphi_2}{\partial\eta^2}+\zeta_D^2\frac{\partial^2\varphi_2}{\partial\zeta^2}=0\quad\left(\zeta_D=\frac{D}{L}\right),$$

terms beginning with n = 2 can be neglected with error $O(\zeta_D^2)$ in the series φ_2 for $\zeta_D \ll 1$. Only the first two terms need be retained in the series φ_1 for $\eta_d \ll 1$, with error $O(\eta_d^4)$. The application of the matching conditions

$$\left(\varphi_1(\eta_d,\zeta)=\varphi_2(\eta_d,\zeta);\quad \frac{\partial\varphi_1(\eta,\zeta)}{\partial\eta}\bigg|_{\eta=\eta_d}=\frac{\partial\varphi_2(\eta,\zeta)}{\partial\eta}\bigg|_{\eta=\eta_d}\right)$$

and the boundary condition $[\varphi_2(1,\zeta) = 0]$ to φ_1 and φ_2 and the substitution of φ_1 into Eq. (3) then gives

$$\varphi=\begin{cases}-4\pi e(n-n_0)dD\left(1-\frac{\eta_d}{2}-\frac{\eta^2}{2\eta_d}\right), & |\eta|\leqslant\eta_D,\\ -4\pi e(n-n_0)dD(1-|\eta|), & \eta_D\leqslant|\eta|\leqslant 1.\end{cases}$$

Inasmuch as $\eta_d \ll 1$, inside the sheath with error $O(\eta_d)$ we have

$$\varphi = -4\pi e(n - n_0)\,dD. \tag{4}$$

Substituting (4) into (1) and writing $\lambda = 4\pi e^2 dD/m$, we obtain the equation

$$\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial z} + \lambda\frac{\partial n}{\partial z} = 0, \tag{5}$$

which, in conjunction with (2), determines n and v as functions of z and t.

The system of equations (2) and (5) has a solution in the form of simple waves. All variables in the simple waves are expressed in terms of one of them, for example the velocity v. In particular, the propagation velocity w of a point on the wave profile corresponding to a given value of the velocity v is itself a function of v. By definition

$$\frac{\partial v}{\partial t} + w\frac{\partial v}{\partial z} = 0, \tag{6}$$

so that the system (2)-(5) in combination with (6) implies the relations

$$\lambda n = (v - w)^2 \tag{7}$$

and

$$w = w_0\left(\pm 1 + \frac{3}{2}\frac{v}{w_0}\right), \tag{8}$$

in which $w_0 = \omega_0/\varkappa$, $\omega_0^2 = 4\pi e^2 n_0/m$, $\varkappa^2 = (dD)^{-1}$.

What is specific to the given problem is the designation of the particle velocity rather than the particle displacement as the primary function. Thus, the plasma is perturbed by the application of a modulating voltage at a certain point. It follows from (4), (7), and (8), however, that the velocity is then modulated by a corresponding relation at that point. Therefore, the problem of how to include the initial particle displacements having been eliminated, nonlinear "streaming" (a constant velocity component), which is directly attributable to that problem,[10,11] does not occur in the thin plasma sheath.

If an initial perturbation $v(0, t_0) = F(t_0)$ arises at the point $z_0 = 0$, the solution of Eq. (6) takes the form

$$v = F\left(t - \frac{z}{w(v)}\right). \tag{9}$$

Waves propagate in the plasma layer symmetrically about the excitation point $z_0 = 0$, so that we only consider $z > 0$ and, accordingly, choose the plus sign in (8).

If we consider the case of special significance, in which the initial perturbation is sinusoidal, we find that a wave with a changing profile propagates in the system; the slope of the wave front becomes steeper with increasing z, and harmonics of the fundamental frequency appear in the spectrum.[10,11]

With the intention of describing not only harmonic generation, but also wave interaction, we assume that the initial velocity perturbation represents a superposition of harmonics with frequencies ω_1 and ω_2 and amplitudes A_1 and A_2:

$$F(t_0) = \sum_{j=1}^{2} A_j \sin(\omega_j t_0). \tag{10}$$

Equation (9) then assumes the form

$$\xi = \sum_{j=1}^{2} a_j \sin\left(\psi_j + \frac{q_j\xi}{1+\xi}\right), \tag{11}$$

where

$$\xi = \frac{3}{2}\frac{v}{w_0},\quad a_j = \frac{3}{2}\frac{A_j}{w_0},\quad q_j = \frac{\omega_j z}{w_0},\quad \psi_j = \omega_j\tau,\quad \tau = t - \frac{z}{w_0}.$$

We now determine the values of ξ, τ, and z for which wave overturning takes place. In overturning $\partial\xi/(\partial z) = \infty$, the following equation follows from (11):

$$(1+\xi)^2 = \sum_{j=1}^{2} a_j q_j \cos\left(\psi_j + \frac{q_j\xi}{1+\xi}\right). \tag{12}$$

Since we are concerned with the minimum distance $z_{\min}$ at which overturning can take place, we augment (12) with the following expression, implied by the condition $\partial^2\xi/(\partial z^2) = 0$:

$$-2(1+\xi)^3 = \sum_{j=1}^{2} a_j q_j^2 \sin\left(\psi_j + \frac{q_j\xi}{1+\xi}\right). \tag{13}$$

The system of equations (11)-(13) determines $z_{\min}$ and the corresponding quantities $\xi_{\min}$ and $\tau_{\min}$.

We only estimate $z_{\min}$. We proceed from the fact that for any τ other than $\tau_{\min}$ the overturning distance calculated from Eqs. (11) and (12) must be greater than $z_{\min}$. If we choose $\tau = 0$, we infer from (11) that $\xi = 0$ as well, whereupon it follows from (12) that $z_{\min}$ and, thus, any z for which our solution is valid must satisfy the condition

$$a_1q_1 + a_2q_2 < 1. \tag{14}$$

If we regard ξ as a function of a_1 and a_2 we find that it has continuous partial derivatives $\partial^{n+m}\xi/(\partial a_1^n \partial a_2^m)$ (n, m ≥ 0) in the neighborhood of the point (0, 0). The derivatives all go to infinity "simultaneously" at a certain line in the plane $\{a_1, a_2\}$, and the condition for this event coincides with condition (12). This means that ξ is an analytic function of a_1 and a_2 up to overturning.

3. WAVE INTERACTION IN THE SHEATH

The problem at this stage is to derive the spectrum of combination frequencies from the transcendental equation (11) and to describe its evolution with z.

The analogous problem for the case of one harmonic perturbation has been solved[10,11] on the assumption that $a_1 \ll 1$.

The remainder of the analysis is carried out for the weaker condition $(a_1 + a_2) < 1$.

We rewrite (11), using an exponential relation for the sine:

$$\xi = \sum_{j=1}^{2} \frac{a_j}{2i} \left[e^{i\left(\psi_j + \frac{q_j \xi}{1+\xi}\right)} - e^{-i\left(\psi_j + \frac{q_j \xi}{1+\xi}\right)} \right], \tag{15}$$

and then we apply to (15) the equation for the generating function for Laguerre polynomials (see ref. 12, Table 8.975-1):

$$(1-z)^{-\alpha-1} \exp\left(\frac{xz}{z-1}\right) = \sum_{n=0}^{\infty} L_n^{\alpha}(x) z^n, \quad |z| < 1, \tag{16}$$

where

$$L_n^{\alpha}(x) \doteq \sum_{m=0}^{n} (-1)^m \binom{n+\alpha}{n-m} \frac{x^m}{m!}.$$

We find that

$$\xi = \sum_{n=0}^{\infty} \sum_{j=1}^{2} (-1)^n a_j G_n^{(j)} \xi^n, \tag{17}$$

where

$$G_n^{(j)} = \frac{e^{i\psi_j} L_n^{-1}(iq_j) - e^{-i\psi_j} L_n^{-1}(-iq_j)}{2i}. \tag{18}$$

As the condition for the applicability of (16) implies, Eq. (17) is valid for $(a_1 + a_2) < 1$.

We represent ξ as a double series:

$$\xi = \sum_{k,\, m=0}^{\infty} A_{km} a_1^k a_2^m, \tag{19}$$

which we use to obtain the relation

$$\xi^n = \sum_{k,\, m=0}^{\infty} \left(\sum_{\sum_{l=1}^{n} i_l = k,\ \sum_{l=1}^{n} j_l = m} \prod_{l=1}^{n} A_{i_l j_l} \right) a_1^k a_2^m. \tag{20}$$

Substituting (20) into (17) and comparing the result with (19), we have

$$\begin{aligned} \underset{k+m\neq 0;\ 1}{A_{km}} = \sum_{n=1}^{k+m-1} (-1)^n \Bigg\{ & G_n^{(1)} \sum_{\sum_{l=1}^{n} i_l = k-1,\ \sum_{l=1}^{n} j_l = m} \prod_{l=1}^{n} A_{i_l j_l} \\ & + G_n^{(2)} \sum_{\sum_{l=1}^{n} i_l = k,\ \sum_{l=1}^{n} j_l = m-1} \prod_{l=1}^{n} A_{i_l j_l} \Bigg\}. \end{aligned} \tag{21}$$

Equation (17) implies that

$$A_{00} = 0, \quad A_{10} = G_0^{(1)}, \quad A_{01} = G_0^{(2)}. \tag{22}$$

Using these values we obtain the coefficients A_{km} in explicit form from the recursion relation (21):

$$A_{km} = (-1)^{k+m-1} \frac{(k+m-1)!}{k!\,m!} \sum_{\sum_{l=1}^{k} i_l + \sum_{r=1}^{m} j_r = k+m-1} \prod_{l=1}^{k} G_{i_l}^{(1)} \prod_{r=1}^{m} G_{j_r}^{(2)}. \tag{23}$$

In (23) $k + m \neq 0$; all quantities associated with the index k(m) drop out for k = 0 (m = 0).

We use Eq. (18) to compute the derivative of the functions G:

$$\begin{aligned} \prod_{l=1}^{k} G_{i_l}^{(1)} \prod_{r=1}^{m} G_{j_r}^{(2)} = {} & \frac{1}{(2i)^{k+m}} \\ & \times \sum_{s=0}^{k} \sum_{f=0}^{m} (-1)^{s+f} \exp\{i[(k-2s)\psi_1 + (m-2f)\psi_2]\} \\ & \times \sum_{\sum_{l=1}^{k} x_l = (k-2s) i q_1,\ \sum_{r=1}^{m} y_r = (m-2f) i q_2} \prod_{l=1}^{k} L_{i_l}^{-1}(x_s) \prod_{r=1}^{m} L_{j_r}^{-1}(y_r), \end{aligned} \tag{24}$$

where each x and y in each term assumes one value from the respective sets $(iq_1, -iq_1)$ and $(iq_2, -iq_2)$.

The sum of the G products

$$P = \sum_{\sum_{l=1}^{k} i_l + \sum_{r=1}^{m} j_r = k+m-1} \prod_{l=1}^{k} G_{i_l}^{(1)} \prod_{r=1}^{m} G_{j_r}^{(2)}$$

acquires the following form after the substitution of (24) and a change in the order of summation:

$$\begin{aligned} P = \frac{1}{(2i)^{k+m}} & \sum_{s=0}^{k} \sum_{f=0}^{m} (-1)^{s+f} \exp\{i[(k-2s)\psi_1 + (m-2f)\psi_2]\} \\ & \times \sum_{\sum_{l=1}^{k} x_l = (k-2s) i q_1,\ \sum_{r=1}^{m} y_r = (m-2f) i q_2} \\ & \times \sum_{\sum_{l=1}^{k} i_s + \sum_{r=1}^{m} j_r = k+m-1} \prod_{l=1}^{k} L_{i_l}^{-1}(x_l) \prod_{r=1}^{m} L_{j_r}^{-1}(y_r). \end{aligned} \tag{25}$$

Applying the addition theorem for Laguerre polynomials:[12]

$$L_n^{\sum_{l=1}^{k} \alpha_l + k - 1} \left(\sum_{l=1}^{k} x_l \right) = \sum_{\sum_{l=1}^{k} i_l = n} \prod_{l=1}^{k} L_{i_l}^{\alpha_l}(x_l),$$

we find that the last sum in (25) is

$$L_{k+m-1}^{-1} \left(\sum_{l=1}^{k} x_l + \sum_{r=1}^{m} y_r \right).$$

After summation over x and y we find

$$\begin{aligned} P = \frac{1}{(2i)^{k+m}} & \sum_{s=0}^{k} \sum_{f=0}^{m} (-1)^{s+f} \exp\{i[(k-2s)\psi_1 + (m-2f)\psi_2]\} \\ & \times \binom{k}{s} \binom{m}{f} L_{k+m-1}^{-1} \{i[(k-2s) q_1 + (m-2f) q_2]\}. \end{aligned} \tag{26}$$

It then follows from (19), (23), and (26) that

$$\xi=\sum_{\substack{k=0\\ k+m\neq 0}}^{\infty}\sum_{m=0}^{\infty}\frac{(-1)^{k+m-1}(k+m-1)!}{(2i)^{k+m}k!\,m!}a_1^k a_2^m\sum_{s=0}^{k}\sum_{f=0}^{m}(-1)^{s+f}\exp\times\{i[(k-2s)\psi_1+(m-2f)\psi_2]\}\binom{k}{s}\binom{m}{f}L^{-1}_{k+m-1}\times\{i[(k-2s)q_1+(m-2f)q_2]\}. \tag{27}$$

Changing the order of summation on s, f and k, m in (27), we obtain ξ as a series in sines and cosines of the combination phase angles:

$$\xi=\sum_{\substack{l=0\\ l+p\neq 0}}^{\infty}\sum_{p=0}^{\infty}\sum_{k=0}^{\infty}\sum_{m=0}^{\infty}\frac{(-1)^{k+m-1}(2k+2m+l+p-1)!}{k!\,(k+l)!\,m!\,(m+p)!}\left(\frac{a_1}{2}\right)^{2k+l}\left(\frac{a_2}{2}\right)^{2m+p}\times\sum_{j=1}^{2}(-1)^{jp}\operatorname{Re}\{e^{i\psi_{lp}}(i)^{2m+2k+l+p}L^{-1}_{2k+2m+l+p-1}(iQ_{lp})\}, \tag{28}$$

where $Q_{lp} \equiv Q = lq_1 + (-1)^j pq_2$ is the combination argument describing the wave amplitude and $\psi_{lp} = l\psi_1 + (-1)^j p\psi_2$ is the combination phase.

Equation (28) is symmetric under the permutation of indices. This fact makes it possible to treat Q in the subsequent calculations as a positive quantity. The summation on j is not carried out in (28) for $l = 0$. The case in which $l = 0$ is obtained from the preceding case by a simple change of indices.

Equation (28) gives an explicit solution of the two-wave interaction problem. When $l = 1$ and $p = 0$ ($l = 0$, $p = 1$) we obtain the variation of the fundamental-frequency amplitudes with z. If p = 0 and m = 0 ($l = 0$, k = 0), we obtain the harmonic variation induced by the self-action of a wave; if p = 0 and m ≠ 0 ($l = 0$, k ≠ 0), we obtain the variation induced in the same harmonics by wave interaction. The case in which $l \neq 0$ and $p \neq 0$ gives the combination-frequency spectrum, where j = 1 corresponds to the red satellites, and j = 2 to the violet satellites.

Expression (28) can be simplified. We use the integral representation for the Laguerre polynomials (ref. 12, Table 6.631.10):

$$\int_0^{\infty}e^{-x^2}x^{2n+\mu+1}I_{\mu}(2x\sqrt{z})\,dx=\frac{n!}{2}e^{-z}z^{\frac{1}{2}\mu}L_n^{\mu}(z), \tag{29}$$

where

$$n=0,\ 1\ \ldots;\quad \operatorname{Re}\mu+n>-1. \tag{30}$$

The contour of integration in (29) is chosen so that the expression $e^{-x^2}x^{2n+\mu+2}I_{\mu}(2x\sqrt{z})$ is zero at its end points.[13]

Inasmuch as $\mu = -1$ and $n = 2m + 2k + l + p - 1$ in (28), the restriction (30) renders Eq. (29) invalid for the sets of indices (m = 0, k = 0, l = 1, p = 0) and (m = 0, k = 0, l = 0, p = 1), so that the case $l + p = 1$ requires special consideration.

Replacing the Laguerre polynomials in (28) in accordance with (29), changing the order of integration on x and of summation on k and m, and truncating the series thus formed, we obtain the expressions

$$\left.\begin{aligned}&\xi=\xi_1+\xi_2,\\ &\xi_1=2\sum_{m=1}^{2}\operatorname{Re}\left\{e^{i\psi_m}\left[\frac{a_m}{2i}(1-2R(q_m))+2M_{10}(q_m;\ a_m;\ a_k)\right]\right\},\\ &\xi_2=4\sum_{\substack{l=0\\ l+p\neq 0;\ 1}}^{\infty}\sum_{p=0}^{\infty}\sum_{j=1}^{2}(-1)^{jp+1}\operatorname{Re}\{e^{i\psi_{lp}}(-1)^{l+p}M_{lp}(Q;\ a_1;\ a_2)\},\end{aligned}\right\} \tag{31}$$

in which m + k = 3,

$$R(q_m)=e^{iq_m}(iq_m)^{1/2}\int_0^{\infty}e^{-x^2}I_{-1}(2x\sqrt{iq_m})\,dx, \tag{32}$$

$$M_{lp}(Q:a_1:a_2)=e^{iQ}(iQ)^{1/2}\int_0^{\infty}\frac{e^{-x^2}}{x^2}I_{-1}(2x\sqrt{iQ})\,I_s\left(\frac{a_1x^2}{i}\right)I_p\left(\frac{a_2x^2}{i}\right)dx. \tag{33}$$

The integration in (32) and (33) is carried out over the same contour; ξ_1 is the result obtained for cases with $l + p = 1$ when M_{10} is derived artificially without violating conditions (30) by the introduction of a term containing $R(g_m)$.

Because of the integral form of M_{lp} and R Eq. (31) provides a relatively simple means for obtaining asymptotic expressions and estimates.

4. ASYMPTOTIC REPRESENTATIONS

We first use the method of steepest descent to find asymptotic expressions for M_{lp} and R for $Q \gg 1$, making the change of variable $x = 2i\sqrt{iQy}$ in (32) and (33). If it is assumed that $y = \alpha + i\beta$, the change of variable makes it necessary to choose a contour of integration below the line $\beta = -\alpha$, and the expressions themselves assume the form

$$R(g_m)=2q_m e^{iq_m}\int_0^{\infty}e^{4iq_m y^2}I_1(-4q_m y)\,dy, \tag{32'}$$

$$M_{sp}=\frac{ie^{iQ}}{2}\int_0^{\infty}\frac{e^{4iQy^2}}{y^2}I_1(-4Qy)\,I_s(-4a_1Qy^2)\,I_p(-4a_2Qy^2)\,dy. \tag{33'}$$

The contour of integration C in (32') and (33') is assumed to consist of C_1 and C_2, where C_1 is the part of C on which $4Q|y| \ll 1$ and C_1 terminates inside the circular domain, in which $4Q|y^2| \ll 1$. It can be shown that M_{lp} can be made at least of order $O(1/Q^2)$ on C_1 for $l + p > 1$. Terms with R and M_{10} in ξ_1 cancel one another on C_1, because they become asymptotically equal and opposite in sign. Since $a_m q_m < 1$ in our problem, an error not greater than $O(1/q^2)$ is guaranteed.

The function $I_1(-4Qy)$ can be replaced on C_2 by its asymptotic representation

$$I_1(-4Qy)=\frac{1}{\sqrt{-2\pi Qy}}\cos\left(4Qy+\frac{3}{4}\pi\right)\left[1+O\left(\frac{1}{Q}\right)\right]. \tag{34}$$

The substitution of (34) into (32') and (33') yields

$$R(q_m)=\sqrt{\frac{q_m}{2\pi}}\,e^{iq_m+i3/4\pi}\left(\int_{C_1}+\int_{C_2'}\right)\left(e^{4iq_m(y^2+y)}\frac{dy}{\sqrt{-y}}\right), \tag{32''}$$

$$M_{lp}(Q,a_1,a_2)=\frac{ie^{iQ+i3/4\pi}}{4\sqrt{2\pi Q}}$$

$$\times\left(\int_{C_2}+\int_{C_2'}\right)\left(e^{4iQ(y^2+y)}\frac{I_l(-4a_1Qy^2)\,I_p(-4a_2Qy^2)}{y^2\sqrt{-y}}dy\right), \qquad (33'')$$

where C_2' is a contour above the line $\beta=-\alpha$. We assume that C_2 begins at the point (α_0, β_0) $(\alpha_0=-B/Q^{\eta};\ \beta_0=E/Q^{\eta};$ $B, E>0;\ 1/2<\eta<1)$ and then goes to infinity. Thus, C_2' begins at the point $(-\alpha_0, -\beta_0)$, from which it also goes to infinity. It can be shown that the integrals along C_2' are exponentially small. We compute the integral along C_2 by the method of steepest descent.

We first consider the case in which $a_m \ll 1$. The functions I_l and I_p vary only slightly in comparison with e^{4iQy^2}, and their dependence on Q can be neglected. The contour C_2 is drawn through the saddle point $y = 1/2$ along the line of the steepest cent $\beta=\alpha+1/2$. The integral along C_2 is of the type $F(Q)=\int_{C}\varphi(z)e^{Qh(z)}dz$, for which the contribution from the saddle point a is given by the expression[14,15]

$$V_a(Q)=\sqrt{-\frac{2\pi}{Qh''(a)}}\,\varphi(a)\,e^{Qh(a)}\left[1+O\left(\frac{1}{Q}\right)\right]. \qquad (35)$$

Inasmuch as the contribution of the beginning of the contour C_2 and the part of it with $|y|\gg 1$ to the integral is exponentially small and $\mathrm{Re}[4i(y^2+y)]$ is a maximum at the saddle point $y=-1/2$, the asymptotic behavior of M_{lp} and $R(q_m)$ for $Q\gg 1$ $(q_m\gg 1)$, according to a theorem given in ref. 14 (1.6.2), is determined by Eq. (35).

Carrying out the calculations, we obtain

$$R(q_m)=\frac{1}{2}\left[1+O\left(\frac{1}{q_m}\right)\right], \qquad (36a)$$

$$M_{lp}(Q,a_1,a_2)=\frac{i(-1)^{l+p}}{2Q}I_l(a_1,Q)\,I_p(a_2,Q)\left[1+O\left(\frac{1}{Q}\right)\right]. \qquad (36b)$$

In the case $a_m \not\ll 1$, when the dependence of I_l and I_p on Q cannot be neglected in (33"), integral representations are used for I_l and I_p in accordance with the relation

$$I_n(z)=\frac{1}{2\pi}\int_{-\pi}^{\pi}e^{-in\theta+iz\sin\theta}d\theta. \qquad (37)$$

Substituting I_l and I_p into (33") and integrating over y by the method of steepest descent, we obtain

$$M_{lp}=\frac{ie^{iQ}}{8\pi^2Q}\int_{-\pi}^{\pi}e^{-li\theta_1-pi\theta_2-\frac{iQ}{1-a_1\sin\theta_1-a_2\sin\theta_2}}$$

$$\times(1-a_1\sin\theta_1-a_2\sin\theta_2)^2\,d\theta_1 d\theta_2. \qquad (38)$$

Equation (36b) follows from the latter expression for $a_m \ll 1$, with error $O(a_m)$. For larger values of a_m the method of steepest descent is used $(Q\gg 1)$. The saddle points are $\theta_m=\pm\pi/2$. Applying Eq. (35) several times, we have

$$M_{lp}=\frac{ie^{iQ}}{4\pi Q^2\sqrt{a_1a_2}}\sum_{m,n=1}^{2}\exp\left\{i\frac{\pi}{2}[l(-1)^m+p(-1)^n]\right.$$

$$\left.-\frac{iQ}{1+(-1)^m a_1+(-1)^n a_2}+i\frac{\pi}{4}[(-1)^m+(-1)^n]\right\} \qquad (39)$$

$$\times[1+(-1)^m a_1+(-1)^n a_2]^4\,[1+O(1/Q)].$$

Equation (36b) holds not only for $Q\gg 1$, but also for $Q\ll 1$ and for $Q\sim 1$. This fact can be verified by applying Eq. (29) to (33') after differentiation with respect to a_m, replacement of I_p by the representation (37), and changing of the order of integration. It is then sufficient to assume that a_m and Qa_m^2 are small in order to obtain (36b). An error $O(\varepsilon)$ is guaranteed for small values of Q, where $\varepsilon=\max(a, Qa^2)$, $a=\max(a_1, a_2)$.

The substitution of (36a) and (36b) into (31) yields the asymptotic expression

$$\xi=2\sum_{\substack{l=0\\ l+p\neq 0}}^{\infty}\sum_{p=0}^{\infty}\sum_{j=0}^{2}(-1)^{jp}\frac{1+O(\delta)}{Q_{lp}}I_l(a_1Q_{lp})\,I_p(a_2Q_{lp})\sin\psi_{lp}, \qquad 40)$$

in which $\delta=\max(a,\sigma)$, $\sigma=\min(Qa^2, 1/Q)$.

For the case in which only one wave is excited, i.e., for $p=0$ and $a_2=0$, the classical Bessel–Fubini equation[10,11] is obtained from (40):

$$\xi=2a_1\sum_{l=1}^{\infty}\frac{I_l(la_1q_1)}{la_1q_1}\sin l\psi_1, \qquad (41)$$

so that (40) is the generalization of that equation to the case of wave interaction.

If we put $a_1Q_{ep}\ll 1$ in (40), we obtain the following expression for $p=x(p=1, 2, \ldots)$ satellites of the fundamental frequency ω_1:

$$\xi_{1p}=a_1\sum_{j=1}^{2}(-1)^{jp}I_p(a_2Q_{1p})\sin\psi_{1p}, \qquad (42)$$

which coincides with the result obtained by the method of truncated equations.[4]

If also $a_2Q_{1p}\ll 1$ in this case, then

$$\xi_{1p}=a_1\sum_{j=1}^{2}\frac{(-p)^{jp}}{p!}\left[\frac{a_2(\omega_1+(-1)^j p\omega_2)}{2w_0}z\right]^p\sin\psi_{1p}, \qquad (43)$$

whence it follows that energy is transferred predominantly into the high-frequency part of the spectrum under the conditions of applicability of Eqs. (42) and (43). The asymmetry in the amplitudes of the "red" and "violet" satellites increases as the frequencies ω_1 and ω_2 come closer together.

We obtain the following expression from (40) for oscillations at the fundamental frequency ω_1:

$$\xi_{10}=\frac{2}{q_1}I_1(a_1q_1)\,I_0(a_2q_1)\sin\psi_1, \qquad (44)$$

from which, by condition (14), it is inferred that the fundamental-frequency amplitudes decay monotonically up to inversion of the simple wave.

Another asymptotic representation for ξ in the case of small l and p, $Q \nless 1$, and $a_m \ll 1$ can be obtained from (28) by putting m = 0 and k = 0:

$$\xi = \sum_{\substack{l=0 \\ l+p\neq 0}}^{\infty} \sum_{p=0}^{\infty} \frac{(l+p-1)!}{e!\,p!} \left(\frac{a_1}{2}\right)^l \left(\frac{a_2}{2}\right)^p [1 + 0(p)] \times \sum_{j=1}^{2} (-1)^{jp+1} \mathrm{Re}\,\{e^{i\psi_{lp}} (i)^{l+p} L_{l+p-1}^{-1}(lQ)\}, \tag{45}$$

where

$$\xi = \sum_{\substack{l=0 \\ l+p\neq 0}}^{\infty} \sum_{p=0}^{\infty} \sum_{j=1}^{2} \frac{(-1)^{l+p+jp}[1 + 0(1/Q)]}{\pi Q_{lp}^{\frac{1}{2}} \sqrt{a_1 a_2}} \sum_{m,n=1}^{2} [C_{mn}]^{l} \sin(\psi_{lp} + \Phi_{mn}),$$

If Eq. (39) is substituted into (31), an asymptotic expression suitable for any a when $Q \gg 1$ is obtained:

$$C_{mn} = 1 + (-1)^m a_1 + (-1)^n a_2$$

$$\Phi_{mn} = \frac{\pi}{2}[l(-1)^m + p(-1)^n] + \frac{\pi}{4}[-1)^m + (-1)^n] + Q_{lp}\left(1 - \frac{1}{C_{mn}}\right).$$

where

$$C_{mn} = 1 + (-1)^m a_1 + (-1)^n a_2\ ,$$

$$\Phi_{mn} = \frac{\pi}{2}[l(-1)^m + p(-1)^n] + \frac{\pi}{4}[-1)^m + (-1)^n] + Q_{lp}\left(1 - \frac{1}{C_{mn}}\right).$$

In using Eq. (46) it is important to remember that $(a_1q_1 + a_2q_2) < 1$ in our problem, so that for small l and p the condition $Q \gg 1$ is not satisfied for arbitrary a ($a <$ 1), and (46) can have low accuracy. Moreover, the situation can arise in which Q is small for the "red" satellites, i.e., for j = 1, so that even though the "violet" satellites (j = 2) are described by Eq. (46), it is necessary to use another asymptotic expression.

When $Q \sim 1$ and a is not small, it is necessary to use Eq. (28) with however many terms are required to attain the necessary accuracy. Inasmuch as this asymptotic expression is needed for small l and p, only a few terms are required.

We point out that Eq. (40) is easily derived from (28) by replacing the Laguerre polynomial with its leading term for large values of Q.

We also note that oscillations with initial phases φ_1 and φ_2, which must be related by the condition $v|_{t=0} = 0$, can be specified at the driving point $z_0 = 0$. The introduction of φ_1 and φ_2 alters the determination of ψ_1 and ψ_2, but does not affect the form of any of the other expressions [except condition (14)].

The condition relating φ_1 and φ_2 has the form

$$a_1 \sin \varphi_1 + a_2 \sin \varphi_2 = 0.$$

The phases φ_1 and φ_2 are involved as terms in ψ_1 and ψ_2, respectively, and (14) goes over to the inequality

$$a_1 q_1 \cos \varphi_1 + a_2 q_2 \cos \varphi_2 < 1. \tag{14'}$$

Since the expressions derived above originate from an analysis of wave interaction in a thin plasma sheath, they must not be used for values of z close to the overturning distance, because the condition $D \ll L$ is violated in that case, i.e., the thin-sheath model becomes invalid.

Zh. Tekh. Fiz., 44, 1161-1167 (June 1974)

The generation of drift-waves in an argon plasma by rf fields at frequencies near the lower hybrid frequency is studied. Within a single pulse the nature of the spectrum changes gradually from a monochromatic spectrum near the beginning of the discharge to a noisy spectrum at the critical plasma parameters, corresponding to an abrupt change in the regime. At this abrupt change an equally abrupt restoration of the monochromatic drift-wave spectrum is observed. It is also found that when added, the spectra of two neighboring probes become different, apparently implying nonlinearity of the drift wave. It is suggested that the observed turbulence leads to additional charged-particle loss and is one of the factors responsible for the cutoff of the absorption of the rf radiation by the plasma.

Using a photomultiplier Galaktionov et al. have observed the emission from a plasma produced in a magnetic field by a source at frequencies between the electron, cyclotron, and lower hybrid frequencies.[1] During a pulse the magnetic field increases rapidly to its maximum value and then decays smoothly in a time of the order of 1 sec. The integrated emission also decays; however, this decay is not smooth, but proceeds in characteristic steps whose positions are governed by the field B and the plasma density n_e. The origin of these steps is not completely clear, but there is reason to believe that they are associated with the linear transformation of electromagnetic waves into plasma waves. It is also noted that the discharge is always characterized by low-frequency noise whose nature varies considerably during the pulse. We report here on a study of these waves and the relation between the stepped signal from the photomultiplier and the absorption of electromagnetic waves in the plasma.

EXPERIMENTAL PROCEDURE

The experimental apparatus (Fig. 1) consists of a glass tube 50 mm in diameter and more than 1 m long, located in a magnetic mirror. Around the middle of the tube there is a coil, which is connected to a source which produces pulses at 70 MHz which coincide in time with the magnetic field pulses (~ 1 sec). The overall characteristics of the discharge, such as the plasma density and the electron temperature, are measured by means of a double probe, which can be moved in the radial and axial directions without disrupting the vacuum. The probe characteristics are recorded point to point; a rectangular voltage pulse, whose amplitude is varied from discharge to discharge, is fed to the probes.

The oscillograms of the probe current reveal fluctuations at characteristic frequencies up to 30 kHz. The modulation of the probe saturation current reaches 20% to 50%, depending on conditions. These fluctuations and the imperfect reproducibility of the discharge conditions limit the accuracy of the measurements. The scatter in the temperature values measured under identical conditions is 25%, while the scatter in the absolute densities is 15%-20%. It should be noted that these absolute plasma densities, measured with the probe, agree within the specified experimental error with the densities measured previously[1] by a resonator method under similar conditions.

The plasma waves are studied with a system of miniature single probes of tungsten wire 0.1 mm in diameter which are inserted into the plasma in the radial direction to a position 6 mm from the inner wall. The lateral surfaces of the probes are insulated with alundum film. Only a part of the tip about 1 mm long remains exposed; this part serves as a local plasma-potential pickup. The probes are located in one cross section of the tube (Fig. 1) and are used to study the azimuthal propagation of the waves. There is also a pair of probes which are located 50 mm apart on a single magnetic line of force and used to detect the longitudinal component of the wave vector, k_z. The measurements are carried out in the floating-probe mode, i.e., the potential oscillations are measured with an instrument with an input impedance of 4 MΩ, which is large in comparison with the internal impedance of the probe–plasma system.

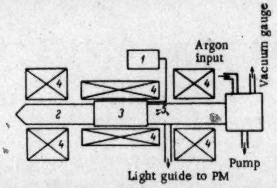

Fig. 1. The experimental apparatus. 1) rf oscillator; 2) glass tank; 3) rf circuit; 4) magnetic field coils; 5) probes.

The frequency characteristic of the measuring system is uniform over the entire frequency range studied.

The signals from the two probes, displayed as functions of the time, are photographed simultaneously from the screens of special high-resolution cathode-ray indicat-

ing devices^2 and are then converted to digital form. A given sample lasts 1-2 msec and contains more than 1000 resolved points. Then the information is fed to a BÉSM-4 computer, which carries out a programmed correction of the systematic errors due to the nonlinear sweep of the indicating device and then produces Fourier transforms of the signals. By this procedure it is thus possible, in a single pulse, to find the oscillation spectra which prevail for a time of the order of 1 msec at two points in the plasma and to find the phase difference between these points for each of the spectral lines. All the experiments are carried out with argon.

Oscillation spectra are obtained for various discharge regimes in which the pressure and the rf power are varied. Below we report the results for only one regime, the one for which the light signal decays most rapidly. The corresponding pressure is $6.4 \cdot 10^{-4}$ torr and the voltage on the anode of the rf oscillator is about 400 V – the minimum value at which the discharge is stably triggered. We are interested in the data for successive times (and thus successive values of the magnetic field) before and after the first step in the photomultiplier signal. We are not able to proceed to the second or third step because of the limited sensitivity of the indicating device.

EXPERIMENTAL RESULTS

Measurements with the movable double probe show that both the electron temperature and the plasma density remain essentially constant along the discharge. At the chamber axis the value of T_e before the jump is 5-7 eV; after the jump it is 10-15 eV. Figure 2 shows the radial profile of n_e before and after the jump.

The primary result of the oscillation measurements is the discovery that the signals from two probes separated in the azimuthal direction produce markedly different signals. These results imply $k_\parallel \ll k_\perp$, i.e., that the perturbations are considerably elongated along the magnetic field. In all subsequent measurements we therefore use two probes separated by an azimuthal angle of $\varphi = 40°$. The upper curve in Fig. 3 shows an oscillogram of a photomultiplier signal with the characteristic step; the total duration of the discharge is about 1 sec. Shown at the bottom are the times of the measurements; the results of the measurements are shown in Fig. 4. Here the ordinate axes show (in relative units) the absolute value squared of the oscillation amplitude as a function of frequency. The solid and dashed curves in each figure show the results of the computer calculation for the two probes.

In connection with the data shown in this figure it is interesting to note the following circumstance:

a. The spectrum has a line structure; the line halfwidth corresponds well in essentially all cases to the theoretical value of 1/T, where T is the observation time. The error in the determination of the line shape is monitored in an experiment in which part of a sine wave photographed from the screen of the indicating device is fed to the computer for processing and the result is compared with the Fourier integral of the same part of the wave, introduced mathematically. In both cases the results agreed within 1% with that shown in Fig. 5.

b. Comparison of the spectra obtained with this line shows that in the initial stages of the discharge the oscillations are almost purely sinusoidal. The phase shift between the oscillations from the two probes 40° apart is also 40°, implying that the first azimuthal mode predominates. Then the phase velocity of the perturbation can be easily determined from

$$v_{\text{p}} = m_\varphi R\omega,$$

where m_φ is the mode number, R is the radial position of the probes, and $\omega = 2\pi f$ is the oscillation frequency. The direction of v_{p} is the same as the Larmor drift of the electrons, and its magnitude is $9 \cdot 10^4$ cm/sec. This result is very nearly equal to the theoretical value for the drift-wave phase velocity:

$$v_0 = \frac{cT_e}{eB}\frac{\nabla n}{n} \approx 1 \cdot 10^5 \text{ cm/sec},$$

where T_e, ∇n, and n are evaluated from the data obtained by the double probe (Fig. 2). We note that in our case of a weakly ionized argon plasma the correction for the revolution velocity due to the radial ambipolar field is small:

$$u = \frac{c\theta}{eB}\frac{\nabla n}{n},$$

where

$$\theta = \frac{T_e m_e \nu_{e0} - T_i m_i \nu_{i0}}{m_e \nu_{e0} + m_i \nu_{i0}} \approx T_i \ll T_e.$$

c. On the basis of the line nature of the spectra we conclude that drift waves propagate in the azimuthal direction and that the wavelength is equal to the circumference of the circle divided by the integer m_φ. In principle, for the more complicated spectra, which, as Fig. 4 shows, are observed toward the step we can obtain a dispersion relation for the waves by constructing the functional dependence $m_\varphi(\omega)$. In this manner we could study the nature of the waves in more detail. However, two experimental circumstances rule out this procedure: First, it turns out that the phase shift between the oscillations of the two probes ceases to be a constant within a single line for the more complex spectra; second, a difference arises between the spectra from the two probes and increases in front of a step to such an extent that it becomes impossible to compare the different lines (Fig. 4e).

d. We record 15-20 spectra for each case; Fig. 4 shows typical examples from each group. The reproducibility of the spectra from discharge to discharge is very good for the first groups, but it worsens as the spectra becomes more complicated, so that, e.g., in Fig. 4e, the reproducibility of the individual lines has been lost completely. However, the overall nature of the spectrum is reproducible.

e. A typical result is that the abrupt change in the light signal to the photomultiplier is accompanied by an equally abrupt change in the nature of the oscillation spectrum, from a noisy spectrum (Fig. 4e) to a nearly monochromatic spectrum (Fig. 4f). Then the spectrum begins to broaden again, but we are not able to follow this behavior to the next step because the signal amplitude falls below the limiting sensitivity of the indicating device.

Generally, similar results are obtained in other experiments at different pressures and oscillator power levels. We can definitely assert that in those cases in which the step in the photomultiplier signal degenerates into a smooth slope the evolution of the oscillation spectra is also smooth.

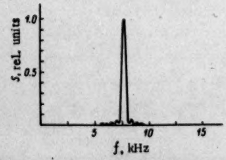

Fig. 5. Shape of the spectral line.

DISCUSSION

From the standpoint of the model of drift-wave propagating throughout the plasma volume, the significant difference between the spectra of the two probes, combined with the narrowness of the observed lines, is not understood.

The preservation of the natural line half-width $\Delta f \approx 1/T$, observed in all cases (the broadened lines in Fig. 4d result from a reduction of the sweep time T), implies that oscillations of a given frequency occur throughout the observation time. It is easy to see that over this time the wave front moves a distance three orders of magnitude larger than the distance between the probes (1.5 cm). The fact that the oscillation spectra are different under these conditions implies that each of the waves is azimuthally (or radially) localized in part of the plasma volume. Such a situation can arise because of nonlinear mechanisms when[3]

$$v_{\mathrm{dr}} \approx v_{\mathrm{p}},$$

where v_{dr} is the amplitude of the oscillatory velocity in the drift wave. If we adopt this possibility, we should interpret the divergence of the spectra from neighboring probes as indicating a transition of the wave into a nonlinear regime.

Turning to the role of drift waves in the mechanism for the maintenance of the discharge, in particular, to the relationship between these waves and the nature of the photomultiplier-signal steps, we note that, by itself, the coincidence of these steps with the abrupt change in the nature of the spectrum does not rule out the possibility that the drift waves are only a concomitant phenomenon and do not exert an inverse influence on the discharge regime. In this connection it is interesting to take into account the turbulent diffusion related to drift waves. While the regular oscillations observed in the initial stage do not contain an addition mechanism for particle loss across the magnetic field, the diffusion coefficient in pronounced turbulence can reach limiting values of the order of the Bohm value:[3]

$$D_{\perp \max} \approx \frac{1}{16} \frac{cT_e}{eB}.$$

An estimate shows that in this case the loss of charged particles, governed by their motion across H, is comparable to the loss due to ambipolar diffusion along the field, with the coefficient

$$D_a = \frac{T_e}{M_i \nu_{ia}},$$

where ν_{ia} is the frequency of resonance charge exchange in argon. On the basis of this circumstance we can suggest that if the turbulent oscillations are caused by the growth of drift waves and do not directly influence the mechanism for the absorption of the rf oscillations (it is assumed in ref. 1 that this mechanism is the linear transformation of electromagnetic into plasma waves), they can in any case be one of the factors governing the particle and energy balance in the plasma. In this sense, the low-frequency waves, along with the change in the magnetic field, can shape the functional dependence of the basic plasma parameters on the time, including the step observed in the light signal.

The experimental data available are not adequate for drawing more definite conclusions; it is necessary to measure the functional dependence of the density on the time, which is required for a solution of the balance equation.

In conclusion the authors thank A. D. Piliya, V. I. Fedorov, O. N. Shcherbinin, and V. V. D'yachenko for useful discussion.

Coaxial plasma injector with programmed injection

V. A. Burtsev, V. N. Litunovskii, and M. P. Nadgornaya

D. V. Efremov Scientific-Research Institute of Electrophysical Apparatus, Leningrad

(Submitted December 26, 1972; resubmitted August 15, 1973)
Zh. Tekh. Fiz., 44, 1168-1175 (June 1974)

An experimental study has been made of the physical processes in the interelectrode region of a coaxial injector with closely spaced electrodes, a short ringing time, programmed injection, and preliminary ionization of the gas by an induction electric field. Phenomena which precede the current front and which were observed in previous work are also observed here. In addition, plasma-conductivity and emission fronts are observed; these move with velocities governed by the pressure gradient in the leading part of the initial gas distribution. The present results are compared with earlier results.

INTRODUCTION

We report here a continuation of the experiments reported in refs. 1-4 on the physical processes occurring in the interelectrode region of a coaxial injector with electrode diameter ratio of unity.

It was shown earlier[1,2] that the discharge (without preliminary gas ionization) develops from the very beginning as a current filament because of the channel nature of the initial gas breakdown and the subsequent influence of pinching forces.

The addition of a preliminary ionization system, homogeneous in the azimuthal direction,[4] causes the discharge to begin simultaneously at various points along the annular gap between the electrodes. The current sheaths formed in this manner remain azimuthally closed throughout the discharge, regardless of the initial gas distribution.

The azimuthal stability of the current sheaths in an injector with an electrode diameter ratio of unity, makes it possible to study the influence of the nature of the gas distribution on the phenomena preceding the current front detected earlier.[1-3]

EXPERIMENTAL APPARATUS AND PROCEDURE

The coaxial injector is described in detail in ref. 4. The outer diameter of the central electrode is 36 mm, the inner diameter of the outer electrode is 44 mm, the electrode length from the point at which the discharge is initiated to the aperture is 100 mm, and the distance to the insulator is 120 mm. The capacitor, with a capacitance of $C_0 = 3.6\ \mu F$, can be charged to $U_0 = 20$ kV, and the ringing time of the discharge circuit is $\tau_0 \simeq 1\ \mu sec$.

The programmed injection system and the system for the preliminary gas ionization are shown schematically at the left in Fig. 1. Gas is injected through a pulsed valve into the cavity within the central electrode. It then passes through longitudinal slits in this electrode to the interelectrode region. For a given gas-injection time the spatial distribution of the gas is governed primarily by the position of the movable partition and the variation of the transmission of the slits along the electrodes. This injection system permits study of various gas distributions with a fixed position of the inner edge. Current fronts are shaped at the inner edge of the distributions through preliminary gas ionization caused by the induction electric field. The length of this preliminary ionization step is varied from 0.3 to 1 μsec in the various experiments.

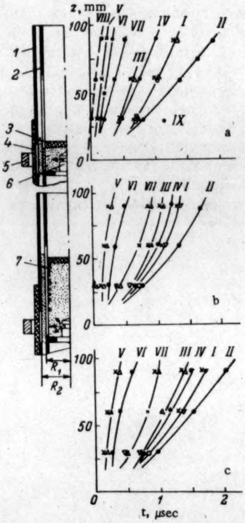

Fig. 1. Gas-injection system and curves showing the current, conductivity, and emission fronts of the plasma. $U_0 = 15$ kV. 1, 2) Outer and central electrodes; 3) movable partition; 4) porcelain tube; 5) preliminary-ionization loop; 6) pulsed valve; 7) cylindrical spiral with an adjustable pitch. Data are obtained by means of photomultipliers (1'), current probes with a shunt resistance of R = 75 Ω (2'), current probes with R = 0.6 Ω (3'), conductivity probes (4'), and magnetic probes (5'). I) Motion along the electrodes of the leading current front and the conductivity front of the first plasmoid; II) motion of the emission front of the first plasmoid; III-VII) motion of the conductivity and emission fronts due to preceding phenomena; VIII) motion of the emission front of the plasma produced by the preliminary-ionization system; IX) arrival time of the emission front of the slow plasma flow. a) Short gas distribution, $p_{z=0} = 1.5$ mm torr; regimes with a gas-pressure distribution characterized by a pressure drop toward the injector exit slower than in the interior of the interelectrode region. b) $p_{z=0} \simeq 1$ torr, $\Delta p_z \simeq 0.2$ torr/cm for z > 0. c) $p_{z=0} \simeq 1.5$ torr, $\Delta p_z \simeq 0.3$ torr/cm.

The voltage on the preliminary-ionization loop, U_{ion}, is detected by a magnetic probe.[4] The total discharge current between the injector electrodes, I_d, is measured by an integrating Rogowski loop,[1] and the voltage between the end parts of the electrodes, U_{el}, is measured by a low-inductance resitive divider.

The azimuthal and longitudinal magnetic fields in the interelectrode region are measured by magnetic probes[2] inserted in the radial direction; the diameter of the probe coils is 0.8 mm, the length is 0.8 mm, the conductor diameter is 0.03 mm, and there are 32 turns. The structure of the current fronts is studied by probes which detect local radial currents.[2,3] The current probes are surface elements of the outer electrode (the elements are 0.4 mm in diameter), connected to the discharge circuit of the injector through shunt resistances. These resistances are varied from 0.1 to 75 Ω in the various experiments.

The propagation of the ionized medium or the ionization wave through the gas is detected by coaxial conductivity probes[2,3], whose central electrodes are supplied a positive bias voltage. The end surfaces of the probe electrodes are flush with the working surface of the outer electrode of the injector.

The motion of the emission fronts is studied by photomultipliers which detect the emission in directions perpendicular to the injector axis, through the use of systems of irises and light guides.

The longitudinal electric field in the interelectrode gap is measured by a double probe inserted in the radial direction. The probe electrodes, made of tungsten wire 0.2 mm in diameter and insulated with alundum, are 1.5 mm apart.

The plasmoids in the region behind the electrode are studied with a plasma "absorber," which can be used to detect the plasma flux density nv (n is the plasma density and v is the flow velocity) on the basis of the dissipation in a transverse electric field. A coaxial absorber with a low-inductance capacitive power supply[5] which we have developed makes it possible to achieve the necessary time resolution (~ 50 nsec).

The pressure of the neutral gas in the interelectrode region of the injector is measured by ionization gauges and discharge gauges.

PRECURSOR PHENOMENA

Study of the propagation along the injector electrodes of the fronts of the radial discharge current, the conductivity, and the visible emission of the plasma reveals that the current front is preceded by faster conductivity and emission fronts whose velocities have different functional dependences on the gas distribution. Figure 1 shows the longitudinal motion of the fronts obtained in three operating regimes of the injector, differing in the gas-pressure gradient in the leading part of the distribution. Curve I shows the propagation of the current and conductivity fronts toward the injector exit, while curve II shows the motion of the emission front of the corresponding plasma front. The other curves in Fig. 1 correspond to phenomena preceding the current front.

On the basis of the experimental data obtained in the study of the propagation of the current, conductivity, and emission fronts for many operating regimes of the injector, including the regime with a homogeneous gas distribution in the interelectrode region, we can draw the following conclusions, and make the following assumptions regarding the mechanisms responsible for the observed pehnomena.

1. The observed phenomena can be divided into two groups. The first group includes the phenomena which occur in the leading part of the current sheath or in the gas ahead of the current front, so that they are assumed to precede the current front as it moves along the injector electrodes.

The second group includes the phenomena which occur shortly after the gas breakdown, while the electric field is still strong, and the plasma conductivity is low. We also treat these as precursor phenomena, since they cause changes in the interelectrode region of the injector before the current front begins to propagate through it.

2. To the first group we can assign the separation of the leading part of the current front, which occurs as the front moves through the gas at a pressure which falls off toward the injector exit. Figure 1 (curves III and IV) shows the motion of the separated current front along the injector electrodes, along with the conductivity and emission fronts of the accelerated plasma component. Figure 2 shows a typical oscillogram of the signals from the current probes to illustrate this phenomenon.

The separation of the leading part of the current sheath as it moves through a gas in which the pressure falls off, first predicted in ref. 6, can in fact be one of the mechanisms leading to the formation of the plasmoids observed by many workers in the case of short gas distributions.

3. We do not have an unambiguous interpretation for curves V-VII in Fig. 1. Conductivity front VII (Fig. 1, b

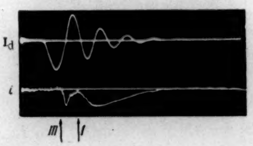

Fig. 2. Oscillograms of the signals from the Rogowski loop (I_d) and from the current probe (i) at z = 30 mm for the case of a short gas distribution with $p_{z=0} \approx 1.5$ torr.

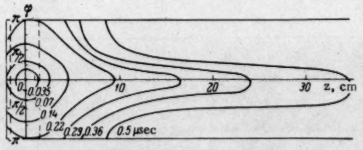

Fig. 3. Propagation of the emission front through the interelectrode region of an injector without a preliminary ionization system.[1] The dashed lines show the boundaries of the gas distribution ahead of the front.

and c) displays the most dynamic behavior; its velocity increases significantly with the pressure gradient in the leading part of the distribution, despite the slowing of current front I.

4. The second group of precursor phenomena includes the isotropic thermal expansion of the electron gas, which acquires a high temperature in the electric field immediately after the breakdown of the neutral gas (the heavy particles remain essentially cold because of the low efficiency with which energy is transferred to them by electrons). As the expanding electron gas entrains the ions it produces a plasma component which propagates in all directions away from the breakdown region.[7,8]

Figure 3 shows an expanded diagram of the propagation of the emission front through the interelectrode region of the injector without a preliminary ionization system.[1] This figure is plotted from an analysis of the measurements of the lateral photomultipliers at various positions along the φ and z coordinates. The origin of coordinates is at the point at which the original gas breakdown occurs. We see from this figure that the emission front propagates first uniformly in all directions, including the direction toward the insulator, going beyond the initial gas distribution. Only 0.2 μsec after the breakdown does an emission "tongue" begin to form rapidly in the direction toward the injector aperture (see ref. 2 for the results of a detailed study of this plasma tongue in the r, z cross section through the breakdown point).

In the present experiments the electron gas expands isotropically immediately after the breakdown, upon initiation of the preliminary discharge. However, this phenomenon is much less pronounced in the case of an azimuthal gas breakdown than in the case of a radial breakdown, and is thus not reflected in Fig. 1a. Curve VIII in this figure shows the thermal expansion of the plasma heated by the preliminary-discharge current.

5. Also among the phenomena preceding the formation of the current front is the longitudinal propagation of an avalanche discharge, discussed in detail in ref. 3: When the voltage is supplied to the discharge electrodes, electron avalanches of the Townsend stage of the discharge arise primary where the conditions are optimal, according to the Paschen-breakdown curve. Photons of the primary avalanches initiate adjacent secondary avalanches, leading to their rapid formation, i.e., to the propagation of the Townsend discharge along the electrodes.

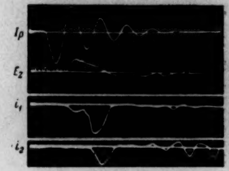

Fig. 5. Oscillograms of the signals from the Rogowski loop (I_d), the double electrostatic probe at z = 30 mm (E_z), and the current probes at z = 60 mm (i_1) and z = 90 mm (i_2). U_0 = 15 kV. Short gas distribution, $p_{z=0} \simeq$ 1.5 torr.

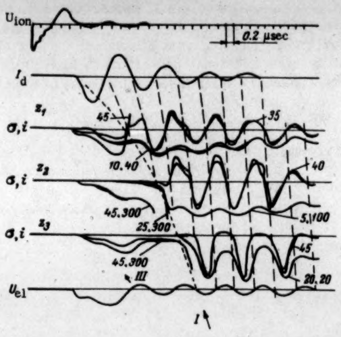

Fig. 6. Signals from the current probes (i), the conductivity probes (σ), the Rogowski loop (I_d), the magnetic ionization probe (U_{ion}), and the voltage divider at the ends of the electrodes (U_{el}) in the case of a short gas distribution. U_0 = 10 kV. The amplification (in decibels) is shown near the signals from the current probes, and the amplification (decibels) and the bias voltage (in volts) are shown near the signals from the conductivity probes. Dotted curve) Motion of the main plasma front, I; dashed curves) motion of the points of zero oscillation phase.

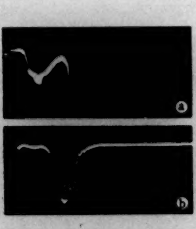

Fig. 4. Oscillograms of the signals from the plasma "absorber," which are proportional to the plasma flux density. Case of a short gas distribution, with $p_{z=0} \simeq$ 1.5 torr. The "absrober" is z = 65 cm from the ionization turn. a) Background plasma, sweep rate of 2 μsec/div, shunt resistance of R_s = 75 Ω; b) main plasmoid, 5 μsec/div, R_s = 0.07 Ω.

When the preliminary gas ionization takes place in a local zone (in the case of spark ignition, as in ref. 3, or in the case of spatially confined ionization by an induction electric field, as in ref. 4), the rapid formation of electron avalanches is triggered by gas ionization by photons emitted by the background. In the present experiments, in which the electrodes are shorter and the gap wider than in ref. 3, this phenomenon takes a slightly different form.

The avalanche discharge develops essentially simultaneously in the gas-filled interelectrode region, from the time at which the voltage is supplied to the injector electrodes (Fig. 1, b and c, t = 0) to the appearance of the fastest front V, due to the main discharge. The plasma emission intensity and conductivity increase monotonically over this time interval.

6. The precursor phenomena contribute to the formation of a background plasma, which is detected behind the electrode (short gas distribution) by means of the plasma absorber (Fig. 4). Its front velocity is equal to that of the fastest front, V, in Fig. 1a.

In the case of longer gas distributions the precursor phenomena lead to a situation in which the current front encounters a partially ionized gas, rather than a neutral gas, so that the snowplow behavior of the front can be affected.

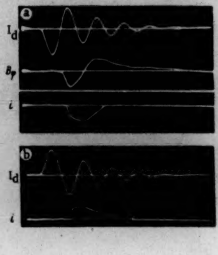

Fig. 7. Oscillograms of the signals from the Rogowski loop (I_d), the magnetic probe (I_p), and the current probes (i) for different electrode polarities. The probes are at z = 30mm. a) With central electrode as cathode; b) with central electrode as anode.

STRUCTURE OF THE CURRENT FRONT AND PLASMA FLOW

It is difficult to study the structure of the current front and the plasma flow behind it in this injector, with its interelectrode gap of ~4 mm, both from the diagnostic standpoint and because of the physical consequences of the strong influence of the electrode surfaces on the plasma properties. We therefore simply report some observations which we believe to be interesting and which illustrate the complexity of the physical processes in the injector.

1. Study of the distribution of the radial current in the interelectrode region reveals one or two movable current fronts corresponding to the fronts of current loops, and an essentially fixed sheath carrying most of the current in the discharge-formation region. Through the use of a double probe we find an opposite longitudinal field behind the moving current fronts, due to the existence of a potential well for ions (Fig. 5); this well is predicted in ref. 9 under the condition $v_0/v_A \sim 1$ (where v_0 is the velocity of the current front and v_A is the Alfvén velocity in the plasma behind the current front). A calculation of v_A based on the data from the magnetic measurements and an estimate of the plasma density based on the balance equation for the magnetic and gas-kinetic pressures shows that this condition is satisfied. However, the actual situation is more complicated than in the theory: In the inner part of the well the electric field oscillates at the frequency of the total current; these oscillations propagate in the plasma toward the injector exit. The magnetic and current probes show that these oscillations can be amplified both in time and in space as they propagate along the electrodes (Fig. 5). In experiments with relatively low discharge currents and a relatively large amount of gas in the interelectrode region, in which case the moving current fronts have much lower velocities and are rapidly disrupted (the ion potential well vanishes), the oscillations grow much more rapidly. The phase velocity of the oscillations propagating out of the fixed-discharge region toward the plasma front is much higher than that of the front, and the velocities of the subsequent oscillations are higher than those of the oscillations which precede them (Fig. 6).

2. The current fronts are studied with miniature magnetic probes inserted to the radial midpoint of the interelectrode region and with current probes at the walls. Comparison of the results found with the current probes for different initial polarities of the injector electrodes show that the motion of the current fronts is essentially independent of this polarity. It is thus possible to obtain information about processes occurring near the cathode and anode by switching the electrode polarity while the current probes are held at the outer electrode.

Figure 7 shows the signals from the magnetic and current probes for the different electrode polarities; comparison shows that the current front of the first loop is planar and perpendicular to the electrode surfaces. Behind the front, near the electrodes, there are current "tails," with those of the radial current more pronounced at the anode than at the cathode. The current front of the second loop is detected only by the magnetic probe in the center of the interelectrode gap. This result implies a bell-shaped second front.

CONCLUSION

1. The experimental results reported here represent a continuation of studies$^{1-4}$ of the possibility of accelerating plasma in a coaxial injector with an electrode diameter ratio of unity with a short ringing time. This paper is also a summary.

2. These experiments have shown that in a coaxial injector with closely spaced electrodes, in which it is more difficult for the current fronts to close in the azimuthal direction than in injectors of the usual geometry, the problem can be solved by arranging for azimuthally symmetric preliminary ionization of the gas.

3. A careful study of the propagation along the injector electrodes of the radial-current, plasma-conductivity, and plasma-emission fronts in various operating regimes of the accelerator and over a broad sensitivity range of the detectors (more than four orders of magnitude) has revealed several phenomena which precede the current front. Under the appropriate conditions, some of them contribute to the formation of the background plasmas which have been observed by many workers using pulsed coaxial injectors, while others alter the state of the gas in front of the current front. Which particular precursor phenomena appear is governed by many factors, including, to an important degree, the nature of the initial gas distribution.

4. Several interesting phenomena have been observed behind the current front, including an oscillatory process which is amplified in both time and space as it propagates along the electrodes; however, a detailed study of these phenomena is hindered by the small dimensions of the interelectrode gap.

5. We have not been able to fully exploit the advantages of the low-inductance power supply, the short ringing time of the discharge circuit, and the small change in the azimuthal magnetic field in the radial direction in this injector, because of the low dielectric strength of the interelectrode gap in the discharge-initiation region. These advantages can be exploited in a larger-scale injector of similar design.

Conversion of neutral hydrogen into protons in dense plasmas

T. A. Bazilevskaya, L. I. Krupnik, and N. G. Shulika

(Submitted December 29, 1972; resubmitted November 5, 1973)
Zh. Tekh. Fiz., 44, 1176-1182 (June 1974)

The efficiency of conversion of neutral hydrogen atoms with energies from 300 to 10,000 eV into protons by passage through plasma fluxes produced by a conical plasma injector with a pulsed hydrogen supply is studied. The plasma target density varies from 10^{12} to 10^{14} particles /cm^3. The efficiency of conversion into protons is compared for gaseous and plasma targets.

INTRODUCTION

Considerable attention has recently been given to the analysis of fluxes of neutral particles emitted by a plasma; these fluxes yield valuable information about the parameters and state of the plasma.[1]

In the neutral-particle analyzers developed thus far, the principle of partial ionization of the flux is used with subsequent analysis of the conversion ions. The most widely used method is stripping of hydrogen atoms in a gas target.[2]

This method is effective in the study of particles with energies above 1000 eV. The use of thin foils,[3] an electron beam,[4] and a gas-discharge plasma[5] as targets for the conversion of neutrals into charged particles does not lead to a significant increase in the efficiency for conversion of hydrogen atoms into protons in the low-energy region. In the present work, a hydrogen plasmoid with a charged-particle density of $\sim 10^{14}$ cm^{-3} is used as a target for the conversion of hydrogen atoms into protons.

The use of plasma as a conversion target offers an opportunity to take advantage of resonance charge exchange between hydrogen atoms and plasma protons, in which case the cross section rises sharply as the energy of the colliding particles decreases (Fig. 1).

EXPERIMENTAL ARRANGEMENT

Experimental measurements of the efficiency for conversion of hydrogen atoms into protons are made with the apparatus shown in Fig. 2.

A flux of neutral hydrogen atoms with energies in the range 300-10,000 eV is produced by means of the high-frequency ion source 1, the accelerating system 2, the magnetic mass monochromator 3, and the charge-exchange chamber 5. The charge exchange of protons into hydrogen atoms is accomplished in a gas target (air). Introduction of the beam into the charge-exchange chamber is made through the channel 4, which is 5 cm long and 5 mm in diameter. Protons which do not undergo change exchange are deflected by the electrostatic field of the plane condenser 18 and the primary beam of hydrogen atoms passes through the channel 7 into chamber 8, along which an accelerated plasma flux moves.

The plasma flux is produced by means of the conical plasma injector 9 with a pulsed hydrogen supply.[6]

The ion density in the flux is measured with the electrostatic probe 17.

From chamber 8, the beam of hydrogen atoms is directed through the channel 10 into the analyzer chamber 14. In this chamber, separation of the beam with respect to charge state takes place in the field of the plane condenser 11. The intensity of the undeflected beam is measured with the detector 16 through the number of secondary electrons ejected from a metal plate, and the intensity of charge-exchange protons is measured with detectors 12 or 13. The principle of particle detection in these detectors is similar to that described in ref. 2.

The test beam is incident on the bottom of the cylinder 19, and produces secondary electrons which are accelerated in the gap of the electrostatic lens formed by the two electrodes 19 and 20. The electrons are directed to the plastic scintillator 21, the light yield from which is recorded by the photomultiplier 22.

EXPERIMENTAL METHOD AND RESULTS

The conical plasma injector produces an accelerated plasmoid with an average particle velocity of $\sim 5 \cdot 10^6$ cm/sec and an electron temperature of $\sim$3-5 eV. The plasma density in the plasmoid can be varied over the range 10^{11}-10^{15} particles/cm^3.

The parameters of the plasma flux used as a target for the conversion of hydrogen atoms into protons are first studied by means of active particle diagnostics[10] and are checked during the course of an experiment by means of the electrostatic probe. Figure 3 shows an oscilloscope trace of the probe current obtained in a single picture covering 50 firing pulses of the plasma injector. The figure indicates that injector operation is satisfactorily stable, but some longitudinal nonuniformity of plasma is observed.

There are two density maxima in the flux. For the injector operating mode shown the plasma densities in the first and second maxima are 10^{12} and 10^{13} particles/cm^3 respectively. A characteristic feature of the plasma flux employed is a nonuniform degree of ionization of the plasma. The leading portion (first maximum) is characterized by a high degree of ionization (close to 100%). Then there is a decrease in the degree of ionization, which amounts to only 40-50% in the region of the second maximum.

The intensity of the beam of hydrogen atoms mea-

sured at the end of the analyzer is 10^{-10} A for a beam energy of 300 eV and 10^{-7} A at 10 keV.

The efficiency for conversion of hydrogen atoms into protons is evaluated from the ratio between the intensity of the proton current in the beam, as measured by the detector 13, and the intensity of hydrogen atoms passing through the entire system with no plasma target present.

Figure 4 shows the dependence of conversion efficiency on the initial energy of the hydrogen atoms.

The target thickness nL, where n is the plasma density and L is the beam path length is plasma, is used as a parameter for the curves.

The energy dependence of the conversion efficiency correlates with the energy dependence of the effective resonance charge-exchange cross section (Fig. 1) only for two target thicknesses: $nL = 2.5 \cdot 10^{12}$ and $6 \cdot 10^{12}$ cm^{-2}. A variation in target thickness by a factor of 2.4 leads to a rise in conversion efficiency also by a factor 2.4.

However, an increase in conversion efficiency is not observed for nL values greater than 10^{13} cm^{-2} and for beam energy < 500 eV. This fact is explained by the increase in beam particle scattering at large target thicknesses and by the boundedness of the analyzer aperture.

Nevertheless, if one compares the conversion efficiency in a plasma target, even under these nonoptimum, conditions, with the conversion efficiency in a gas target obtained under the same conditions, which is shown in Fig. 4 by the dashed curve, a choice in favor of a plasma target must be made.

The dashed curve for a gas target is obtained under conditions such that the optimum value (for charge exchange) of gas density (hydrogen) in the chamber 8 is selected for each value of hydrogen-atom beam energy.

DISCUSSION OF RESULTS

Despite the obvious advantage in conversion of hydrogen atoms into protons at low energies (less than 1000 eV)

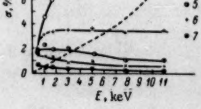

Fig. 4. Efficiency for conversion of hydrogen atoms into protons. 1) For a plasma target; 2) for a gas target; plasma density nL, cm^{-2}: 3) $2.5 \cdot 10^{12}$, 4) $6 \cdot 10^{12}$; 5) $1 \cdot 10^{13}$; 6) $1 \cdot 10^{14}$; 7) $1 \cdot 10^{15}$.

through collisions with protons (Fig. 1), we have not succeeded in completely realizing this advantage in experiments on the characteristics of neutrals emitted by a plasma. This is explained by the fact that distortion of the energy spectrum of the neutrals is not permissible in such experiments. Therefore an increase in target density to an optimum value from the viewpoint of producing maximum conversion efficiency is not always possible because of the large energy loss by the particles in collisions, particularly in the low-energy region.

The limits on the linear density nL of a plasma target for which the energy loss of a proton moving through the target will not exceed acceptable values can be determined from the expression[11]

$$\frac{dE}{dt}=-\frac{4\pi e^2}{v}\sum \lambda n_k e_k^2\left[\Phi\left(\frac{v}{v_k}\right)-\frac{2v}{\sqrt{\pi}\,v_k}\frac{m+m_k}{m\,m_k}e^{-\frac{v^2}{v_k^2}}\right]\ \ldots. \quad (1)$$

Here, dE/(dt) is the rate of change of the energy of an ion moving through the plasma; e, m, and v are the charge, mass, and velocity of the ion; e_k, v_k, m_k, and n_k are the charge, velocity (thermal), mass, and density of plasma particles; $\Phi(v/v_k)$ is the probability integral and λ is the Coulomb logarithm.

From Table 1, one can trace the magnitude of the quantities obtained by means of Eq. (1).

Table 1 gives the thicknesses of a plasma target for which there is a 1% change in energy of a proton passing through the target. Also given are values of $\Delta N/N$ corresponding to complete detection of protons created in the atomic flux by charge exchange with ions in the plasma target.

The calculation assumes that the plasma target consists of protons and electrons. The presence of neutral hydrogen atoms and of impurity atoms and ions in the plasma is not taken into account. In addition a value of 5 eV is assumed for the ion and electron temperatures of the plasma; this value is close to that obtained experimentally.

The values for target thickness presented are obtained under the assumption that the test particle passes through the plasma in a charged state. In the calculations, the average value of the Coulomb logarithm is assumed to be 15 for the entire range of particle energies and plasma densities.

A second factor, which reduces conversion efficiency at low energies, is large-angle particle scattering and the limited aperture capabilities of the analyzer.

We define the efficiency for conversion of hydrogen atoms into protons as the ratio

$$\alpha=\frac{J_1^+}{J_1^0} \quad (2)$$

for a device with a plasma target, where J_1^+ is the photon intensity recorded by the detector and J_1^0 is the intensity of the beam of atomic particles reaching the detector in the absence of plasma.

TABLE 1

	E, eV									
	20	50	100	200	300	400	500	1000	2000	5000
$nL\cdot 10^{-12}$, cm^{-3}	0.98	4.1	10	19	25.6	30.9	35.6	53.8	82.2	158
$\frac{\Delta N}{N}$, %	0.45	1.6	3.3	5.5	7.3	7.9	8.7	10.8	13.4	19

In turn, the quantity J_1^+ is related to J_0^+, the number of ions created in the target by charge exchange, by

$$J_1^+=kJ_0^+. \quad (3)$$

The coefficient k determines that portion of the protons which are scattered in collisions at angles greater than the aperture of the detection device.

The magnetude of particle deflection from the initial direction is conveniently characterized by the magnitude of the mean-square transverse component of the momentum, the mean rate of change of which for a Maxwellian velocity distribution of plasma particles is given by[11]

$$\frac{dp_\perp^2}{dt}=\frac{8\pi e^2}{v}\sum \lambda_k e_k n_k \Phi\left(\frac{v}{v_k}\right). \quad (4)$$

Here, $p_\perp$ is the perpendicular component of the particle momentum; e_k, n_k, and v_k are the charge, density, and velocity of plasma particles; e and v are the charge and velocity of scattered particles, λ is the Coulomb logarithm.

Assuming the deflection of particles from their initial direction is small, using Eq. (4) we obtain for the mean-square angle of deflection

$$\Theta^2=\frac{8\pi e^4 L}{m^2 v^4}\sum_k n_k \lambda_k \Phi\left(\frac{v}{v_k}\right), \quad (5)$$

where m is the mass of a particle moving through the plasma.

In the penetrating beam the angular distribution of particles in the neighborhood of $\varphi = 0$ obeys the Gauss law

$$N(\varphi)\,d\varphi=N_0\frac{\sqrt{2}}{\sqrt{\pi}}e^{-\left(\frac{\varphi}{\sqrt{2}\,\Theta_1}\right)^2}d\Theta. \quad (6)$$

The particle flux intensity $J_1^+(\varphi)$ reaching the detector is defined in the following manner, using Eq. (6):

$$J_1^+(\varphi)=J_0^+\frac{\sqrt{2}}{\sqrt{\pi}\,\Theta}\int_0^{\varphi} e^{-\left(\frac{\Theta_1}{\sqrt{2}\,\Theta}\right)}d\Theta_1 \quad (7)$$

or

$$J_1^+(\varphi)=\Phi(x)_1 J_0^+, \quad (8)$$

where $x = \varphi/\sqrt{2}\Theta$.

Comparing Eqs. (3) and (8), one can write

$$k=\Phi(x). \quad (9)$$

The defined parameter α can be written in the form

$$\alpha = \Phi(x)\left(1 - e^{-\sigma_n n L}\right) \tag{10}$$

(σ_n is the effective resonance charge-exchange cross section for hydrogen particles).

Where neutrals are present in the plasma it is necessary to consider in the calculation of α the possibility of secondary charge exchanges, which convert protons into neutral atoms and which lead to a decrease in the value of α. If the degree of ionization of the plasma used as a target is not very low, $n \gg n^0(\sigma_i/\sigma_n)$, Eq. (10) takes the form

$$\alpha = \frac{n}{n^0 + n}\Phi(x)\left(1 - e^{-\sigma_n (n^0+n) L}\right). \tag{11}$$

Here, n and n^0 are respectively the densities of charged and neutral particles in the plasma, and σ_i is the effective cross section for stripping of beam atoms by plasma atoms.

Equation (11) is valid in the region of low colliding-particle energies, where the effective resonance charge-exchange cross section is considerably greater than the effective cross sections for all other processes leading to the formation of protons in an atomic beam passing through the plasma.

Figure 5 shows the theoretical dependence for the detection efficiency for charge-exchange particles scattered at various angles. In the calculation of these curves and in all subsequent calculations, we select a plasma target thickness corresponding to a beam-particle energy loss of no more than 1%. Numerical values of all plasma parameters are selected on the basis of previously obtained experimental data.

Curves 1, 2, and 3 correspond to scattering at angles of 1, 2, and 3° respectively. Curve 4 is a graphical representation of the data in Table 1 and corresponds to the complete detection of all charge-exchange particles.

This figure indicates that an analyzer aperture of 2-3° is sufficient for satisfactory detection of secondary ions. The corresponding aperture for satisfactory collection of secondary protons which are converted in a gas target[12] is 15°. However, a rough calculation of the aperture of the analyzer used by us gives a value an order of magnitude less, ~ 0.2°.

A comparison of the experimental and theoretical data is shown in Fig. 6 which gives a graph of the energy dependence of the efficiency for conversion from atomic hydrogen into protons for several values of plasma target density. The solid lines are theoretical values and the points are experimental data. The results are obtained for various modes of plasma injector operation, producing different degrees of ionization in the plasma flux.

Satisfactory agreement of the calculations with experimental values justifies extrapolation of the results to a beam energy of 50 eV and permits comparison with data for conversion in a gas target.[12]

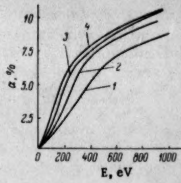

Fig. 5. Calculated values of the coefficient for conversion of atomic hydrogen into protons. 1) Particles recorded which are scattered by no more than 1°; 2) 2°; 3) 3°; 4) all charge-exchange particles recorded.

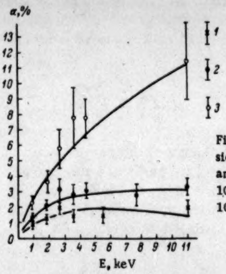

Fig. 6. Energy dependence of conversion efficiency. Target densities n^+L and n^0L (cm^{-2}), respectively: 1) $1.4 \cdot 10^{13}$ and $7 \cdot 10^{13}$; 2) $3.2 \cdot 10^{13}$ and $1 \cdot 10^{14}$; 3) $1.4 \cdot 10^{14}$ and $4.5 \cdot 10^{14}$.

For a beam energy of 50 eV and an analyzer angular aperture of ~ 1°, the coefficient for conversion of hydrogen atoms into protons is 10^{-3} for a plasma target and $5 \cdot 10^{-7}$ for a gas target.

The results presented here indicate the advantage of a plasma target for the conversion of hydrogen atoms into protons and are especially pertinent for experiments in the low-energy region.

Model for the low-voltage arc.
I. Stationary solution

Yu. Yu. Abramov and G. G. Gladush

(Submitted August 14, 1972; resubmitted September 7, 1973)
Zh. Tekh. Fiz., 44, 1183-1187 (June 1974)

1. It is well known from experimental studies (see, for example, refs. 1, 2 and citations therein) that at relatively high temperatures the transition from the diffusion mode in the thermionic converter to the arc mode is smooth, the striking and quenching voltages of the arc coincide, and the discharge is uniform along the electrodes. The picture changes with a reduction in temperature. The transition from the diffusion mode into the arc mode is accompanied by the appearance of luminosity at the anode and, subsequently, by a pronounced nonuniform distribution of plasma density and potential along the gap. The arc striking and quenching voltages do not coincide. These phenomena are associated with nonreproducibility of the volt–ampere characteristic (VAC). A theoretical description of the thermionic converter in the transition region requires an explanation of this effect; it is also necessary to have an "ideal" VAC, i.e., one calculated assuming uniformity along the electrodes. One would then investigate the solution for stability with respect to perturbations that are nonuniform along the electrodes and study the possibilities of describing a finite nonuniform state and the experimental VAC.

This paper is devoted to a theoretical description of an ideal VAC, which assumes a nonuniform distribution of plasma density and potential over the gap. It should be pointed out that a number of papers[1,3-5] have been devoted to a theoretical description of a VAC with a segment having a negative slope. All (except for ref. 5) are based on numerical calculations, and the general physical picture of the transition remains unclear; moreover, all obtain a VAC segment with negative differential resistance which is too small. The negative-resistance mechanism proposed in ref. 5 is associated with the energy balance of the system; a qualitatively different mechanism is proposed here. In addition, the region of applicability is relatively small in ref. 5.

2. Our calculation is based on the following model. It is assumed that ionization begins near the anode. As the current rises the ionization region spreads. The plasma gap is divided into two regions: a high-density region bordering on the anode, where ionization occurs, and a region near the cathode, in which there is no volume ionization and the electron space charge is neutralized by ions from the "arc" region. These regions are separated from one another by a double sheath of electric charge where there is a potential jump which accelerates electrons arriving from the diffusion region into the arc region, producing ionization there (see Fig. 1). We describe in qualitative fashion the reason for the creation of a negative slope in the VAC of such a model.

We first note that from the overall neutrality of the double layer it follows that the electron current from the diffusion region into the arc region is proportional to the counter ion current ($j_i \sim j_e \sqrt{m/M}$ is the Langmuir relation[6]). As the electron current increases (associated with a rise in the current emitted into the plasma, i.e., with a reduction in the cathode potential jump) the ion current also increases proportionately. On the other hand, the ion current at the cathode is proportional to the plasma density and, in addition, increases as the cathode jump decreases. It then follows that the plasma density at the cathode does not rise in proportion to the current, but more slowly. Therefore the size of the diffusion region, $x_0 \sim D_e n_0^{(1)}/j_e$ (where D_e is the electron diffusion coefficient and $n_0^{(1)}$ is the plasma density at the cathode), decreases with increasing current, and the size of the arc region increases. With a fixed potential jump in the double sheath, the plasma density in the arc region rises rapidly because of the increase in the current and the size of the region; it increases to such an extent that the ion current from the arc region increases more rapidly than the electron current. The rise in plasma density can be reduced by a reduction in the energy of the electrons producing ionization, i.e., by a reduction in the potential jump. Thus the potential jump decreases as the current increases, which is a basic reason for the reduction in the maintaining voltage of the arc. As a result a segment of the VAC has a negative differential resistance.

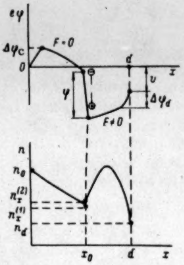

Fig. 1. Dependence of electron potential energy on the coordinate x. Schematic plasma density profile.

Certain assumptions are made in the following to obtain the analytic dependence of current on voltage: In particular, the electron temperature is assumed to be independent of coordinates. From the qualitative description and the results obtained below it follows that this assumption is not fundamental, but that makes it possible to simplify the calculations, which would otherwise be rather cumbersome. A number of other assumptions are specified in the text.

3. We consider the diffusion region. The x axis is directed from the cathode to the anode, and the plasma is uniform in the y and z directions. Since ionization and recombination do not occur in this region, the density profile of the quasineutral plasma must be linear:

$$n(x) = (n_x^{(1)} - n_0^{(1)})\frac{x}{x_0} + n_0^{(1)}, \tag{1}$$

where $n_x^{(1)}$ is the plasma density in the diffusion region at the boundary with the arc region. Substituting Eq. (1) in the usual boundary conditions for the ion and electron currents,[1] we obtain the following system of equations:

$$j_R \exp\left(\frac{-\Delta\varphi_k}{T}\right) - \frac{1}{2} n_0^{(1)} v_e = D_e \frac{n_0^{(1)} - n_x^{(1)}}{x_0} - u_e nE = \frac{1}{2} n_x^{(1)} v_e = j, \quad (2)$$

$$j_S - \frac{1}{4} n_0^{(1)} v_i \exp\left(-\frac{\Delta\varphi_C}{T}\right) = D_i \frac{n_0^{(1)} - n_x^{(1)}}{x_0} + u_i n(x) E(x) = -\frac{1}{2} n_x^{(2)} v_i, \quad (3)$$

where j_R is the Richardson emission current; T is the cathode temperature; j_S is the Saha–Langmuir current; $\Delta\varphi_C$ is the cathode potential jump, which retards electrons entering the plasma from the cathode; $n_x^{(2)}$ is the plasma density in the arc region at the boundary with the diffusion region; j is the current through the device.

The remaining notation is conventional. In the derivation of Eqs. (2) and (3), it is assumed that the potential drop at the jump is sufficiently great so that the ion current from the diffusion region into the arc region and the electron current from the arc region into the diffusion region can be neglected.

The ion and electron currents, which move in opposite directions through the collisionless double sheath, are coupled by the Langmuir relation

$$j_i = j_e \sqrt{\frac{m}{M}} \left(1 - \sqrt{\frac{T_e}{\varphi}}\right) (T_e \ll \varphi), \quad (4)$$

where T_e is the electron temperature.

This expression can be obtained from the Poisson equation on the basis of the overall neutrality of the sheath.

From Eq. (4) and the right-hand equations in the system (2)-(3), we obtain an expression for the current through the device by neglecting terms of order l/x_0 (l is the electron mean free path):

$$j = D_e \left(1 + \frac{T_i}{T_e}\right) \frac{n_0^{(1)}}{B x_0}, \quad (5)$$

where

$$B = 1 - \frac{\sigma_i}{\sigma_e} \sqrt{\frac{T_i}{T_e}} \left(1 - \sqrt{\frac{T_e}{\varphi}}\right),$$

$\sigma_{i,e}$ is respectively the scattering cross section for ions or electrons.

Since it is assumed that $j > 0$, it is necessary to satisfy the condition $B > 0$. Since $\sigma_i > \sigma_e$, this imposes certain conditions on the value of the electron temperature; these are assumed below. One can show that consideration of the finiteness of the width of the double sheath reduces these conditions, but consideration of a sheath with a dimension comparable with the mean free path complicates the problem tremendously (particularly the study of stability). Therefore the double sheath will be assumed to be collisionless and the quantity B is taken to be a constant of order unity.

Eliminating the quantity $\Delta\varphi_C$ from the left-hand equations of the system (2)-(3) and neglecting the Saha–Langmuir current, we obtain an expression for the plasma density at the cathode:

$$n_0^{(1)} = 2 \sqrt{\frac{j_R n_x^{(2)}}{v_e}}. \quad (6)$$

Substituting Eq. (6) in Eq. (5) and using Eq. (4), we obtain an expression for the current:

$$\frac{j}{j_R} = 8 \frac{D_e^2 \left(1 + \frac{T_i}{T_e}\right)}{B^2 x_0^2 v_e^2} \sqrt{\frac{T_e}{T_i}} \left(1 - \sqrt{\frac{T_e}{\varphi}}\right). \quad (7)$$

Since x_0 varies from quantities of the order of the mean free path l to the value d (size of the gap), it follows from Eq. (7) that $j_R (l/d)^2 \leqslant j \leqslant j_R$, i.e., the region of current variation is rather large.

The potential drop $\Delta\varphi_d$ in the diffusion region is found from the right-hand equations of the system (2)-(3) by integration of the quantity nE between the limits $(0, x_0)$ using Eq. (1),

$$\frac{\Delta\varphi_d}{T_e} = \frac{1-B}{B} \ln \frac{n_0^{(1)}}{n_x^{(1)}} = \frac{1-B}{B} \ln \frac{x_0 v_e B}{2D_e} \cong \frac{1-B}{B} \ln \frac{x_0}{l}. \quad (8)$$

The magnitude of the cathode potential jump is found from Eq. (3),

$$\frac{\Delta c_k}{T} = \ln \frac{1}{2} \sqrt{\frac{T_e}{T_i}} \frac{n_0^{(1)}}{n_x^{(1)}} \left(1 - \sqrt{\frac{T_e}{\varphi}}\right). \quad (9)$$

A comparison of Eqs. (8) and (9) indicates that $\Delta\varphi_d$ and $\Delta\varphi_C$ are quantities of the same order of magnitude.

4. To find the VAC it is necessary to determine the potential drop in the arc region and, in addition, the dimension of this region $d - x_0$. It is assumed that ionization in the arc region is produced by fast electrons which are accelerated in the potential drop of the double sheath, with the ionization length λ being greater[7] than d. In addition, we assume that excitation of the atom to some level E_1 is the limiting state.[3] This assumption is not essential for this model, but facilitates the analytic calculation.

Because of the assumption $\lambda > d$, the density of fast electrons decreases with distance, and in the diffusion limit

$$n_f = n_{fx} \left(1 - \frac{x - x_0}{d - x_0}\right), \quad (10)$$

where $n_{fx} = j(d - x_0)/D_{ef}$ is the density of fast electrons at the jump, $D_{ef} = D_e(\varphi / T_e)$ is the diffusion coefficient for fast electrons.

In this case, the expression for the generation function takes the form

$$F = \frac{3j}{\lambda^2} (d - x) \exp\left(\frac{\varphi - E_1}{T_e}\right) \quad (\varphi < E_1). \quad (11)$$

A relatively cold plasma is formed ($T_e \ll \varphi$) as a result of ionization in the arc region. From the equation

$$\operatorname{div} j_i = F$$

using quasineutrality and the standard boundary conditions for the ion current, we find a value for the density n(d) of the cold plasma at the anode and the density $n_x^{(2)}$ at the jump,

$$n_x^{(2)} = 2n(d) = \frac{2j}{\lambda^2 v_i}(d - x_0)^2 \exp\left(\frac{\varphi - E_1}{T_e}\right). \qquad (12)$$

The potential jump at the anode is found by integration of the continuity equation for slow electrons:

$$j_e = 2\int_{x_0}^{d} F(x)\,dx = \frac{1}{4} n(d) v_e \exp\left(-\frac{\Delta\varphi_a}{T_e}\right). \qquad (13)$$

From Eqs. (12) and (13), we have

$$\frac{\Delta\varphi_a}{T_e} = +\ln \frac{1}{12}\sqrt{\frac{M}{m}}\sqrt{\frac{T_e}{T_i}}. \qquad (14)$$

The size of the diffusion region, x_0, is found from Eqs. (4) and (12):

$$\frac{\varphi - E_1}{T_e} = \ln\left[\sqrt{\frac{m}{M}}\frac{\lambda^2}{(d - x_0)^2}\left(1 - \sqrt{T_e/\varphi}\right)\right]. \qquad (15)$$

The plasma potential drop in the arc region is determined by the ambipolar field, which is proportional to the logarithm of the density ratio. In view of Eq. (12), this means that

$$\frac{\Delta\varphi_p}{T_e} = -\ln 2. \qquad (16)$$

Equations (7)-(9) and (14)-(16) describe the VAC of a converter in the particular mode studied here. Since Eq. (7) indicates that x_0 decreases monotonically as the current rises, the simple relation which follows from these same equations,

$$\frac{\partial u}{\partial j} = \frac{T_e}{j}\left(\frac{d - 2x_0}{d - x_0} - \frac{1}{B}\right) \qquad (17)$$

shows that with a decrease in x_0 from d to a value of the order of the electron mean free path, the voltage u across the discharge gap decreases everywhere if $B < 0.5$.

Generally speaking, calculation of the VAC for such a system is a difficult problem. Difficulties arise primarily because of the complex form of the generation function, the necessity for considering heating of plasma electrons in the arc region, etc. It should be noted that the self-consistent problem of the calculation of a developed low-voltage arc in the parameter region where the cathode beam is important has not been solved at the present time, even with the help of a computer.[8] Therefore the simplifications made above are unavoidable.

Nevertheless, one can indicate the parameter region in which the model proposed above is strictly valid, although it appears possible that the actual region of applicability is broader.

We shall assume that ionization is mainly achieved by direct collision of fast electrons. In this case, the maximum voltage on the device is equal to the ionization potential of the gas, $E_1 = E_i$; $E_i = 3.89$ eV for Cs. The absence of fast-electron reflection from the arc region and also the requirement $\lambda > d$ limits analytic consideration to values $d \leqslant 20l$. In accordance with Eq. (15), the reduction in voltage does not exceed a quantity of the order of one volt. As an illustration, we consider a specific physical situation. Let $l \sim 0.1$ cm ($p \sim 3 \cdot 10^{-2}$ mm Hg), $d - x_0 = 0.5$ cm, $d = 0.8$ cm, and the maximum density $n_e = 2 \cdot 10^{11}$ cm^{-3}. In this case, the current is approximately 60 mA. From the balance between heating of cold plasma electrons by the beam and the cooling at the anode barrier, it follows that the temperature of the cold plasma is no more than 0.2 eV. Estimates show that in this case the effect of the cold plasma on ionization of Cs atoms can be neglected. One can estimate from Eq. (7) the Richardson current j_R which must be selected in order to obtain the assigned parameters; $j_R \sim 0.5$ A. Knowing j_R, one can estimate the current at maximum voltage, $j_V \sim 10$ mA. The voltage falls by 0.3 V when the current is increased to 60 mA. With further increase in current, the temperature and density of the cold plasma rises and its role in ionization becomes significant. The example presented is not inconsistent with available experimental data.

Model for the low-voltage arc.

II. Stability

Yu. Yu. Abramov and G. G. Gladush

(Submitted August 14, 1972; resubmitted September 7, 1973)
Zh. Tekh. Fiz., 44, 1188-1192 (June 1974)

The instability growth rate for the transition from the diffusion mode to the arc mode is calculated in the linear approximation. It is shown that homogeneous perturbations along the electrode can be stabilized by high external resistance; inhomogeneous perturbations can grow under these conditions.

In the preceding paper,[1] a model is proposed for the stationary state of the low-voltage hot-cathode arc. In this model, the negative segment in the volt–ampere characteristic (VAC) results from a nonuniform distribution of potential and plasma density over the gap. The plasma can be divided into two regions: a diffusion region close to the cathode in which there is no volume ionization and an arc region near the anode. The present paper considers the stability of this state.

The time-dependent equation for the variation of plasma density δn in the diffusion region is the ordinary equation for ambipolar diffusion (the notation used is the same as that in ref. 1):

$$\frac{\partial}{\partial t}\delta n - D_a\frac{\partial^2}{\partial x^2}\delta n = 0. \tag{1}$$

It is assumed here and in the following that the characteristic frequencies of these perturbations do not exceed the electron–neutral and ion–neutral collision frequencies or the electron and ion plasma frequencies. We seek a solution of Eq. (1) in the form

$$\delta n(x, t) = e^{-i\omega t}\delta n(x). \tag{2}$$

If we substitute the solution of Eq. (1) in the usual boundary conditions, we obtain equations which connect the perturbed densities at $x = 0$ and $x = x_0$ with the current variation δj. As in ref. 1, $x = 0$ is the plasma boundary at the cathode and $x = x_0$ is the boundary between the diffusion and arc regions. In the derivation of the boundary conditions one should consider the fact that the current variation at $x = x_0$ results not only from the change in plasma density at the boundary, but also from its displacement by an amount δx_0:

$$\delta j\,|_{x=x_0} = \frac{1}{2}\bar{v}_e\delta n_x^{(1)} + \left.\frac{\partial n}{\partial x}\right|_{x=x_0}\delta x.$$

The next two equations are obtained from the Langmuir condition (1.4) [here and in the following (1.4) denotes reference to Eq. (4) of ref. 1] and from the expression for the perturbation of the potential drop in the plasma, which is obtained by variation over the variables x_0, j, and n in the expression [see (1.8)]:

$$\Delta\varphi_d = \frac{j_e}{u_e}\int_0^{x_0}\frac{dx}{n(x)} + \frac{D_e}{u_e}\int_0^{x_0}\frac{\partial n}{\partial x}\frac{dx}{n(x)}.$$

By variation of the relation $j = j_R\exp(-\varphi_k/T) - {}^1\!/_2 n_0^{(1)}\bar{v}_e$ under the condition $j \ll {}^1\!/_2 n_0^{(1)}\bar{v}_e$, we obtain a relation between the current perturbation and the perturbation of the cathode potential jump:

$$\delta j = \frac{1}{2}\frac{n_0^{(1)}\bar{v}_e\delta\varphi_k}{T} + \frac{1}{2}\delta n_0^{(1)}\bar{v}_e.$$

Thus, we have six equations for the seven unknowns $\delta\varphi_k$, $\delta n_0^{(1)}$, $\delta n_x^{(1)}$, $\delta\varphi_d$, $\delta n_x^{(2)}$, δx_0, and δj. These equations are not presented in complete form because of their complexity.

The remaining unknown quantities are found from an analysis of the equations in the arc region. The equation for ambipolar diffusion in this region has the form

$$\frac{\partial}{\partial t}\delta n - D_a\frac{\partial^2}{\partial x^2}\delta n = \delta F, \tag{3}$$

where

$$\delta F = F(x)\left(\frac{\delta j}{j} + \frac{\delta\varphi}{T_e}\right) \tag{4}$$

is the variation of the generation function [see (1.11)].

One can represent δF in such a form if the ionization process is successfully established during the time of variation of the quantities δj and $\delta\varphi$. It is necessary that the characteristic time of the instability be greater than the fast-electron diffusion time over the distance $(d - x_0)$:

$$\omega \ll D_{e\varphi}\frac{D_{\mathrm{ef}}}{(d - x_0)^2}. \tag{5}$$

Substituting the solution of Eq. (3) in the boundary conditions at the left and right ends of the arc region, we obtain two equations in which the new unknowns $\delta\varphi$ and $\delta n(d)$ appear. Still another equation can be obtained from the condition for the continuity of the electron current of the cold plasma,

$$\delta j_e(d) = \frac{1}{4}\delta n(d)\bar{v}_e\exp\left(-\frac{\varphi_d}{T_e}\right) - \frac{1}{4}n(d)\bar{v}_e\exp\left(-\frac{\varphi_d}{T_e}\right)\frac{\delta\varphi_d}{T_e}$$

$$\delta j_e(d) = \frac{\partial}{\partial t}\int_{x_0}^{d}\delta n(x)\,dx + 2F\delta x_0 - 2\int_{x_0}^{d}\delta F(x)\,dx. \tag{6}$$

In the last equation the increase in electron current at the anode due to the increase in the size of the arc region is taken into account. For the plasma in the diffusion region this condition degenerates into an equality of the perturbed electron current at the cathode and at the jump. This difference is associated with the fact that the electron and ion currents are of the same order of magnitude in the arc region since the cold plasma does not transport current. Still another equation is the expression for the perturbation of the potential drop $\delta\varphi_p$ in the plasma of the arc region, which is obtained in a manner similar to that for $\delta\varphi_d$. A final equation is Ohm's law for the external circuit:

$$\delta u = -R\int\delta j ds = -R\delta I, \tag{7}$$

where δu is the perturbation of the potential drop in the interelectrode space, which is equal to the sum of the perturbations of the potential jumps and the perturbations of the potential drops in the plasma of the diffusion and arc regions, δI is the perturbation of the total current through the converter, and R is the external resistance.

The integral in Eq. (7) is taken over the area of the emitter.

Thus we have 11 equations for the 11 unknowns, and from the consistency conditions there follows an equation for ω (intermediate calculations are not given because of their complexity):

$$\Phi - 1 + \Psi\left[\frac{1}{2B} - \frac{x}{1-x} + \frac{1}{4}\varkappa^2 x(1-x) + \Phi\right]$$

$$-\frac{1}{2B}\Psi\int_0^1 (\cos\varkappa x\tau - 1)\frac{d\tau}{\tau^2}$$

$$\frac{1}{B}\int_0^1 \frac{d\tau}{\tau^2}\left[\frac{\sin\varkappa x\tau}{\varkappa x} - \tau\right] = -\frac{RI}{T_e}, \qquad (8)$$

where

$$\Phi = \left[\frac{1}{3} - \frac{1}{3}\cos\varkappa(1-x) + \frac{1}{2}\varkappa(1-x)\sin\varkappa(1-x)\right]$$

$$\times\left[\frac{\sin\varkappa(1-x)}{\varkappa(1-x)} - \cos\varkappa(1-x)\right]^{-1},$$

$$\Psi = [1 - B\cos\varkappa x - 2(1-B)\sin\varkappa x \mid \varkappa x]$$

$$\left[(1-B)\cos\varkappa x - \frac{1}{2}B\varkappa x\sin\varkappa x\right]^{-1},$$

$$\varkappa = \sqrt{\frac{\omega i}{D_a}}\,d, \quad x \equiv \frac{x_0}{d}.$$

Equation (8) can be simplified when $\varkappa \ll 1$. This condition means that during the growing time, all processes in the discharge plasma reach completion, i.e., a condition of quasistationarity exists. As expected, the variation of such quantities as φ_p, and φ_a, which do not depend on current in the stationary case, then goes to zero and Eq. (8) becomes the following equation:

$$\frac{j}{T_e}\frac{\partial u}{\partial j} - \varkappa^2\left[\frac{x^2}{4B} + \frac{11}{120}(1-x)^2 + \frac{19}{120}x(1-x)^2 + \frac{1}{6}\frac{x^3}{1-x}\right] = -\frac{RI}{T_e}. \qquad (9)$$

The condition $\varkappa \ll 1$ means that this equation is valid when the differential and external resistances are similar. Equation (9) indicates that the stability of the solutions for small $\varkappa$ is determined by the sign of the total (differential plus external) resistance. Since the differential resistance is negative in this case, the system is stable for $R > |\partial u/\partial I|$ and unstable for $R < |\partial u/\partial I|$. This condition is similar to that for any electronics instability and is perfectly reasonable, since the internal structure of the device itself does not manifest itself at low frequencies, and only the existence of a negative differential resistance is important (see Fig. 1).

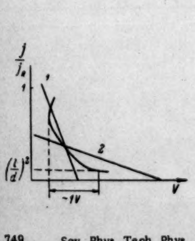

Fig. 1. Approximate form of volt–ampere characteristic and load lines. 1) $R < |du/dj|$; 2) $R > |du/dj|$.

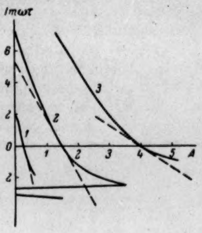

Fig. 2. Dependence of Im ω on $A = IR/T_e$ for various values of $x = x_0/d$, $\tau = d^2/D_a$. x: 1) 0.2; 2) 0.6; 3) 0.8.

Since all the terms in Eq. (9) are of order of unity when $R \sim |\partial u/\partial I|$, one can assume the characteristic roots of Eq. (8) are of the order of unity also, which corresponds to a characteristic growth rate $\Gamma \sim D_a/d^2$. This assumption is confirmed by numerical solution of Eq. (8), the results of which are shown[1] in Fig. 2. The dependence of Im ω on the quantity $A = RI/T_e$ is also shown in the figure.

The dashed curves correspond to the approximate equation (9). It is clear that when x is not very close to unity the approximate and exact solutions are similar up to $\varkappa \sim 1$. For $A < A_{cr} = |\partial u/\partial I|(I/T_e)$ (i.e., $R < |\partial u/\partial I|$), there are both positive and negative values of Im ω (Re ω = 0) and for $A > A_{cr}$, Im $\omega < 0$. The results shown indicate that the growth time is of the order of the time for ambipolar diffusion of an ion over a distance d, $\tau = d^2/D_a$, i.e., time for establishment of the stationary state.

The growth rate is a maximum for R = 0, which is reasonable since the resistance has a stabilizing effect.

It is of interest to consider the stability of the system with respect to perturbation with wave vector parallel to the plane of the electrodes. Such perturbations, on the one hand, will be stabilized by particle diffusion; on the other hand, the effect of resistance on such perturbations is not stabilizing since they do not change the total current in the circuit. For consideration of spatial dispersion along the y axis, the term $-k_y^2 D_a \delta_n$ appears in Eq. (1), which is equivalent to the substitution $i\omega \to i\omega + D_a k_y^2$, and the right sides of Eqs. (8) and (9) go to zero. For $k_y d \ll 1$, which is possible when $L \gg d$ where L is the dimension of the device, the system is absolutely unstable along the electrode, and even for resistances as high as desired can break down into regions with higher and lower current densities. In the nonlinear stages, this can lead to the formation of the current filament which is also observed experimentally.[2] Since the growth rate is greater than the reciprocal time for establishment of the stationary state, even for fast turn-on of the device, the stationary state should be established immediately as a nonuniform state (along the electrodes), bypassing the uniform stage, as has also been observed experimentally.[3] For devices with small longitudi-

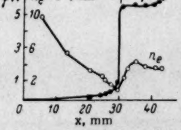

Fig. 3. Distribution of potential φ and density n on the axis of a discharge gap. L = 30 mm, d = 45 mm, $p = 2 \cdot 10^{-3}$ torr, $T_k = 950°K$.

nal dimensions, the quantity k_y can not be small, and transverse diffusion will be the significant stabilizing factor. In this case current flow along the electrodes can play an important role. Without considering such currents, however, one can estimate in order of magnitude the minimum dimension of the device for which the "transverse" instability will be quenched. Replacing $i\omega$ by $k_y^2 D_a$ in Eq. (9) and substituting for $\partial u/\partial j$ in accordance with (1.17), we obtain

$$L_{\min} = 2\pi d\,[x^2|4B + 11(1-x)^2|120$$

$$+ 19(1-x)x|120 + x^3|6(1-x)]^{1/2}$$

$$\times|(1-2x)|(1-x)-1|2B|^{-1/2}$$

$L_{\min} \sim d$ for $x \sim 0.5$.

This estimate agrees qualitatively with previous results[4] where for gaps of the order of the cathode dimension volt–ampere characteristics are obtained with a large segment of negative differential resistance with a plasmoid having sharply defined boundaries growing from anode to cathode as the current increases. A similar phenomenon is also observed in the development of the hot-cathode arc in inert gases.[5]

It should be noted that the assumptions upon which this theory is based and its results can find qualitative justification and confirmation in the phenomenon of anode spot formation in low-pressure arcs and in glow discharges.[6] Probe measurements show that the anode sheath (and after contraction, the anode spot also) is separated from the positive column by a double sheath of electric charge in which there is a potential drop of the order of the ionization potential of the gas. This plasma has a higher density and the rate of ion generation in it is greater than the rate of ion production in the plasma of the positive column. It is positively charged both with respect to the main plasma and with respect to the anode. The reason for the formation of an anode spot in this case may be the development of the transverse instability described here.

In conclusion, the authors thank D. V. Karetnikov for his interest.

Immediately after this paper was submitted an experimental paper of A. I. Kiryushchenko and M. A. Lebedev (Zh. Tekh. Fiz., 42, 1657 (1972) [Sov. Phys. – Tech. Phys., 17, 1322 (1973)] was published which confirms the basic assumptions of this model; in particular, the experimentally measured potential and plasma density profiles (Fig. 3) are in good agreement with the theoretical profiles (Fig. 1 of ref. 1). The arc region is separated from the diffusion region by a collisionless potential jump, and a beam of fast electrons is observed in the arc region.

Interferometer measurement of the neutral cesium distribution in a short low-voltage arc

Yu. L. Serov and I. P. Yavor

(Submitted July 19, 1973)
Zh. Tekh. Fiz., 44, 1193-1199 (June 1974)

An experimental study of the distribution of unexcited cesium atoms in a short low-voltage arc is described. The measurements use a Rozhdestvenskii interferometer and superposition of interference patterns. A significant radiation in the density of unexcited cesium atoms is observed in an arc in the interelectrode gap of a hot-cathode diode.

1. The short low-voltage cesium arc has been the subject of much experimental and theoretical study. Usually, however, attention has been focused on the charged components of the low-voltage plasma; the density and distribution of unexcited cesium atoms in the narrow gap of a thermionic converter or cesium diode are usually inferred from the thermal conditions in the apparatus and in the cesium reservoir. No direct measurements have been reported of the neutral cesium density. However, an important redistribution of neutrals can occur in a discharge plasma, and this redistribution can affect the plasma.[1]

In this work we describe measurements of the density and distribution of unexcited cesium atoms in the interelectrode gap of a hot-cathode planar diode. The measurements are carried out under various operating conditions of the diode by means of a dual-beam interferometer used with a spectrograph. We use the Rozhdestvenskii hook method[2] and the superposition of interference patterns.[3]

2. Figure 1 shows the experimental apparatus, including the dual-beam interferometer and the spectrograph. Continuum light from an arc lamp is focused by a lens onto the first semitransparent mirror of the interferometer. Here it is split into two beams of equal intensity. After one of these beams is reflected from a total-reflection mirror, it passes through the gap of the cesium diode. After the second beam is passed through a compensation tube and a glass plate to rotate the interference fringes, it strikes a second total-reflection mirror; then it strikes a second semitransparent mirror, beyond which the two beams are combined and directed to the slit of the spectrograph.

The hook method is usually used for measurement in homogeneous vapor or gas columns. The interferometer is adjusted by the classical method,[2] and the interference fringes are localized at infinity. It has been argued[1] that the hook method cannot be used to study objects in which there are strong density gradients: When the interference fringes are localized at infinity a large density gradient transverse to the axis of the light beam causes the hooks to become blurred.

In the narrow gap of a cesium diode with markedly different electrode temperatures the neutral density varies considerably over the gap, even in the free-running mode. Certain measures must be taken to avoid blurring of the hooks and to make it possible to determine the distribution of atoms over the gap from a single interferogram. The gap must be focused onto the spectrograph slit, and the spatial resolution in the direction perpendicular to the electrode surfaces (to the gap) must be good. In practice this second requirement can be met by using a narrow defining slit parallel to the gap to stop down the optical system in the specified direction. Furthermore, the interference fringes must be localized at the center of the diode gap. In this case the fringes and the gap are focused on the spectrograph slit. The interferometer is adjusted by the method of ref. 4 to localize the interference fringes at the center of the gap. Under the specified conditions, the interferogram contains a spectral sweep of the image of the gap with the interference fringes. The upper edge of the interferogram corresponds to the anode surface, while the lower edge corresponds to the cathode surface. Each narrow part of the interferogram parallel to the gap is formed by beams passing through the corresponding part of the gap and carries information about it.

The thermionic energy converter is a cesium diode with molybdenum electrodes. The working surfaces are the flat

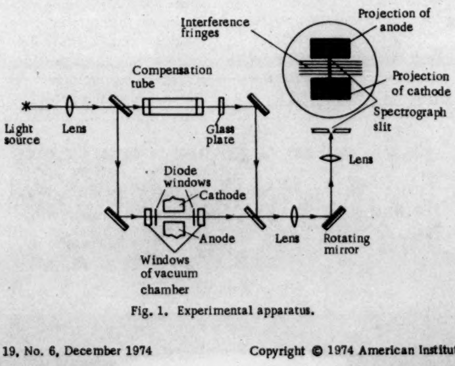

Fig. 1. Experimental apparatus.

ends of cylindrical electrodes, between which a gap from 0 to 2 mm can be established. The lateral electrode surfaces are covered by a BeO ceramic. The electrodes are 11 mm in diameter (this is the path length of the beam in the discharge region). The housing of the apparatus containing the electrodes has two windows through which the gap can be illuminated. The distance between these windows, i.e., the total path length of the light in the cesium vapor, is 50 mm. The diode housing is placed in a vacuum chamber, also fitted with windows.

The interferometer measurements yield information about the total neutral density along the path of the light, which is $\int_0^l N(x)dx$, where N(x) is the neutral density and l is the total length of the vapor column. It is necessary to take account of the comparatively cold layers of cesium vapor surrounding the interelectrode gap. To determine quantitatively the contribution to Nl from these layers and the changes in these layers which occur when conditions in the interelectrode gap are varied, we have an aperture 1 mm in diameter through the anode housing, parallel to its working surface and very close to it; part of the light beam passes through this aperture. The changes which occur in the neutral density in the gap upon, e.g., a change in the discharge current, are determined from the difference ΔNl along the paths of two light beams, one passing through this aperture, where there is no discharge, and the other passing through the interelectrode gap. Certain results obtained in this manner are monitored under conditions corresponding to the closest possible arrangement of windows (in which the distance between a window and the edge of the gap is 2 mm). However, this window arrangement causes difficulties so that it is used only in control experiments to check the validity of the basic series of measurements.

3. The hook method is used to measure the density of cesium atoms in the apparatus; the cesium vapor pressure can easily be determined from this density. Comparison of this pressure with that determined from the temperature of liquid cesium, on the basis of the data of ref. 5 shows the discrepancy to be less than 8% from 10^{-1} to 10 torr. This discrepancy lies within the total experimental error. The oscillator strength of the $6P_{3/2} - 6S_{1/2}$ transition (the line wavelength is λ_j = 8521 Å) used in these measurements f = 0.66 is calculated from the data of ref. 6.

A significant gradient in the neutral cesium density in the gap deforms the hooks. Figure 2 illustrates this behavior with three interferograms with hooks at the resonance line λ_j = 8521 Å. The cesium vapor pressure P = 4 torr and the interelectrode gap d = 1.6 mm. The lower interferogram is obtained under isothermal conditions, i.e., with the cathode, anode, and wall at the same temperature. The hooks have the usual shape. The central interferogram is obtained in the free-running mode (with the anode–cathode circuit opened), and at a cathode temperature T_c = 1600°K and an anode temperature T_a = 800°K. There is a significant density gradient in the gap; the densities at the electrodes differ by a factor of 2. The change in the neutral cesium density over the gap can be determined in the usual manner by measuring the distance between the hook vertices. The average gradient can be determined by counting the numbers of hooks to the right and left of the absorption line.[7] Taking account of the doublet structure of the cesium levels we can write

$$\overline{\frac{dN}{dy}} = \frac{m-n}{ald}\left(\sum_j \frac{f_j\lambda_m\lambda_j^2}{\lambda_m^2-\lambda_j^2} - \sum_j \frac{f_j\lambda_n\lambda_j^2}{\lambda_n^2-\lambda_j^2}\right)^{-1}, \tag{1}$$

$$a = \frac{e^2}{2\pi mc^2},$$

where m and n are the numbers of interference fringes or hooks along the vertical direction to the right and to the left, respectively, of absorption line λ_j, and λ_m and λ_n are the wavelengths at which the hooks or fringes are counted.

The upper interferogram is obtained with an arc discharge in the gap, at an arc current of i = 7 A. Here the hooks have contracted and become more deformed.

An important change in the density gradient over the gap can severely distort the hooks, which can become closed figures like the rings in Fig. 3.

From the condition $\partial\chi_{12}/(\partial y) = 0$ (χ_{12} is the phase difference between the interfering beams) we can find an equation for the neutral density gradient at the point at which, at wavelength λ_m, there is a "side" extremum on the interference fringe:

$$\frac{dN}{dy} = \frac{b}{al\lambda_m}\sum_j \frac{1}{f_j}\left(\frac{\lambda_m^2}{\lambda_j^2} - 1\right), \tag{2}$$

where b is the number of fringes per unit length at wavelength λ_m in the y direction in the absence of the vapor.

To determine the relative distributions of the neutral density in the interelectrode gap and the changes in these distributions with changes in the diode conditions it is more convenient to use a superposition method. From the blurs on the interferogram we can immediately determine the neutral distribution over the gap, since the distance $\lambda - \lambda_j$ from the blur at a given cross section of the gap to the center of the absorption line is proportional to the change in the product Nl along the beam in question:

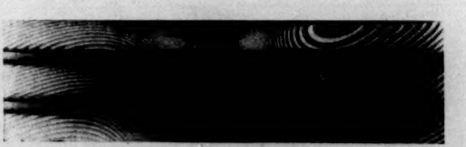

Fig. 2. Interferograms with hooks at the Cs λ = 8521 Å line. P = 4 torr, d = 1.6 mm.

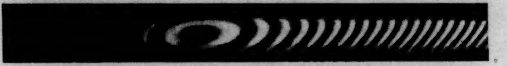

Fig. 3. Interferogram with closed fringes.

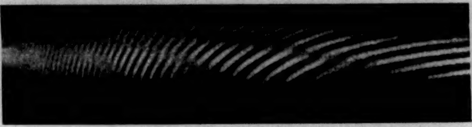

Fig. 4. Interferogram with blurs.

$\Delta(Nl) \sim \lambda - \lambda_j$. Figure 4 illustrates this situation with a blurred interferogram obtained by superimposing the interferogram corresponding to the free-running mode on the interferogram obtained with an arc.

When a resonant doublet is used it is necessary to take account of the total change in the dispersion near both absorption lines. Inspecting the interference pattern with blurs on both sides of the absorption line, we see that it is not symmetric with respect to the center of the line, because of the influence of the neighboring doublet component. The positions of the two neighboring blurs, of orders of m_1 and m_2, near the component λ_{j_1} of the resonance doublet are given by

$$\left.\begin{aligned} \Delta Nal\sum_j \frac{\lambda_{m1}^2\lambda_j f_j}{\lambda_{m1}^2-\lambda_j^2} &= \frac{2m_1+1}{2}\lambda_{m1}, \\ \Delta Nal\sum_j \frac{\lambda_{m2}^2\lambda_j f_j}{\lambda_{m2}^2-\lambda_j^2} &= \frac{2m_2+1}{2}\lambda_{m2}, \\ m_2 &= m_1+1. \end{aligned}\right\} \tag{3}$$

From these equations we can easily find an equation for the blurring order:

$$m_2=\frac{1}{2}\,\frac{\sum\limits_j \lambda_j^3 f_j\left[\frac{1}{\lambda_{m2}^2-\lambda_j^2}+\frac{1}{\lambda_{m1}^2-\lambda_j^2}\right]}{\sum\limits_j \lambda_j^3 f_j\left[\frac{1}{\lambda_{m2}^2-\lambda_j^2}-\frac{1}{\lambda_{m1}^2-\lambda_j^2}\right]}. \tag{4}$$

After rounding off the value of m_2 found from this equation to the nearest integer, we can determine the value of ΔN from (3). In addition, if we subtract the first equation in (3) from the second, we find

$$\Delta Nal\left[\lambda_{m2}^2\sum_j \frac{\lambda_j^3 f_j}{\lambda_{m2}^2-\lambda_j^2}-\lambda_{m1}^2\sum_j \frac{\lambda_j^3 f_j}{\lambda_{m1}^2-\lambda_j^2}\right] = \frac{(2m_1+1)(\lambda_{m2}-\lambda_{m1})+2\lambda_{m2}}{2}. \tag{5}$$

If the distance between the blurs satisfies $\lambda_{m2} - \lambda_{m1} < 50$ Å and if $\lambda_{m2} - \lambda_{j_0} < 100$ Å with $m_1 < 3$, we can neglect the first term on the right side of Eq. (5) for the resonant cesium doublet with an error of less than 1%. Then ΔN can be found without determining the order of the blur if the best-separated blurs are used:

$$\Delta N=\frac{\lambda_{m2}}{al}\left[\lambda_{m2}^2\sum_j \frac{\lambda_j^3 f_j}{\lambda_{m2}^2-\lambda_j^2}-\lambda_{m1}^2\sum_j \frac{\lambda_j^3 f_j}{\lambda_{m1}^2-\lambda_j^2}\right]^{-1}. \tag{6}$$

To incorporate the displacement of the interference pattern over the time between two exposures, we must insert identical terms (independent of λ) into the left sides of the first two equations of system (3). In this manner the displacement of the pattern between two exposures does not affect the value of ΔN determined from Eq. (5) or (6).

Figures 5a-5e show the distributions of the cesium-atom density in the arc discharge obtained by this method. These measurements are carried out at a fixed interelectrode gap of d = 1.6 mm and at a cathode temperature of 1400°K. We see that the density is governed by the vapor pressure and the current. As a current flow the neutral density in the discharge region falls off. As the vapor pressure is increased the relative change in the density at a fixed current increases. At a pressure of $P \approx 1$ torr the greatest change in the density occurs near the cathode; toward the anode surface, the neutral density approaches the level governed by the anode temperature. As the cesium vapor pressure is increased the maximum of the change in the neutral density shifts toward the anode, as can be clearly seen on the interferograms with blurs. The maximum value ΔN_{max} at a current of 10 A varies from 20% to 60% as the cesium vapor pressure is raised from 1 to 6 torr. The functional dependence on the current becomes smoother. We can assume (Fig. 5) that the neutral density in the arc near an electrode surface is governed by the electrode temperature, while that at the center of the gap is governed by processes occurring in the arc. To check this point, we carry out measurements using interferograms obtained with the spectrograph slit oriented parallel to the diode gap, and we determine the neutral density in a narrow (0.1mm) layer near the anode. These measurements show the density near the anode to be governed by the anode temperature.

The temperatures of the neutrals and ions in the arc can be compared if we take account of elastic scattering of electrons by ions and resonant charge exchange of ions. Over the time preceding the resonant charge exchange of an ion, the ion acquires from electrons an energy

$$\varepsilon=\frac{2m_e}{m_a}\frac{\tau_{ei}}{\tau_{ia}}k(T_e-T_i), \tag{7}$$

where τ_{ei} and τ_{ia} are the effective electron–ion and ion–neutral collision times.

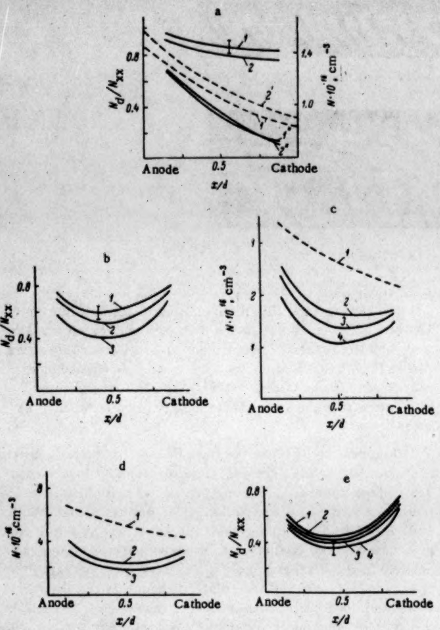

Fig. 5. Density distribution of the Cs atoms in the diode gap. a: 1-1") P = 1.15 torr. 1) $(N_d/N_{xx})(x/d)$, i = 5 A; 1') N(x/d), i = 0; 1") N(x/d), i = 5 A. 2-2") P = 1.3 torr. 2) $(N_d/N_{xx})(x/d)$, i = 10 A; 2') N(x/d), i = 0; 2") N(x/d), i = 10 A. b: P = 3 torr, $(N_d/N_{xx})(x/d)$. 1) i = 10 A; 2) 15 A; 3) 20 A. c: P = 3 torr, N(x/d). 1) i = 0; 2) 10 A; 3) 15 A; 4) 20 A. d: P = 6 torr, $N(x\cdot d)^{-1}$. 1) i = 0; 2) 5 A; 3) 20 A. e: P = 6 torr, $(N_d/N_{xx})(x/d)$. 1) 5 A; 2) 15 A; 3) 10 A; 4) 20 A.

At a pressure of a few torr and at an electron density of $N_e = 5\cdot 10^{14}$ cm^{-3} an ion manages to acquire an energy of $\varepsilon \sim 10^{-3}$ eV, i.e., the temperatures of the ions and neutrals become equal as a result of energy transfer, so that we can speak of a common heavy-particle temperature T. To evaluate the neutral temperature we use the heat-balance equation[8]

$$\frac{d}{dx}\left(\varkappa_a \frac{dT}{dx}\right) = -\frac{3m_e}{m_i}\frac{N_i}{\tau_{ei}}k(T_e - T)$$

$$4\frac{m_e}{m_a}k(T_e - T)\frac{v_e}{l_{ea}}N_e, \tag{8}$$

where $\varkappa_a$ is the thermal conductivity of the neutrals.

Assuming an interelectrode gap of d = 2 mm, a pressure of P = 4 torr, $N_e = 7\cdot 10^{14}$ cm^{-3}, T_e = 3000°K, T_c = 1400°K, T_a = 600°K, and $\bar{\varkappa} = 1.65\ T_{av}^{1/2}$, we find T = 2300°K from Eq. (8) for the center of the gap.

We can thus conclude from these measurements that in the weakly ionized plasma of a low-voltage arc there is an important redistribution of unexcited cesium atoms caused by the significant heat evolution in the discharge region. We believe that it would be worthwhile to carry out a more detailed comparison of the plasma parameters and neutral density by means of the appropriate calculations. We note that in our experiments we have observed hooks at lines corresponding to transitions from the $6P_j$ level; these can also be used for more detailed studies in a cesium plasma.

In conclusion the authors thank Yu. A. Dunaev for his constant interest in this work, for assistance, and for discussion.

Formation of a narrow gas jet in vacuum

G. I. Dimov and V. Ya. Savkin

(Submitted June 25, 1973)
Zh. Tekh. Fiz., 44, 1200-1205 (June 1974)

Experiments on the formation of a narrow hydrogen jet in vacuum in which the jet diameter and gas density remain constant are described. It is possible to form such a jet if a conical limiter is used to block the peripheral part of the jet from a Laval nozzle. A hydrogen jet whose diameter decreases from 1 to 0.3 cm over a length of 20 cm with density of 10^{16} molecules/cm^3 has been produced. Experimental data on the formation of thin gas jets which condense into a supersonic hydrogen jet are also reported.

The experimental apparatus described in ref. 1 has been used to study the influence of a conical limiter on a gas jet issuing from a Laval nozzle into vacuum with a Mach number of ~10. The Laval nozzle has an exit cone 44 mm long, and the diameters of the minimum and exit cross sections of the nozzle are 0.2 and 6 mm, respectively. Gas is supplied to the nozzle in pulses 1500 μsec long by means of an electromagnetic valve.[2] As it enters the nozzle, the gas is at room temperature and at a pressure between 10 and 100 absolute atmospheres.

The conical limiter (a truncated cone) is arranged coaxially with the Laval nozzle, at a distance s = 0-25 mm from the exit end of the nozzle (Fig. 1). The front edge of the cone is rounded off to a radius of ~0.01 mm, shorter than the local mean free path of the molecules in the jet. In the volume between the nozzle and the limiter, P_1, which is evacuated separately, the vacuum is better than 10^{-2} torr at the end of the gas pulse. The gas pressure in the working part of the chamber, P_2, does not exceed 10^{-3} torr at the end of the gas pulse.

The density of the gas flow is measured by the dividing-cone method, by means of a special ionization tube (Fig. 1). The front part of the tube housing, a truncated cone with a vertex angle of 45°, separates a small jet from the overall gas flow and directs it into the tube. Since the edge of the entrance aperture has a small radius of curvature ~0.01 mm, gas flows at densities up to 10^{18} molecules/cm^3 can be divided without shock waves. The entering gas reaches equilibrium in the tube, volume of 13 cm^3, over a time on the order of 10 μsec. The time required for the gas flow throught the entrance aperture, from 0.2 to 1 mm in diameter, is 20-500 times as long as the gas pulse. A three-electrode system with an external collector is used to measure the gas density in the tube; the current in the collector circuit is monitored by an oscilloscope through a matching amplifier. When a differentiating unit is inserted into the measuring circuit, the time behavior of the rate at which gas is supplied to the tube (which is proportional to the density in the channel) can be observed directly. The time constant of the measuring circuit is ~10 μsec. The sensitivity of the tube to air is 33 mA/torr. In control measurements with a homogeneous flow the readings from the tube are proportional to the area of the entrance aperture as the aperture diameter is varied from 0.2 to 1 mm, provided that the gas density in the tube does not exceed $3 \cdot 10^{15}$ molecules/cm^3. The gas density can be measured up to the point at which the tube enters the nonlinear region and the gas-discharge regime is approached. The distribution of the gas flow is found by moving the ionization tube in three directions between pulses. The error of these measurements is 20%. The spatial resolution is governed by the diameter of the entrance aperture of the tube, but the sensitivity of the tube falls off as this diameter is reduced.

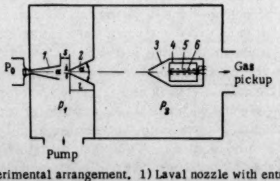

Fig. 1. Experimental arrangement. 1) Laval nozzle with entrance valve; 2) limiter (nickel); 3) housing of ionization tube (nickel, stainless steel); 4) ion collector (nickel); 5) grid (molybdenum); 6) cathode (thoriated tungsten).

Formation of a narrow jet of pure hydrogen. Under certain conditions, as the supersonic hydrogen jet passes through the conical limiter a narrow jet with a complex structure forms beyond the limiter. Figure 2a shows the jet structure beyond a conical limiter with an aperture diameter of d = 2 mm, a vertex angle of α = 45°, and a length of l = 40 mm for a hydrogen pressure of P_0 = 30 abs. atm at the entrance to the nozzle, as it appears τ = 850 μsec after the jet is turned on. The primary effect of the limiter is the formation of a tubular

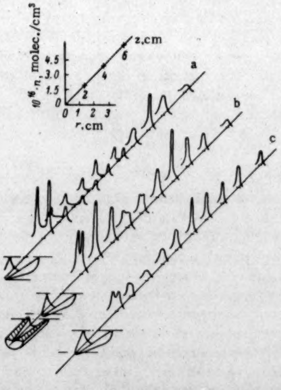

Fig. 2. Distribution of the hydrogen in the jets with respect to the radius r and the z axis. d = 2 mm, l = 40 mm, s = 6 mm, τ = 850 μsec. a) α = 45°, P_0 = 30 abs. atm; b) α = 35°, P_0 = 14 abs. atm; c) α = 40°, P_0 = 14 abs. atm).

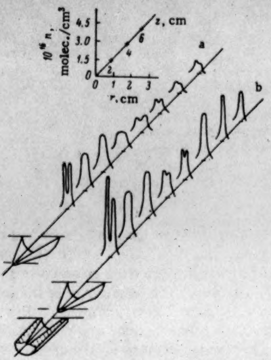

Fig. 3. Distribution of the hydrogen in the jet with respect to r and z. d = 3 mm, l = 40 mm, s = 6 mm, α = 40°, P_0 = 14 abs.atm. τ, μsec: a) 350; b) 850.

structure beyond the limiter; this structure contracts toward the axis. This tubular structure forms only if the diameter of the limiter aperture is much larger than the local mean free path of the molecules. With d < 1 mm the jet diverges significantly, and its intensity falls sharply. As the aperture is increased in size, the diameter of the gas tube at the exit from the limiter increases, as does the density of the jet at the point at which it contracts to the axis. With P_0 = 30 abs. atm, e.g., the tube diameter increases from 10 to 20 mm as the aperture diameter is increased from 2 to 15 mm. The vertex angle of the conical limiter, α, primarily affects the rate at which the jet contracts toward the axis. The point at which the jet contracts to the axis moves toward the limiter as the angle is reduced (in our experiments, to 30°). At the larger angles α = 55-60° the tubular structure becomes less well defined, and its diameter increases. As the cone is lengthened, the point at which the jet contracts to the axis moves toward the limiter, but with cones longer than 40 mm this effect weakens. As the entrance pressure P_0 is reduced, the gas jet beyond the limiter narrows, and the point at which it contracts to the axis moves toward the limiter, as the gas density in the jet falls off. At P_0 < 10 abs. atm the jet becomes blurred. Removing the limiter from the nozzle is equivalent to reducing the entrance pressure.

When the jet contracts toward the axis relatively rapidly (i.e., at small values of P_0 and α), the jet is observed to have a tubular structure with two successive necks (Fig. 2b; α = 35°, P_0 = 14 abs. atm, d = 2 mm). In Fig. 3, which shows the jet structure at 350 and 850 μsec after the beginning of the gas pulse, we see that as time elapses the jet slowly contracts toward the axis, and the contraction point moves toward the limiter. By 800-1000 μsec the jet becomes quite stationary. When flat or conical limiters are inserted beyond the conical shaping limiter, and if these additional limiters have aperture diameters which are less than the diameter of the jet at the point at which the density reaches 0.1 of its maximum in a given cross section, we observe partial or complete disruption of the fine jet, especially if the additional limiters are flat. When the apertures of these additional limiters are large the fine jet is not disrupted, but the rate at which it contracts toward the axis increases.

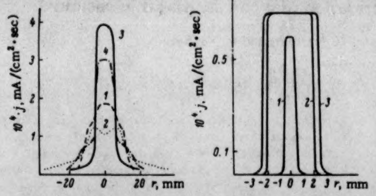

Fig. 4. Radial distribution of the jet density (expressed in milliamperes of the collector current of the tube per cm² per sec) at P_0 = 14 abs.atm. a: No limiter, z = 7 cm. 1) 100% H_2; 2) 100% CO_2; 3) 10% CO_2, 90% H_2; 4) 2% CO_2, 98% H_2. b: With a limiter, l = 20 mm, s = 5 mm, α = 45°, z = 10.5 cm, 10% CO_2 and 90% H_2. 1) d = 0.2 mm; 2) 1 mm; 3) 2 mm.

The narrowest hydrogen jets are formed when the vertex angle of the limiter is 40°. Figure 2c shows the jet structure for d = 2 mm, α = 40°, and P_0 = 14 abs. atm. The jet emerges from the limiter with a diameter of 10 mm and then gradually contracts toward the axis. In the 9-cm region, 11 cm from the exit of the limiter, the jet diameter is less than 3 mm (measured between the points at which the density is 0.2 of its maximum). In this part of the jet the radial distribution of the axial flow density is characterized by a 10-fold density drop at a radius of 5 mm and a 100-fold drop at a radius of 15 mm. If we assume the flow to be a supersonic hydrogen flow, we conclude that the gas density at the axis of the flow is $4.5 \cdot 10^{16}$ molecules/cm³ at the beginning of this part of the flow and $1.5 \cdot 10^{16}$ molecules/cm³ at the end of this part. While the flow density at the axis in the jet from a Laval nozzle without a limiter falls off roughly in proportion to the reciprocal square of the distance from the end of the nozzle, the density in the jet formed by the conical limiter varies only slightly. In the jet from a nozzle with the limiter shown in Fig. 2c the hydrogen density at the axis 24 cm from the end of the nozzle is 15 times higher than that in a jet from a nozzle without a limiter, for the same entrance pressure.

These experiments are carried out with liquid-nitrogen-cooled hydrogen of technical purity, with an impurity level of ~0.01%; similar results are obtained with pure helium. When a few hundredths of 1% of carbon dioxide is added to the hydrogen, the formation of a fine hydrogen jet is not observed.

From these experimental results we conclude that the formation of a nondiverging jet by the conical limiter and the contraction of this jet toward the axis are due to both the counterpressure of the scattered gas and "evaporation" from the jet surface of hydrogen molecules heated by the scattered molecules reflected from the cone (the mean free path in the jet is less than the thickness of the jet). Heating of the scattered molecules at the reflecting surface of the cone apparently plays an important role here. Before the jet contracts to the axis, its axial density falls off in proportion to the reciprocal square of the distance from the nozzle, because of the divergence of the supersonic jet. Because of this rapid decrease of the gas

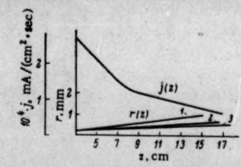

Fig. 5. Axial density of the jet, j(z), and jet radius, r(z), for various jet densities: 1) at the 0.1 level; 2) at the 0.5 level; 3) at the 0.8 level.

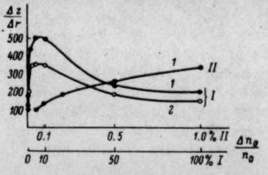

Fig. 6. Reciprocal vertex half-angle of the jet at the 0.5 level as a function of the relative volume concentration of CO_2 (curves 1) and of N_2 (curve 2) in mixtures with H_2. P_0 = 14 abs. atm, s = 25 mm, d = 0.2 mm.

density in the axial part of the jet and because of the radial contraction of the jet along its periphery, a tubular structure forms. The role of the entrance aperture of the conical limiter probably reduces to one of separating the central part of the jet from the Laval nozzle, by analogy with the limitation of a jet by freezing rings.[3]

This regular and quite pronounced effect on the structure of a jet of the surfaces surrounding it may be found useful in controlling the motion and deformation of gaseous formations in low vacuum.

Formation of narrow jets of condensing gases. When heavy gases are added to hydrogen in a supersonic jet, the heavy molecules are accelerated.[4] The divergence angle of the heavy impurity can be less than that of the hydrogen. If the impurity condenses in the jet the decrease in its divergence must be amplified. When the hydrogen condenses on the drops of impurity, the divergence of the jet as a whole must decrease. In this manner thin jets of a material in a "fog" can be produced.

We have attempted to form fine jets of carbon dioxide and nitrogen in a supersonic hydrogen jet. Figure 4a shows the distribution of the ionization-tube indications over the jet cross section 7 cm from the exit from the Laval nozzle. The jets of pure hydrogen and carbon dioxide (curves 1 and 2) diverge in similar ways. When carbon dioxide is added to the hydrogen, the jet contracts appreciably (curves 3 and 4), and the axial density increases significantly. Figure 4a shows that in a hydrogen jet with a CO_2 impurity the divergence of not only the carbon dioxide but also the hydrogen decreases. Jets with a very slight divergence cannot be obtained from the Laval nozzle used because of the large vertex angle of its exit cone.

Using a truncated cone to limit a jet of hydrogen with condensing impurities, we are able to produce jets with a very slight divergence in vacuum, and we are able to determine the "true" or thermal divergence of the slightly diverging component of the condensing jet from the Laval nozzle. The structure of a jet with condensing impurities has no features of any kind beyond the conical limiter over a broad range of diameters of the limiter aperture. Figure 4b shows the transverse distribution of a hydrogen jet containing 10% CO_2 (by volume) at a point 10 cm from the entrance to the conical limiter for various limiter apertures. The nature of the transverse distribution of the jet remains the same along the length of the jet, but the jet diameter increases essentially linearly with the length. The axial density of the jet is essentially independent of the diameter of the limiter aperture, falling off roughly in proportion to the reciprocal square of the distance from the nozzle and in proportion to the entrance pressure. The jet divergence beyond the limiter increases monotonically with increasing limiter aperture and is independent of the entrance pressure over the range 10-30 abs. atm. When the limiter is removed from the nozzle the axial density of the jet does not change, while the jet divergence beyond the limiter decreases. Figure 5 shows the axial density and radius of the jet, according to measurements made with the measuring tube, as functions of the distance from the end of the nozzle beyond a conical limiter with an aperture diameter of d = 0.2 mm (α = 45°, l = 20 mm, s = 25 mm, P_0 = 30 atm) for hydrogen with 10% CO_2. The axial density of the flow at 19.5 cm from the end of the nozzle ranges from $2 \cdot 10^{19}$ to $6 \cdot 10^{19}$ molecules/(cm^2·sec), depending on the relative amount of hydrogen at this point. The vertex angle of the jet is very small, less than 0.005 rad; the jet diameter 17 cm from the entrance to the limiter is 1.5 mm and at the 0.1 level, according to the indications of the tube.

Moving the conical limiter in the radial direction, we find that a jet consisting of a mixture of hydrogen with carbon dioxide has a component with an extremely slight thermal divergence not only at the axis but over the entire cross section, except in the outer layer, where the density falls off rapidly in the radial direction. For example 25 mm from the end of the nozzle a jet of H_2 with 10% CO_2 has a radius of 2.5 mm at the 0.5 level and a radius of 3.5 mm at the 0.05 level, according to the tube indications. A conical limiter placed in this cross section separates out a jet with a slight divergence, independent of the radial position of the limiter; in the central part of the cross section the density of this jet falls off radially more slowly than the density of the primary jet. At a radius of 2.5 mm the density of this smaller jet falls rapidly to zero. The axial density of the low-divergence jet formed by the limiter is several times lower than the corresponding density of the primary jet from the nozzle, according to the indications of the tube, when the CO_2 concentration is above $\sim 1\%$.

From the divergence of a jet beyond a limiter with a sufficiently small aperture we can determine the equivalent Mach number M $\sim \Delta z/\Delta r$, where Δr is the increase in the jet half-width over a length Δz. Figure 6 shows the ratio $\Delta z/\Delta r$ as a function of the volume concentration of CO_2 or N_2 in hydrogen for jets limited by a limiter with an aperture of d = 0.2 mm (α = 45°, l = 20 mm, s = 15 mm, P_0 = 14 abs. atm). The increase in the jet half-width is determined at the 0.5 level, from the indications of the tube. Figure 6 shows that CO_2 in a jet reduces the thermal divergence more effectively than does N_2. There is a weakly defined optimum impurity concentration in the range 2–10%. Jets of pure CO_2 and N_2 also have a high equivalent Mach number in the axial region. It follows from Fig. 6 that the gas composition plays an important role in reducing the thermal divergence in a jet. The rapid increase in the equivalent Mach number of the slightly divergent jet component with increasing concentration (up to an optimum concentration) is apparently due to accelerated condensation alone. Nevertheless, the acceleration of the impurity by the hydrogen contributes significantly to the reduction of the thermal divergence at a low impurity concentration.

The curves in Fig. 6 give only an approximate picture of the thermal divergence in the jet from a Laval nozzle, since the quantity $\Delta z/\Delta r$ is a function of d and s. Nevertheless, these experimental results show that it is possible in principle produce in vacuum an extremely slightly diverging jet of a material (e.g., pure hydrogen), in a "fog" by means of a Laval nozzle of the appropriate geometry, with the appropriate input temperature, and with a slight limitation of the jet from the nozzle.

The authors thank P. A. Zhuravlev for constructing the measuring tube and the conical limiters.

(Submitted February 12, 1973; resubmitted September 4, 1973)
Zh. Tekh. Fiz., 44, 1206-1209 (June 1974)

The ignition conditions and static characteristics of a discharge maintained by an electron beam (current 0-100 mA, energy 500-3000 V) in a longitudinal magnetic field (B = 0-800 G)and in a radial electric field (E_r = 0-100 V/cm) have been studied. The ignition curves of this discharge are similar to those of a magnetron discharge, and it is called a "beam-magnetron discharge." The critical electron-beam current, the working pressure in the ionization chamber ($p \approx 10^{-4}$ torr), and the magnetic and electric fields required for ignition have been determined. It may be possible to use this discharge in plasma injectors, ion sources, and other devices in which the working medium is a chemically active gas or a solid.

1. The most widely used low-pressure electron-beam excited discharges are direct discharges and reflex arc discharges. The fact that the cathode is in the ionization chamber inhibits the use of arc discharges in the ionization of chemically active gases or of materials which are usually in the solid phase. A beam–plasma discharge seems promising in this regard. An ion source that uses a beam–plasma discharge with a solid working medium is described in ref. 1; other advantages of beam–plasma sources are reported in ref. 2. However, the interaction of an electron beam with a plasma is effective only if the ionization chamber is long enough (L ~10 cm). To maintain a discharge in a short chamber we have recommended the use of a beam–plasma system in crossed electric and magnetic fields.[3] We report here on a study of the ignition conditions for an electron-beam excited crossed-field discharge and the possibility of increasing the ionization of the working medium.

2. Figure 1 shows the experimental apparatus. A steady-state electron beam, with current I_0 up to 100 mA and an energy of 3 kV, is produced by an annular electron gun, whose cathode is insulated from the grounded anode 4. The beam passes through a channel 12 mm long and 12 mm in diameter in the region of the magnetic field (B = 0-800 G) at an angle of 15° with respect to the axis of the discharge chamber. The radial inhomogeneity of the magnetic field in the discharge region is ~1%. The beam is collected by a movable water-cooled collector 11, 4.5 cm in diameter. The working gas (H_2, He, N_2, O_2) is injected (I) through a valve in the top flange of the discharge chamber and evacuated (E) on the electron-gun side. The limiting vacuum of the apparatus with the nitrogen trap in operation is $3 \cdot 10^{-6}$ torr. Most of the measurements are carried out in hydrogen. The radial electric field is produced by cylinder 10 with diameter $D_c = 2r_c$ of 9.5 cm and a length from 4 to 20 cm. The plasma parameters are determined by means of Langmuir probes 8, which can be moved in the axial and radial directions. The energy spectrum of the charged particles (Fig. 4) emerging from the discharge chamber through the beam-injection channel is determined by means of a four-grid analyzer 1 (ref. 4).

3. Ignition of an electron-beam excited discharge in crossed fields requires that the current of the injected beam, I_0, must exceed the critical value $I_{cr} \approx 0.5$ mA (Fig. 2a). Ignition of the discharge (beginning of gas ionization by secondary plasma electrons) is accompanied by a sharp increase in the current I_c to cylinder 10, a change in the current I_k to collector 11 (Fig. 1), from electronic to ionic, and by a jump in the ion current I_i to analyzer 1. This analyzer is at − 100 V with respect to the gun anode 4 and the electron collector 11, whose potential is defined as ground potential. At $I_0 > I_{cr}$ the currents I_c and I_k increase linearly with increasing I_0 (Fig. 2b), i.e., over the range of I_0 studied here, the mechanism for multiplication of the primary beam electrons is independent of the beam current. The nonlinearity observed in the

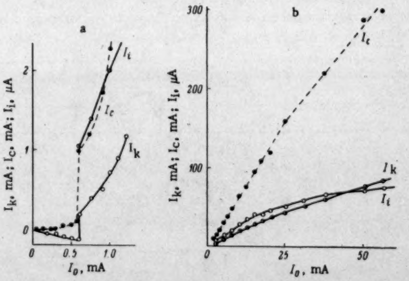

Fig. 2. Effect of the injection current I_0 on the discharge. E_0 = 1.2 kV; B = 180 G, $p = 2 \cdot 10^{-4}$ torr, V_c = 150 V, L = 10 cm.

function $I_i = f(I_0)$ is due primarily to a change in the plasma boundary from which the ions are incident on analyzer 1. The optimum beam energy is 600 eV.

Ionization in the volume can be increased by either increasing the injected current I_0 or by raising the potential V_c of the cylinder, (Fig. 3).

Energy measurements of the ions (Fig. 4) incident from the discharge on analyzer 1 show that the most probable ion energy E_i (in electron volts) is approximately equal to the cylinder potential ($E_i \approx eV_e$). Accordingly, an increase in V_c with $V_c > V_c^*$ has two consequences: an increase in the energy of the secondary electrons entering the plasma column (these electrons result from secondary electron emission from the electron-beam collector and ion– electron emission from both ends of the ionization chamber) and an increase in the number of secondary electrons (in the ion–electron emission yield). These phenomena increase the number and temperature (T_e) of the plasma electrons, whichare trapped at the ends and which cause most of the ionization in the discharge.

We call the cylinder potential V_c^* at which the jumps occur in the currents I_c, I_k, and I_i the ignition potential. Figure 5 shows this potential as a function of the magnetic field. The discharge is ignited at a magnetic field above the critical value, which is described satisfactorily by the approximate relation ($r_c \gg r_0$) (curve 1) given by Hull:[5]

$$B_{cr} \simeq \frac{2c}{r_c}\left(2\frac{m}{e}V_c\right)^{1/2}, \tag{1}$$

where c is the speed of light, e and m are the charge and mass of the electron, and r_0 is the distance from the electron to the axis when the electron is produced.
